Ducks

BIRDWATCH
BIRD BOOK OF THE
YEAR 1992

REVIEWS OF VOLUME 1

I judge this major work to be the single most useful reference on birds of the world.

NED K. JOHNSON, *The Auk, USA*

This volume is an impressive start to what should be an exceedingly useful work.

CHRISTOPHER PERRINS, *The Ibis, UK*

The editors, contributors and artists can be truly proud of the monumental achievement this volume represents.

PAUL SCOFIELD, *Emu, Australia*

There is no book on birds anywhere like this one...The book is superbly researched, formatted and produced.

R. K. BROOKE, *Ostrich, South Africa*

The Handbook should be everyone's first choice for a modern, comprehensive reference on the birds of the world.

FRANK B. GILL, *The Condor, USA*

Perhaps the most ambitious Handbook ever to have used this superlative.

EINHARD BEZZEL, *Journal für Ornithologie, Germany*

If perfection does not exist upon Earth, this first volume comes very close to it.

PAUL GÉROUDET, *Nos Oiseaux, Switzerland*

The authors have done very well and have obviously kept as up to date as practicable on new information as it has come to hand.

BRIAN D. BELL, *Notornis, New Zealand*

We await the subsequent volumes with impatience.

J. F. VOISIN, *L'Oiseau et la RFO, France*

I applaud the combination of readable prose, extensive use of the scientific literature and beautiful, high-quality illustrative materials.

C. R. BLEM, *The Wilson Bulletin, USA*

Authors of Volume 2

Dr R. O. Bierregaard, Jr.

University of North Carolina at Charlotte, North Carolina, USA.

Professor Walter J. Bock

Department of Biological Sciences, Columbia University, New York, USA.

Dr J. P. Carroll

Department of Biological and Environmental Sciences, California University of Pennsylvania, USA.

W. S. Clark

Freelance raptor researcher, Virginia, USA.

Dr S. J. S. Debus

Department of Zoology, University of New England, Armidale, New South Wales, Australia.

A. Elliott

Grup Català d'Anellament, Museu de Zoologia, Barcelona, Spain.

Dr D. C. Houston

Applied Ornithology Unit, Glasgow University, Scotland.

Dr J. del Hoyo

Vice-president, Sociedad Española de Ornitología, SEO-BirdLife, Spain.

Dr E. de Juana

Departamento de Biología Animal, Universidad Complutense de Madrid, Spain.

Dr A. C. Kemp

Head Curator, Department of Birds, Transvaal Museum, Pretoria, South Africa.

Dr L. F. Kiff

Director, Western Foundation of Vertebrate Zoology, California, USA.

I. Martínez

Grup Català d'Anellament, Museu de Zoologia, Barcelona, Spain.

Dr P. J. K. McGowan

Biology Department, the Open University, Milton Keynes, England.

Dr B. U. Meyburg

Chairman, World Working Group on Birds of Prey and Owls (WWGBP), Berlin, Germany.

Dr P. D. Olsen

CSIRO, Division of Wildlife and Ecology, Canberra, Australia.

J. Orta

Consultant, Servei de Protecció i Gestió de Fauna, Generalitat de Catalunya.

Dr A. F. Poole

Managing Editor, The Birds of North America, the Academy of Natural Sciences of Philadelphia, Pennsylvania, USA.

Dr W. F. Porter

College of Environmental Science and Forestry, State University of New York, USA.

Dr J. M. Thiollay

Laboratoire d'Ecologie, Ecole Normale Supérieure, CNRS, Paris, France.

Professor C. M. White

College of Biology and Agriculture, Brigham Young University, Provo, Utah, USA.

Authors for Species Accounts of Accipitridae and Falconidae

Foreword

Communication, or the exchange of information, is the cornerstone of sociality regardless of the species, its social structure and the nature of the information being exchanged. All types of information are exchanged, from simple expressions of the feelings and intents of individual animals, to complex hypotheses about the world around us. Most critical in the development of social organisms is the acquisition of communication abilities, both within and between species. These abilities involve sending proper signals and their correct receiving and interpretation. Humans, as social animals, must exchange information with one another and therefore must acquire the needed abilities to achieve this communication. Information held in isolation by a single person is quickly lost, and, indeed, may be considered as knowledge never gained. As individual humans learn new information about the world around them, they continually pass this knowledge on to others before it is lost. In science, as in other human endeavours, much attention is given to methods by which new knowledge is learned. Equally important are the methods by which this information is conveyed to other persons. Efficiency of communication is decisive. As the information becomes ever more complex and abundant, the organization of its communication is ever more critical. Included in this organization is the cost and time involved in the exchange of information. In planning the *Handbook of Birds of the World*, which will provide a vast amount of information about all living species of birds to ornithologists, professional and amateur alike, and will run to a number of large volumes, the importance of maximizing the efficiency of communication was a major consideration. Success of this undertaking depends not only on the correctness of the included information, but equally on the organization with which this information is presented. Correctness of the information is the responsibility of the authors of individual family and species accounts, but the responsibility for the organization belongs to the editors. The editors had to balance the kind and amount of information presented for each family and species of bird against the number and size of the volumes, and hence the ultimate cost of the entire *Handbook*.

At the onset of planning, the decision was taken to include information on all living species of birds with a summary of the biology of the family-level taxa. Herein, the first major decision was to cover all living species rather than all recent species included in J. L. Peters' *Check-list of Birds of the World*. Extinct birds are excluded, although mentioned in the family texts, partly because one of the goals of this project was to interact with BirdLife International (International Council for Bird Preservation) in raising the awareness of problems in the conservation of extant avian species. The next decision to be made was regarding the sequence in which the families and species were to be presented, as well as the internal classification of each family, including the species recognized. Readers of this *Handbook* do not have to be told that it is impossible to reach agreement between two ornithologists on the limits of all avian species taxa and the classification in which they are arranged.

Regardless of the species definition accepted, recognition of species taxa depends on how allopatric representatives are treated. Haffer (1992) has shown that advocates of each major species concept range from extreme lumpers to extreme splitters. An intermediate course was chosen for purposes of this *Handbook*, but there will be numerous cases in which allopatric species have been recognized herein which other workers include in a broader polytypic species taxon, and vice versa. The editors have attempted to ensure that such cases are commented on. It should be mentioned that the scientific definition of the species concept and recognition of species taxa is totally independent of the legal meaning of species in treaties and laws on the conservation of living organisms.

The arrangement of avian species taxa into higher level taxonomic groups and the order in which the families and orders of birds are treated within the *Handbook* is a much more complicated problem. Over the past decades much research has been undertaken on the macrosystematics of birds and many differing classifications have been published. In 1990, C. G. Sibley and his associates published a classification for birds (Sibley & Ahlquist, 1990; Sibley & Monroe, 1990) which differed radically from the Wetmore-Peters system published in the late 1920's and broadly adopted by ornithologists for most of the twentieth century. In turn, the Wetmore-Peters system replaced the very different system used for birds which was established in the early part of the nineteenth century (1825-1840) and used by most ornithologists into the beginning of the present century. This earlier system was adopted in Sharpe's *Catalogue of the Birds in the British Museum*.

The more neutral term "system" was used above to avoid confusions between the several different concepts embraced within it, namely phylogeny, classification and sequence, as discussed by E. Mayr and W. J. Bock (1994). Birds can be arranged in a phylogeny, or in a classification, or in a sequence, all of which differ from one another and can convey quite different information. Evolutionary relationships (which can be considered roughly equivalent to history) within any group of organisms, including birds, can be expressed either as classifications or as phylogenies, which are distinct, non-redundant ordering systems. Each provides different information about the evolutionary history of these organisms (Bock, 1977, 1981, 1992; Mayr & Ashlock, 1991, chapter 6). Both ordering systems reflect our current and still tentative knowledge of evolutionary relationships, and have to be modified as our understanding improves.

Phylogenies group organisms according to their branching phylogenetic history in which each clade is holophyletic (containing all forms descending from a common ancestor), and they are often presented in a branching diagram. Cladistic classifications or Hennigian phylogenetic diagrams represent branching phylogenies only and are not general reference systems. Any group of organisms has had a single evolutionary history, and hence a single phylogeny exists for each group. Phylogenetic analyses attempt to discover this true phylogeny.

Classifications arrange organisms according to both the amount of phyletic evolutionary change (anagenesis) and the pattern of phylogenetic branching (cladogenesis), and are expressed as a series of monophyletic (having a common ancestor) taxa arranged in a Linnaean hierarchical system of inclusively nested groups. Classifications reflect the entire evolutionary history of organisms, not only the patterns of branching points. They serve as general reference systems and are heuristic (serving to aid learning, discovery, etc.) in nature. Classifications are used to summarize efficiently information about organisms, to formulate useful hypotheses for empirical testing, and as the foundation for all types of information storing systems. Generally more than one equally valid classification can correspond to the single phylogeny of the group. Classifications are usually presented in a linear form, but this is not essential. Because classifications are generally presented in a linear sequence, the concepts of classification and standard sequence are still confused by most systematists and are usually considered to be identical.

Important distinctions exist between provisional classifications and standard sequences which serve two exceedingly different purposes in biology. Standard sequences serve strictly for arranging taxa in a linear order in books and all other information retrieval systems for the convenience of the user, who will be able to find the desired information more quickly. They exist for the general worker, who must organize and exchange information about organisms in a taxonomic group, such as birds. Classi-

fications, on the other hand, are the result of taxonomic studies and serve as the basis of discussion among specialists in systematics. Unfortunately, most workers have confused classifications with standard sequences and have changed the sequences with every proposed modification in classification. The failure of biologists to make the proper distinction between them has caused enormous difficulties since the earliest days of biological taxonomy, and has greatly reduced the usefulness of standard sequences.

Standard sequences are strictly heuristic devices, made necessary because humans arrange knowledge in linear systems, such as books, libraries, information retrieval systems, and the like. These standard linear sequences are derived from classifications, and generally several equally valid standard sequences can be postulated from a single classification. Taxa in a standard sequence are listed in a linear order, following a few general rules, such as more primitive groups placed first, and closely related groups placed close to one another. Discontinuities in relationships will occur in the sequence between the end of one complex of related taxa and the beginning of the next. Most important is that when agreement has been reached on a standard sequence, it be maintained over a long period of time. Changes in a standard sequence should be made only when there has been wide acceptance of radical modifications in the underlying classification.

Hence in the early stages of planning the *Handbook*, the decision was made to follow the Wetmore-Peters' sequence, which has been the widely accepted standard version for ornithologists worldwide ever since its appearance in the late 1920's, as the foundation for the fourth edition of the AOU Check-list of North American Birds in 1931 (Wetmore, 1930, 1960). The sequence given in *The Reference List of Birds of the World* (Morony, Bock & Farrand, 1975) was followed rather than the Peters volumes, because it adopted many later revisions and included taxa described since the early volumes of Peters. Use of the Wetmore-Peters sequence will permit readers of the *Handbook* to compare most easily information given in these volumes with that in most other books on birds published since 1930. No claim is made on the correctness of the classification on which the Wetmore-Peters sequence is based relative to other published classifications. The principal object of this *Handbook* is the maximum exchange of information, rather than an attempt to promote the scientific merits of different avian classifications.

Introduction to Volume 2

As this volume forms part of a series, the *Handbook of the Birds of the World* (HBW), readers are referred to the detailed general introduction to the whole work, on pages 15-33 of Volume 1, where they will find an explanation of the aims of the project, the structure of the whole work, and the objectives and contents of each of the various sections, all of which is, of course, applicable to the present volume. It has been considered unnecessary to repeat all of these details in this and forthcoming volumes, as they will remain essentially the same throughout the series.

One significant change to the original planning is the result of a comprehensive revision of the whole project, taking into account the experience gained in the first volume. This has led to the number of volumes in the series being extended from ten to twelve, a number which can now be considered practically definitive.

A few innovations have occurred with this second volume, the most significant of which involves the extensive internationalization of the team of authors. As the authors are experts in their own particular fields, overall editorial policy has been to respect the diversity of styles as far as possible, while at the same time aiming to maintain a suitable degree of consistency throughout the entire work. It is now up to the individual reader to judge whether or not an appropriate level of consistency has been achieved.

As in Volume 1, each family text and its respective species accounts have normally been prepared by a single author, or sometimes by two working together. However, there was one particularly awkward case in this volume, that of the two large families of diurnal raptors, Accipitridae and Falconidae, which in total amount to some 300 species. Given the size of the task involved, it was decided that the species accounts of the two families might to advantage be divided up amongst a team of regional authors. With so many species involved, each author was likely to have more extensive experience with those of a particular region, and so would be better prepared to cover them. This system has had the obvious benefit of reducing individual workloads, and has undoubtedly enabled each author to give fuller attention to the particular set of species allotted to him. On the other hand, the system has also presented several drawbacks, perhaps most significantly in the different styles and criteria inevitably employed by the eight different individual authors. During the subediting process, a degree of uniformity has necessarily been imposed on the accounts, but this has been balanced with a strong tendency to respect each author's contribution as far as has been possible.

Classification

Another important innovation with Volume 2 is the participation of Walter Bock, in the capacity of Consultant for Systematics and Nomenclature. Professor Bock is Secretary of the International Ornithological Congress (1986-1998) and Chairman of the Standing Committee on Ornithological Nomenclature.

From the first, taxonomy has been considered one of the major concerns in the whole project, and we firmly believe that HBW will prove to be a useful tool for all ornithologists, in this field in particular, as it attempts to cover all the major

taxonomic alternatives, from the level of order right down to subspecies, for all the world's birds, complementing these details with the individual illustrations and map for each species.

It should be stressed that Professor Bock is not to be held responsible for all of the details of the sequence followed, nor for the species, far less the subspecies, accepted. As consultant, he is working in close conjunction with the editors, monitoring particular problem cases and ensuring that taxonomic treatment remains consistent and appropriate throughout the entire work, especially at the level of macrosystematics. We are delighted to be able to count on his participation in HBW, and that the project will gain from his wealth of experience.

In the normal procedure of HBW, while the higher taxonomic levels are decided centrally, the internal classification of each family is a matter for open consultation with the individual authors. In the entire process of preparing Volume 2, there has been a great deal of lively and positive discussion of taxonomic issues with the various authors. This was most notable in the case of the largest family, Accipitridae, in which the family author proposed the original version, and the species account authors made a number of useful proposals, several of which led to slight amendments and an overall improvement in the list. The HBW sequence has benefited greatly from the considerable experience of expert authors, and, as a result of the minor amendments made to several families, some of the taxonomic arrangements presented herein are to a certain extent new.

Nevertheless, as explained in Volume 1, for its basic overriding principle, HBW follows the currently accepted standard sequence of the Class Aves (see Mayr & Bock, 1994, *Ibis* **136**: 12-18.), with a limited amount of modification permitted, where recent work shows it to be appropriate. For instance, there is no apparent advantage in maintaining species status (with a corresponding species account) for taxa that have in the past been considered full species, but are now known to be subspecies, or simply morphs or hybrids, or even, in some cases, juveniles or females of other species. Similarly, newly discovered species must be accommodated, which necessarily requires a few small adjustments. The acceptance of subspecies is not considered to be a matter affected by the concept of "standard sequence", so authors are relatively free to accept the versions that they find most satisfactory on the strength of present evidence; nonetheless, the preference in this respect in HBW is still to limit the incorporation of recent innovations to those that appear to be suitably justified.

Where the standard sequence is of major significance is at the macrosystematic level. For this reason, despite the fact that the New World vultures (Cathartidae) are now generally reckoned to belong alongside the storks (Ciconiidae), they have been treated in their traditional position within Falconiformes, although the issue is given full treatment in the family text. On the other hand, while awarding a full family to the New World quails is an idea that has only fairly recently come into vogue, based largely on the work of C. G. Sibley and J. E. Ahlquist, there appear to be good grounds to support this change, and it has been considered more consistent with the recognition of a narrow concept of Phasianidae with respect to the turkeys, grouse and guineafowl, a subdivision that is steadily gaining support; again, such issues are extensively covered in the relevant family texts. The Hoatzin (*Opisthocomus hoazin*), in its monotypic family, Opisthocomidae, presented a difficult case, as this species has often been placed in the Galliformes, although there has been a strong movement in recent years to transfer it to Cuculiformes, a proposal, which, in turn, has received forceful criticism. The answer seems to be that nobody really knows where this species belongs, so for the time being it has been deemed most suitable to award the Hoatzin an order of its own, Opisthocomiformes, alongside the Galliformes, as it does not appear to be closely related to any other living species. This treatment was already proposed by E. Stresemann in 1934, and was recently revived by H. Sick, in the major reference work covering this species' range.

Of interest is the inclusion in HBW of a newly described perdicine, *Xenoperdix udzungwensis*, a species so distinctive that it has been awarded a genus of its own. The acceptance of newly described species can obviously present a certain degree of risk, as subsequent study has in the past frequently invalidated new "species". However, this particular species is very distinctive, and its inclusion is important both as an additional illustration of the diversity within the family and for a series of possible biogeographical implications. Nonetheless, in a number of other more doubtful cases, in which certain forms have at times been claimed to constitute new species, the tendency in HBW is to avoid the acceptance of such "species" until such time as their validity be proved, or at any rate widely accepted; such was the case, for instance, of the form "*Crax estudilloi*". Again all such cases are discussed in the family texts.

There are other contentious issues. For instance, it was decided, based largely on the arguments of R. L. Potapov, to take two of the three species traditionally placed in *Dendragapus* and remove them to the reinstated genus *Falcipectens*. This proposal has received widespread approval, and, although it is not actually followed by the *Birds of North America*, the most important and most recent regional handbook to deal with either of the species in question, the text therein does comment that this is probably a more accurate version.

Another controversial case has been that regarding the generic name of the Crested Caracara (*Polyborus plancus*). There has been a recent move to annul the name *Polyborus* and replace it with *Caracara*, on the grounds that the former is unidentifiable. However, the almost universal usage of *Polyborus* over the last 150 years or so, together with the fact that it is the basis for the subfamily name Polyborinae, a family-group name, argues strongly in favour of the retention of *Polyborus*.

With respect to the accepted German and Spanish names for the species in this volume, the sources are as credited in Volume 1 (page 26); publication of the list of Spanish names is now under way, the first batch recently appearing in *Ardeola* 41(1): 79-89 (1994). An important advance was the publication in 1993 of a new, comprehensive list of French names carefully selected by an international committee, with the aim of providing a more or less definitive list, which diverges as little as possible from those names already selected by P. Devillers:

– Devillers, P., Ouellet, H., Benito-Espinal, É., Beudels, R., Cruon, R., David, N., Énard, C., Gosselin, M. & Seutin, G. (1993). *Noms Français des Oiseaux du Monde*. Éditions MultiMondes, Sainte-Foy, Quebec, Canada & Éditions Chabaud, Bayonne, France.

Conservation

As readers of Volume 1 will already know, the theme of conservation has a high profile throughout HBW. In the families Megapodiidae, Odontophoridae, Phasianidae and Numididae, each species account carries, in addition to the IUCN threat category, a new Mace-Lande category; at present, these new categories are not available for the other families, although preparation of those for raptors has recently commenced. As the Mace-Lande status provides a more accurate reflection of the information available, it is worth explaining briefly.

It has long been felt that the system for deciding IUCN categories is too subjective. Now, following considerable efforts, a new system is emerging, that of the Mace-Lande criteria, so-named after its originators, G. M. Mace and R. Lande. A certain amount of fine tuning has been necessary, but this new system has now been applied experimentally to certain bird groups.

The new system bases its conclusions, and the ensuing application of categories, on population data, but as this requires the sort of information that is simply not available for most species, the criteria are concerned with the probability of extinction of a given species within various periods of time. Thus, if the species is believed to have a 50% probability of extinction within two generations (of the species), it is considered Critical; a 20% probability of extinction within 20 years qualifies as Endangered; and a 10% probability within 100 years is sufficient for it to be classed as Vulnerable. Criteria based on characteristics such as the sizes of populations, their degree of fragmentation and observed decreases in numbers can be used where the data exist, but, for the time being, in most cases classification has to be based on factors such as the rates of habitat loss or of direct exploitation by humans. For instance, habitat loss may be reckoned to occur on such a scale that, if it continues at the same pace, the species faces the aforementioned probabilities of extinction in the suggested time frames. Even so, assessments are not easy, and in many cases species can only be narrowed down to a range of two categories, such as Vulnerable/Endangered.

Another major step forward with the Mace-Lande system is that it is being applied to all of the species, and to several of the more distinctive subspecies, in a given group or family. Assuming the Mace-Lande experiment prospers, it is hoped that it will eventually be applied to all of the world's birds, and will ultimately replace the traditional IUCN categories. However, for the time being the new system has yet to be perfected, and, as its application requires a great deal of research effort, the IUCN categories are likely to remain the standard for some time to come. Therefore, HBW will continue to stick to the IUCN categories, until such time as they can be replaced for the entire bird world by a new, improved system. For this

reason, in order to enable the different families in the present volume to be compared on an equal basis, the figure referring to the number of threatened species in the summary-box of each family invariably refers only to the IUCN listing, even though within the body of the text, the author may well prefer to follow the Mace-Lande criteria, as is the case in the Status and Conservation section of the family Phasianidae. In the species accounts of the four families affected, both categories have been given: first the IUCN category, in its normal form; and then the Mace-Lande category, appropriately indicated. Note that in several cases individual subspecies or subspecies clusters are awarded independent categories, in which case the category appears written entirely in small case, as opposed to the use of a capital initial letter with the Mace-Lande category of a full species (in the species account); when subspecies are clustered, and thus treated as a single entity, each subspecies is separated from the next by a slash. IUCN categories are taken from the 1994 IUCN Red List of Threatened Animals.

As in Volume 1, all species protected under the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) are thus indicated in the Status and Conservation sections of their respective species accounts. This includes mention of the Appendix (I, II or III) in which the species in question is listed. Briefly, for most purposes, Appendices I and II both indicate strict protection, although the former, used mainly for seriously threatened species, is rather stricter, precluding the possibility of trade permits being granted in virtually all cases. Appendix III indicates a similar level of protection to that implied by Appendix II, but only in the country or countries listed.

Illustrations

Another important innovation with the present volume lies in the fact that several prestigious British artists have joined the already successful HBW team from Volume 1. The workload involved in Volume 2 and foreseen for future volumes has meant that a larger team of artists was required in order to ensure that all the deadlines could safely be met, and that artists were not forced to rush their work. In the interests of consistency and ease of comparison, attempts have been made to have all the members of well defined groups painted by the same artist, but for practical reasons (including the schedule for Volume 2) this has not always been possible. The most extreme case is that of *Accipiter*, which has been painted by four different artists. As a result, some of the differences between species may be less apparent due to the distinctive styles of individual artists; on the bright side, however, it does at least offer a good comparison of the different styles used by these four different artists! Similar efforts have been made to avoid individual genera, or associated species, being split between plates. In general, solutions have been found for most cases, but there are a few exceptions resulting from restrictions imposed by the lay-out, notably in the cases of *Crax*, *Aquila* and *Buteo*.

One of the few points that may be worth repeating from Volume 1 is that HBW does not aim to serve as a field guide, even for those who may be capable of going out into the field carrying twelve large volumes. Nevertheless, in this and subsequent volumes, in the cases of some of the more poorly known species, especially those that are not particularly well served by field guides, a slightly more detailed description may be permitted on occasion, for instance for the *Odontophorus* wood-quails, as it is believed that such information is not otherwise readily available.

The business of selecting the photographs to be published has seen a considerable increase in the amount of time and effort dedicated to research, and, as a result, during the selection process many more photos have been examined from a larger number of photographic agencies, and also from a great many individual photographers who have offered their work for consideration. Inevitably, for some of the galliform families only a rather limited number of photographs of wild birds were available, which has led, in two families, to the inclusion of a number of shots of captive birds, in order to illustrate the diversity of the family adequately. Nevertheless, even in the worst case, the number of photos of wild birds remains high. One slight change with respect to the first volume is in the increase in the number of montages employed. It is hoped that it will be possible to include these useful and highly illustrative series in future volumes, although, of course, this necessarily depends on availability.

As in volume 1, the maps do not normally include a species' introduced range, but in a very few clear-cut cases, such as that of the Canada Goose (*Branta canadensis*) in Volume 1, it has been deemed worthwhile to do so. The one and significant case in Volume 2 is that of the Ring-necked Pheasant (*Phasianus colchicus*), which

is so well established in many parts of Europe and North America. Nonetheless, the introduced range of this species has not been included in the family map, as to do so would give a highly erroneous view of the family's natural distribution, with significant biogeographical implications for the whole of the order Galliformes. A second kind of exception has been permitted, again in an extremely limited number of cases. This has involved the maps of both the Mountain Quail (*Oreortyx pictus*) and the California Quail (*Callipepla californica*) including populations that are very probably, but not certainly, introduced; these populations are included partly because of the doubt as to whether or not they really are introduced, partly because the distributions of the natural populations are contiguous and continuous with those of populations that are probably introduced, and partly because, for practical reasons, it would be difficult to draw the line between natural and probably introduced populations.

Bibliography

Although already explained in the introduction to Volume 1, it must again be stressed that the bibliography listed does not mean that which has been used in composing the text, but rather "recommended further reading", although there is obviously extensive overlap between the two. The bibliography recommended for any one species consists of that listed at the end of the relevant species account, in addition to that listed under the General Bibliography of the family. The latter often includes monographs that deal individually with each and every one of the species in the family, and in some cases may contain more material about a particular species than any of the references listed under that particular species. This might appear illogical, but it was decided that there is little to be gained in repeating the same reference for every single species in a family, particularly when economy of space and concentration of information are two of the dictating factors in the whole project. At the same time, many of the general works that do not actually go through all the species in a family one by one nonetheless present a great deal of important information on particular species, while in any case general considerations on the family as a whole are invariably relevant to the constituent species too. The bibliography of this volume thus follows the same norms as those already employed in the first volume.

A couple of small points may be worth mentioning. First, at variance with usage in Volume 1, it was decided, on the recommendation of K. C. Parkes (*per* J. P. Carroll), to adopt the version "Meyer de Schauensee, R.", as opposed to "de Schauensee, R.M." Second, the Scandinavian forms *å* and *ø* are alphabetized as *a* and *o* respectively; this procedure was already adopted in Volume 1, but an explanation was inadvertently omitted from the introduction. Although this is not the normal order in the relevant languages, it has been considered that it would be most confusing for the vast majority of readers to have them listed otherwise.

Acknowledgements

Museums have again played a most important part in many aspects of the project. We would particularly like to thank the British Museum of Natural History at Tring (Robert Prys-Jones, Peter Colston, Michael Walters, Mark Adams). We are also very grateful for the help received from the American Museum of Natural History in New York (Mary LeCroy, Paul Sweet), the Smithsonian Institution in Washington (Gary R. Graves, Richard L. Zusi, J. Phillip Angle, Carla Dove), and the Academy of Natural Sciences of Philadelphia (Mark Robbins). Generous assistance has also been received from the National Museums of Scotland in Edinburgh (Bob McGowan), the California University of Pennsylvania, the CSIRO Australian National Wildlife Collection in Canberra, the Carnegie Museum of Natural History, the National Museums of Kenya in Nairobi, and Liverpool Museum (Tony Parker).

Visits to collections of live birds are considered to provide important documentation, helping especially in the preparation of the plates. In this field, we are extremely grateful to Jesús Estudillo López, who most kindly put his entire collection at our disposal for the taking of photographs, and extended us the warm hospitality of his home. Most kind help was also received at the Cracid Breeding and Conservation Centre in Belgium (Gerr Scheres), Avifauna in Netherlands (B. J. van der Sluis and Marinus Verkade), the Tracy Aviary, Salt Lake City, USA (D. Grenville Roles), Zôo-Botânica Mário Nardelli in Brazil (P. Nardelli) and Santo Domingo Zoo in the Dominican Republic (Angélica Espinal).

The assistance of libraries is naturally of the utmost importance in many aspects of the project, and we would particularly like to note the kind co-operation received from the libraries of the Museu de Zoologia of Barcelona (Agustí Blanxer, Maria Angeles Iglesias), the Sociedad Española de Ornitología in Madrid (Juan Carlos del Moral), the Station Biologique de la Tour du Valat in the Camargue (J. P. Taris, C. Perennou and J. Crivelli), the British Museum of Natural History at Tring (Effie Warr), BirdLife International (Sue Squire and B. Heredia), the Royal Australian Ornithologists' Union, the Estación Biológica de Doñana (Gaspar Olmedo), Barcelona Zoo (Joaquim La Cueva), the Centre de Documentació del P. N. dels Aiguamolls de l'Empordà (Rosa Llinàs) and ICONA in Madrid (Antonio Troya).

With regard to the content of the texts, a great deal of help was received in different forms, including especially the forwarding of unpublished information, and the checking or completing of certain details. We should first like to mention the kindness of the Royal Australian Ornithologists' Union (RAOU) and P. Higgins and S. Marchant, editors of HANZAB, for sending us proofs of Volume 2 of their own Handbook prior to its publication. We are also very grateful to Lars Dinesen and Thomas Lehmborg, who permitted us access to photographs and information regarding the new perdicine species that they discovered. René Dekker, co-chairman of the Megapode Specialist Group, was unable to take on authorship of this family, but he very kindly revised advanced proofs of the text, and made many useful comments. We would also like to thank Alan Knox (Buckinghamshire County Museum), who at very short notice generously checked details concerning several references of scientific descriptions. F. Weick very kindly sent us a substantial amount of material which has been most helpful, especially in the preparation of the plates. Many thanks also to B. Forrester, who sent us useful data on Brazil. H. Ouellet and P. H. Barthel rapidly and efficiently filled in a few gaps that remained in the lists of accepted French and German names respectively. P. Le Maréchal very kindly provided the list of French names on disc. Amongst those who so generously furnished unpublished information, we would like to pay special tribute to the contributions made by H. A. Barber, C. Beel, V. Belik, K. Bevanger, P. Boudarel, S. M. Caziani, J. C. Chebez, M. Coello, M. Crosby, P. Escalante, G. D. Field, J. Fjeldså, D. Gallegos Luque, V. Galushin, F. González-García, C. Griffiths, J. C. Guix, V. V. Ivanovsky, N. Klestov, I. Mihalevich, M. Puigcerver, G. Rocamora, J. D. Rodríguez-Teijeiro, C. S. Roselaar, S. M. Satheesan, H. Shirihai, D. W. Steadman, A. K. Tishechkin and M. Ueta, and by M. Patrikeev, who kindly sent some manuscripts from his forthcoming book, *The Birds of Azerbaijan*, in addition to supplying addresses for several other scientists of the former USSR.

Others who made valuable and much appreciated contributions in a variety of ways, especially by clearing up particular doubts, include S. Aguilar, D. Amadon, S. Arango, R. Buchholz, S. Dowell, D. Evered, D. García, D. Hernández, A. Hoogesteijn, S. Howell, K. Howman, M. G. Kelsey, W. Kuvleski, Jr., E. Lelov, M. Lentino, S. Mañosa, T. Margalida, D. Mead, R. Moss, P. Mota Hernández, J. Muntaner, A. Negret, D. Noakes, X. Parellada, K. C. Parkes, M. Pomarol, J. Real, E. Ruelas, D. M. Teixeira, J. L. Tella, E. Useche and E. O. Willis. Our thanks also to the Sociedad Conservacionista Audubon de Venezuela, the Louisiana State University of Natural Sciences, the Universidad Central de Venezuela (Estación Biológica, Rancho Grande), and the World Pheasant Association (UK and USA Chapters). Once again, we take this opportunity to offer our sincere thanks to all those people who kindly took the trouble to send offprints.

Relations with BirdLife International have run very smoothly; we would particularly like to thank Leslie Stanton and Neil Parker for their swift and efficient dealings.

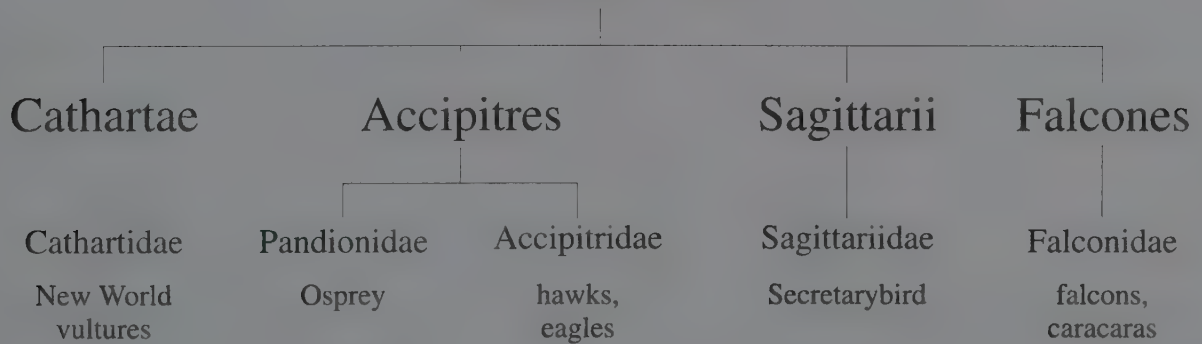

Many thanks to both Robert Bateman and David Houston, who in different ways provided assistance with the jacket design. For help in preparing the plates, in addition to the many museums and collections mentioned above, the artists would like to thank Oriol Alamany, Antoni Brossa, Steen Christensen, Ib Petersen, Marta Puig, Don Turner and Dale and Marian Zimmerman.

For help in many different ways, our grateful thanks go to Maria Josep de Andrés, Ventura Boluda, Dolors Buxó, Juan Antonio Cantí, Pilar Carrasco, Josep Maria Clausell, Oriol Frias, Mirko Geest, Maria del Mar Gispert, Sílvia Martin, Sílvia Muray, Maria Teresa Obiols, Susanna Piñol, Belén Piqueras, Jordi Puig, Montserrat Roldán, César Ruiz, Deli Saavedra, Sílvia Salvador and Erich Streich.

Finally, we would like to take this opportunity to mention collectively all those, especially the authors, who participated in Volume 1 and gave up their time to help get the project off the ground. To them we dedicate a special thank you.

Order FALCONIFORMES

Falconiformes

Class AVES

Order FALCONIFORMES

Suborder CATHARTAE

Family CATHARTIDAE (NEW WORLD VULTURES)

- Medium-sized to very large diurnal birds of prey, with bare head, powerful hooked bill and large wing area for efficient soaring flight; feed mostly on carrion.
- 56-134 cm.

- North, Central and South America
- Wide variety of habitats, from highest mountains to low-land forests and deserts.
- 5 genera, 7 species, 13 taxa.
- 1 species threatened; none extinct since 1600.

Systematics

The seven species of New World vultures are extremely similar in superficial appearance to the fifteen species of Old World vultures found in Africa, Asia and Europe. If seen in a mixed species group in a zoo aviary it is difficult to find clear features to tell them apart.

The most obvious differences are that the New World vultures do not have a functional hind toe, and also have no internal separation of the nostrils, so that when the head is viewed from the side it is possible to see right through the head and out the other nostril. Otherwise the two vulture groups are remarkably alike in general appearance. Both have powerfully hooked bills, bare heads and necks, and massive wings to enable them to ride rising air currents. It is a feature of all vultures that they fly almost entirely by soaring flight and rarely flap their wings. Indeed the larger vultures are incapable of using powered flight for any length of time, and may be completely grounded if they can not find suitable upcurrents of air. This dependence on soaring flight allows them to travel great distances with little energy expenditure. Both groups feed almost entirely by scavenging meat from carcasses, and rarely or never kill prey themselves. Both vulture groups also show little sexual dimorphism, which is unusual among birds of prey. In most species, therefore, the male and female can not be told apart from size or plumage differences.

These similarities between the Old World and the New World vultures are, however, now known to have been derived independently because the two groups are actually descended from totally different ancestry. They are a text-book example of convergent evolution. New World and Old World vultures look alike not because they are closely related, but because they have developed the same adaptations for a similar way of life.

It is perhaps worth emphasizing the remarkable convergence shown by these two lines of vultures. In both Eastern and Western Hemispheres it is usual for several species of vulture to co-exist in the same areas, forming a guild of scavenging birds. The same forms of feeding specialization have evolved independently in the two groups.

Thus, in both the New and the Old World, there have evolved very large species, the condors (*Vultur*, *Gymnogyps*) and the griffon vultures (*Gyps*), which share many features. They are among the largest of all flying birds, have compara-

tively drab, dark plumage with a white neck ruff, travel great distances when foraging, congregate in large numbers at carcasses, and use their long necks to reach the muscle and viscera.

Both vulture groups also evolved medium-sized to large species, such as the King Vulture (*Sarcorampus papa*) of the New World and the White-headed Vulture (*Trigonoceps occipitalis*) and the Lappet-faced Vulture (*Torgos tracheliotus*) in the Old World. These species all tend to be more brightly coloured; may have more restricted foraging ranges; do not usually collect in large numbers at carcasses; have comparatively short necks; and specialize at carcasses in taking the skin and tough tissues, such as tendons and sinews.

Finally, in both the New World and Old World vultures, there have evolved smaller species, such as the American Black Vulture (*Coragyps atratus*) and the Turkey Vulture (*Cathartes aura*) of the New World and the Hooded Vulture (*Necrosyrtes monachus*) and the Egyptian Vulture (*Neophron percnopterus*) in the Old World. These travel considerable distances while foraging, and are very catholic in their diet, catching many prey items for themselves; they are not as dependent on large mammal carcasses as the bigger vulture species. When they do attend large carcasses they tend to feed on food dropped by the other species, and clean scraps of meat from the bones of the carcass after the larger species have left.

Despite these close similarities in appearance and feeding ecology of the two vulture groups, there are many aspects of their detailed anatomy and behaviour which indicate that they are not at all closely related. Huxley, as far back as 1876, recognized that the cathartid vultures were distinct from all other birds of prey, and for over a hundred years it has been known that many of their features are closer to those of the storks than to those of eagles and hawks.

Most of the evidence for this linkage is very technical, and A. Rea and J. D. Ligon have provided good reviews of the anatomical evidence. Storks and cathartid vultures share numerous characteristics of skeletal bone structure and skull formation, together with the arrangement of some of their musculature. There are also behavioural links with the storks: for example, both groups of birds keep cool by squirting their legs with urine, which then evaporates off to leave the legs sometimes looking as if they have been whitewashed. Additional evidence has recently been provided from DNA hybridization studies by C. G. Sibley and J. E. Ahlquist. This technique, which indicates the similarities in the DNA of various animal

Although it is now known that the New World and the Old World vultures evolved independently, there are marked similarities between the two groups. The strongly hooked bill and the bare skin on the head and neck are parallel adaptations to their similar feeding habits. However, this photo highlights one of the most obvious morphological differences, namely the lack of any internal separation of the nostrils in the New World vultures, with the result that it is possible to see clean through, from one side to the other. The other obvious difference in morphology is the lack of a functional hind toe in cathartids.

[*Cathartes aura septentrionalis*.

species, also suggests that New World vultures are more closely related to the storks than to the other birds of prey. In light of all this evidence it is rather surprising how reluctant ornithologists have been to recognize that the taxonomic position of the American vultures ought to be moved away from those of the other birds of prey.

Cathartid vultures have traditionally been placed in the order Falconiformes alongside the eagles and hawks, the falcons, the Osprey and the Secretarybird. L. H. Brown and D. Amadon, in a major text on birds of prey in 1968, recognized that these four groups of birds may not be related, and that the American vultures in particular were distinct in a number of ways. The traditional grouping of the Falconiformes has, however, largely been kept together as a matter of convenience, and because few could agree on what a more taxonomically correct relationship should be. There is some sense in this, because ecologically the cathartid vultures are so similar to the Old World vultures. But this does not reflect their real position, which may be in Ciconiiformes, or in a separate order, Cathartiformes. We should regard the cathartid vultures as sharing a common ancestor with the storks. Some modern stork species, especially the Marabou (*Leptoptilos crumeniferus*), obtain much of their food by scavenging, not only taking dead fish, but also feeding alongside vultures at carcasses. It is not too difficult to imagine a branch of these waterbirds becoming increasingly specialized for scavenging, and slowly evolving the same range of adaptations for this lifestyle as the Old World vultures.

We know very little about the relationships of the species to each other, although current studies on DNA sequence may provide information on this soon. It may prove that some of the genera are not at all closely related. We do know that the cathartid vultures have a very long evolutionary history, much longer than that of many other bird groups, with two fossil species *Palaegyps* and *Phasmagyps* coming from the early Oligocene about 35 million years ago. Modern genera may therefore have diverged long ago. Pliocene deposits, dating back about 5 million years, contain ancestors of the modern Andean Condor (*Vultur gryphus*) and King Vulture. During the Pleistocene in North America, around 2 million years ago, there was a great radiation of all vulture species, and at this time the modern California Condor (*Gymnogyps californianus*), Ameri-

can Black Vulture and Turkey Vulture were already found, together with many other species that have since become extinct.

The two large condor species, the Andean Condor and the California Condor are both massive in size and live in mountainous regions. These species can weigh well over 10 kg, and such huge birds clearly need strong upcurrents of air to sustain their soaring flight, which probably limits their distribution to mountain regions or lowland areas where strong thermal upcurrents are produced. Their huge size gives them superficial similarities, but there is no reason to believe that the two condor species are closely related, and they probably diverged long ago in evolutionary time. Two other distinct genera, which comprise single species showing no obvious similarities with any other vultures species, are those of the King Vulture and the American Black Vulture. The American Black Vulture, in particular, shows a quite different series of social behaviour patterns to all the other species.

The most closely related group of species are undoubtedly the members of the genus *Cathartes*, all of which have a highly developed sense of smell, unlike the four previously mentioned species, which have none. Three species are usually recognized, the Greater Yellow-headed Vulture (*Cathartes melambrotus*), the Lesser Yellow-headed Vulture (*Cathartes burrovianus*) and the Turkey Vulture. The first of these species was, however, only described as recently as 1964. The distinction between these three species is based on overall size and on the colour of the head, a feature which is rather variable between individuals, and, in the case of the yellow-headed species, not well known. There are, however, at least four distinct races of Turkey Vulture, which also differ in size and head colour. The taxonomic position of all these species and races is very uncertain. We know that there are clines, involving a progressive increase in size from the south to the north, in the two North American races of Turkey Vulture. Clear distinctions in size between races or species are often not very apparent. The other characteristic, the skin coloration of the head, is very variable and also fades completely after death, leaving museum skins all looking very similar. The study of these *Cathartes* vultures from museum skins is therefore very confusing. It would not be surprising if future taxonomic studies based on DNA se-

quencing showed that some of the races of the Turkey Vulture were as distinct as the two yellow-headed forms, and should be recognized as distinct species.

One of the more surprising aspects of the evolution of the two vulture groups in the New and the Old Worlds is that their present geographical isolation is a comparatively recent event. There are fossil Old World vultures found in the New World, and fossil New World vultures found in the Old World. The Old World vultures were present in the Americas until very recently; indeed, fossil species from the late Pleistocene deposits of the Le Brea tar pits in California show that they may have become extinct as recently as about 10,000 years ago. They seem to have died out along with the many large mammals and other scavenging birds which perished at the end of the Pleistocene. However, there is no fossil evidence of New World vultures in the Old World from any later than the early Miocene, about 20 million years ago.

Morphological Aspects

Cathartid vultures share the general bill shape of other meat-eating birds, with a hooked tip and cutting edges. The larger species can exert considerable force when feeding, usually holding the food down with one or both feet, and pulling strongly upwards, using their leg and shoulder muscles to help them tear through tough tendons and sinews. The bill can also be used in a surprisingly delicate way, with a gentle nibbling action, being particularly effective at removing small items of meat from complicated bones and hidden crevices in a carcass. When vultures have finished feeding on a carcass the bones are picked clean of virtually all tissues, and this requires them to show great dexterity and delicate bill movements as well as brute strength.

All species have bare skin on the head and neck, which is an obvious adaptation to prevent the birds getting their feathers soiled with gore, when they poke their heads into carcasses. However, only the condors and the American Black Vulture regularly push their heads far inside the skin of animals, and even the other species which would not seem to need to keep their necks bare are still found to show large areas of bare skin.

It is likely that an equally important function of these bare skin areas is to assist with temperature regulation. There is a rich supply of blood vessels to these areas of bare skin, and birds use them to radiate excess heat away from the body. Some species, especially the King Vulture and the Andean Condor, have elaborate skin folds or crests to increase the surface area of bare skin and presumably make heat loss through this route more effective. Vultures may face more problems with head stress than most other tropical birds. This is because they routinely fly at very high altitudes, where the air temperatures can be below freezing and the speed of flight results in a considerable chill factor. They need a thick and effective feather insulation around the body to retain heat in these conditions. When these same birds land on the ground a few minutes later, they are then subjected to high temperatures and they may have problems getting rid of the excess heat through the thick plumage layer. In such circumstances, the bare skin patches may then be important as a route for heat loss to keep the birds from overheating.

These bare areas of skin are also important in some species for display. There can be few bird species which show quite such a spectacular and bizarre range of skin colours as those around the head and neck of the King Vulture, accentuated by skin folds and a pendulous wattle. Like all of the species which have brightly coloured skin around the head, these colours only develop in the adults. The immature birds always have dark grey or black skin. This makes it likely that the main functions of bright colours are individual recognition, threats or dominance interactions between adults. The intensity of these skin colours is, in some species, very variable in an individual, especially in the California Condor and the various species and races of *Cathartes*. There have been no detailed studies made of the function of these colour changes, but the two South American subspecies of Turkey Vulture, *C. a. jota*, which has a bright red head, and *C. a. ruficollis*, which has a duller red head but with a conspicuous whitish band at the back of the head, can both change the intensity of their red skin within a few seconds, presumably by constricting or dilating the blood capillaries in the skin. These colour changes seem to be important indicators of dominance, especially when birds are contesting feeding sites. Neither of the North American migrant

All vultures have huge wings that are well adapted for soaring flight, and these enable the birds to cover immense distances at a minimal cost in energy terms, when searching for carcasses on which to feed. Both condor species show very conspicuous white panels on the upperwing, which are thought to facilitate visual contact between individuals, as they are clearly visible from afar. The Andean Condor is the only member of the family that is sexually dimorphic; the large comb on this bird's forecrown indicates that it is a male.

[*Vultur gryphus*,

species, which have more purplish colours on the head, appear to show such marked colour changes.

Some cathartid vultures have air-sac systems, which can be inflated to increase the effectiveness of these bare skin areas for display, and maybe also to assist in sound production. These air-sacs in the neck are also found in the Marabou and other members of the stork family. They are particularly well developed in the California Condor, where they are important in the courtship display of both sexes, the skin blowing up like a balloon and emphasizing the brilliant colours of the neck. But they are also found to much less dramatic effect in Andean Condors, Turkey Vultures and American Black Vultures.

A conspicuous feature of the *Cathartes* species, the Turkey Vulture and the Greater and Lesser Yellow-headed Vultures, are the large nostrils on the side of the bill. The cathartid vultures, alongside the New Zealand kiwis (Apterygidae) and some petrels (Procellariiformes), are among the few birds in the world which have a highly developed sense of smell. K. Stager carried out some carefully designed experiments to demonstrate that Turkey Vultures could detect some of the chemicals given off by carcasses, and could use them to home in on food. B. Bang has made detailed studies of the brain and olfactory regions of the skulls of *Cathartes* vultures to demonstrate that these species have unusually well developed olfactory lobes to the brain and nasal regions. The sense of smell is extremely important to these birds, and they rely on it entirely to locate food in forests, and can find carcasses that are completely hidden from view as easily as those which are visible.

Historically, this has been rather a controversial subject. John James Audubon carried out some experiments, which were published in 1826 and which he claimed demonstrated that these birds could not smell. But for his feeding trials he chose rotting carcasses, giving off the most foul stench that he could find, and concluded that, because the birds did not come to the putrefying food, they were unable to smell it. In fact, vultures do not like meat which is starting to decompose, and will avoid eating it if they can. This is probably because it is likely to contain unpleasant or dangerous bacterial toxins. Audubon's experiments failed to demonstrate that vultures could smell, because the birds did not bother to investigate the food, knowing that it would be in too foul a condition to eat.

A particularly puzzling aspect of the smelling abilities of these vultures is that it is only the three members of the genus *Cathartes* that have this ability. The condors, the King Vulture and the American Black Vulture all seem to have no functional sense of smell at all. In forest habitats, the two latter species cannot find food themselves, and instead rely on the *Cathartes* vultures finding it first. They then follow close behind and steal the food. If we assume that, taxonomically, these other vulture species are comparatively close to the *Cathartes* vultures, it is curious that the ability to smell should have developed in only these few species. We might expect that all vultures would benefit from being able to smell carrion, and we may well ask why they never developed this ability. We can only guess at the answer, but developing an acute sense of smell and a correspondingly large region of the brain to process the information may be costly. The brain uses far more energy in proportion to its weight than any other organ system in the body, and maybe for these other species the benefits they would gain from being able to smell for themselves are outweighed by the high energetic cost of maintaining the olfactory sense.

The general body plumage of most vulture species is rather dull in colour, usually being black, sometimes with some iridescence of the feathers. The immature plumages are always duller in coloration. However, some species show white patches on the wings when they are flying, these being particularly conspicuous in the Andean and California Condors and the King Vulture. These patches presumably make the birds conspicuous to other birds from a distance.

All vulture species are superbly adapted for soaring flight, and have large wing areas. They make use of rising air currents to gain altitude, rather than having to use flapping flight. The large condors are mostly found in mountainous areas, where they can rely on the wind rising up the windward side of cliffs and hills. In flat country they have to use thermal upcurrents, where the heat from the sun warms an area of bare ground, and causes the patch of air directly above to become hotter than the surrounding air mass, until eventually it breaks away and rises through the atmosphere, as a bubble of light, warm air. Many different soaring birds make use of these thermal upcurrents, and vultures depend on them for gaining altitude. Once they have climbed as high as they need, they then glide away, slowly

In order to take advantage of its acute sense of smell, the Turkey Vulture, like the other two members of the genus *Cathartes*, generally forages over long distances by flying relatively low above the ground. This bird is in active moult. Moult is extraordinarily slow in vultures, and the renewal of all of the flight-feathers takes several years. This strategy is necessary, for it means that the birds never have yawning great gaps in the wings caused by there being several contiguous feathers missing at the same time. The occurrence of such gaps impairs birds' flying proficiency considerably, particularly in terms of soaring and gliding, two abilities that are absolutely fundamental in the daily life of a vulture.

[*Cathartes aura*.

losing altitude until they contact another source of rising air. This method of flying is extremely important, because it enables the birds to travel great distances while using very little energy.

Vultures have an unusual food supply, seeking carcasses that may be unpredictably located and spaced out very far apart. They can only exploit such an ephemeral, dispersed and sparse resource, if they have very low travel costs. They may need to travel enormous distances to find each carcass. If they had to use flapping flight, they would use more energy searching for food than they would ever gain by eating it.

Incidentally, this dependence on gliding flight has probably been the evolutionary force leading to the exclusive scavenging habits of all vultures. Both Old and New World vultures are descended from ancestors that were originally predatory. At some stage in their evolution, they have given up the ability to kill and become reliant on finding dead animals. This must have greatly restricted the potential sources of food available to the birds: if a vulture is hungry it can not go out and kill something; it just has to keep on searching and hope that it will eventually find a carcass. For any meat-eating bird there is always far more live, than dead, prey around. Vultures would seem to have lost a considerable advantage when they gave up the ability to kill for themselves. They would only have done so if there were some strong selective advantage which more than compensated for the loss of predatory abilities. The advantage they gained was that they were able to specialize on highly efficient gliding flight. To do this they developed massive wings and large body size. These changes prevented them from remaining as predatory birds, for they had to lose all the skills needed to be a predator, such as agility, accuracy of landing, ability to manoeuvre fast and take off rapidly if an attack has failed. But in return they have become perhaps the most perfectly adapted soaring land birds in the world, being able to fly for hours on end over hundreds of kilometres, without ever needing to flap their wings and while using minimal energy.

The various species differ considerably in their flying abilities. Some, such as the American Black Vulture, have comparatively low wing-loading (the ratio of body weight to wing area), which makes them rather inefficient gliding birds. They often flap their wings when they are flying, and in flat country can not start flying until several hours after dawn, when the heat of the sun is sufficient to generate powerful thermals. Other species, such as the two species of yellow-headed vultures, have larger wings and can keep flying even when they only have access to very weak areas of lift.

Vultures differ in their flying methods when searching for food. Some species, such as the King and Black Vultures, often fly at high altitudes, which enable them to gain excellent vision over large areas of the ground. But the *Cathartes* vultures fly much lower, close to the ground. In tropical forests, the Turkey Vulture and the Greater Yellow-headed Vulture fly just at the level of the tree canopy. They are able to do this by taking advantage of small patches of rising air on the windward sides of large trees which emerge above the rest of the forest. The Lesser Yellow-headed Vulture, which lives in flat grasslands, also flies only a few metres above the ground, possibly using small patches of rising air from bushes and small ridges on the ground.

Flight is so important to the lifestyle of vultures that they need to keep their flight-feathers in optimum condition. The feathers of all birds eventually become worn and need to be replaced. Most birds moult all of their flight-feathers every year. But moult in vultures is unusually slow. Even the small species take several years to complete the growth of a new set of feathers on the wing. It is very important that vultures do not develop holes in the wing, for this would impair their flying performance. Maybe if moult proceeded at a faster rate there would be a danger of gaps developing where several feathers were in growth at the same time. The sequence in which the feathers grow is also rather unusual. In most birds there is an orderly replacement of the primary, secondary and tail feathers, in which each quill is moulted and regrown in sequence. There

is such an order in the primary feathers in vultures, but secondary and tail moult is very much more irregular with no clearly discernible pattern to the sequence at which feathers are shed.

All vultures have large feet, which are often used in feeding, to help hold the food down while the bill tears off pieces of meat. The cathartid vultures have rather weak feet that are not as well adapted for grasping as are the feet of the Old World vultures. This may indicate their stork-like ancestry. Most species also have slight webbing between the toes, although this is probably not so much an indication of their descent from waterbirds as evidence of the way the feet are used as airbrakes to slow the flying speed of the birds as they come in to land. The larger species, in particular, have high flight speeds, and can have difficulty controlling their descent. They lower their feet to try and reach a safe landing speed, in just the same way as the Old World vultures, which, incidentally, also have slight webbing between the toes for the same reason.

Being a scavenger is rather a precarious way of life. Carcasses are difficult to find, but when one is found it is likely to contain plenty of food. One of the adaptations vultures have developed is the ability to eat large amounts of food. An Andean Condor is alleged to have eaten 8 kg of meat at one meal, which represents about two thirds of its body weight! This figure is not credible, but there is no doubt that some vulture species can really gorge themselves. The large condors can actually eat up to 2 kg, and may find it difficult to fly when they have eaten a large meal. They then wait a few hours, until they have been able to digest part of their food, before trying to take off, or if a predator approaches they may have to regurgitate part of their meal, until they are light enough to fly.

They are able to store these vast quantities of food because they have a capacious crop. This is a sac-like structure just before the stomach. It has very elastic walls, and as the bird fills it up with food the crop skin stretches and begins to bulge forward and become visible between the feathers on the chest. In many species the skin on the crop is brightly coloured, in Turkey Vultures a vivid red, in King Vultures bright pink, and in the Andean Condor a striking yellow or pink colour. These conspicuous crop patches are probably important signals about the feeding status of birds when gathered at a carcass. There can be few other birds which can beat the vultures for gluttonous appetites. When birds have the opportunity to gorge themselves in this way they then lay down large fat stores, to tide them over periods when food may be hard to find. We know that Turkey Vultures can go two weeks without food or water and appear to be quite unharmed. Charles Darwin reported that Andean Condors could last for five or six weeks without food.

Habitat

One of the remarkable aspects of the cathartid vultures is the extreme range of habitats that they occupy. In this respect they are more successful than the Old World vultures, which are not found in any kind of forest or closed woodland habitat.

The Andean Condor occurs amongst the highest peaks of the Andes, flying high over the snowfields seeking animals that have been killed by avalanches. In Argentina it also descends to low grasslands, and in coastal Peru it is found in total desert conditions, feeding on stranded animals along the sea coast. The California Condor has in recent years been confined to the Sierra Nevada range in California, although it formerly occurred over most of southern North America.

The Turkey Vulture is perhaps the most versatile of all the species, being found almost everywhere from extreme deserts to grasslands, temperate forests and even dense tropical rain forest. This species has been extending its range northwards in North America over the past few decades, and this has probably been encouraged by the abundance of food from animals killed by cars on the highways.

Another species that has probably extended its range and benefited from human activity is the American Black Vulture.

The Greater Yellow-headed Vulture is more closely tied to forest habitats than any other member of the family. Indeed, it appears to be almost entirely restricted to primary forest, and tends to shun even disturbed areas. Although both the King and Turkey Vultures also occur regularly in tropical forest, both can also be found in other kinds of wooded habitat, in more open areas, and even, in the case of the latter, in zones of desert.

[*Cathartes melambrotus*, Maraca Island Reserve, near Boa Vista, Brazil. Photo: David Houston]

This was, before the human population explosion, probably quite a rare vulture species, largely confined to the edges of rivers, swamps and wetlands. Today it is the ubiquitous town scavenger, present in thousands around fish markets and rubbish dumps, and walking the streets of most cities in Central and South America, feeding on garbage. It is the one vulture species which has clearly benefited from human activity.

The King Vulture is usually associated with undisturbed areas of tropical forest in Central and South America, but it can also be found in savanna and grassland areas, though usually only where forest pockets also remain.

It is often thought that vultures are tropical species, and do not penetrate into cold climates. But temperature is probably not as important to them as flying conditions: provided they can find the right conditions for soaring, and a suitable food supply, some species live in surprisingly cold conditions, such as the Turkey Vultures in the Falkland Islands or Tierra del Fuego.

General Habits

Every aspect of the ecology and behaviour of vultures is aimed at saving energy. This is the whole secret of their success. Finding cheap ways to travel, minimizing energy expenditure at all times, avoiding energy-wasting fights with colleagues at food sites, avoiding heat stress, digesting food as efficiently as possible, and storing away fat reserves whenever feeding times are good. These are all vital to their lifestyle. They have little control over their food supply, and so must be prepared occasionally to face periods when food is mighty hard to find. We know little about their general metabolism, but Turkey Vultures do seem to have metabolic rates that are considerably lower than we would expect for a bird of this size. It is likely that all of these birds have evolved mechanisms for reducing their energy requirements, especially when food supplies are low.

The American vultures are perhaps not as gregarious in their habits as the Old World vultures, some of which nest socially in huge colonies. Most cathartid vultures are relatively solitary when breeding, although some species, especially the American Black Vulture, will congregate together in large numbers when feeding, and roost in large communal roosts.

Some elegant studies on American Black Vultures by P. P. Rabenold have shown these roosts to be important social congregations. Birds use these communal roosts to learn about good feeding areas. A bird which has not been able to find much food one day can go back to the roost at night, and the next morning follow other individuals, as they leave to feed, so that it is likely to be led to a better food site. The members of the family group, the parents and their young, tend to remain together throughout the year. They preen each other, help feed each other, and defend themselves against attacks by other birds. Some family groups also tend to associate with certain other families, and family members probably assist each other when foraging, and co-operate in finding food. This species has, perhaps, the most complex social behaviour of all the New World vultures. It has a range of aggressive interactions that birds use in encounters with other American Black Vultures, which are more varied and unlike those known by any of the other vultures.

We do not know if other vulture species show similar social interactions. Turkey Vultures will often roost alongside American Black Vultures, and may benefit from learning about good places to feed in the same way. California Condors are known to have used communal roosts, and Koford, who was working in the 1940's, reports roosting groups of about twenty birds: presumably roosts were much larger earlier this century when the population was greater. Andean Condors also roost in groups. King Vultures seem to forage in family parties, and it is common for a pair of adults and their young to attend feeding sites together. Larger numbers will collect at the carcass of a big animal, but it is very uncommon to see more than two adults coming down to feed together. This species seems to have a more restricted foraging range than some other vulture species.

All of the vultures show well developed sunning behaviour. They stretch out their wings to their fullest extent, holding them either towards or away from the sun. They do this particularly in the early morning, but also regularly throughout the day. A whole roost of Turkey Vultures suddenly expanding their huge wings simultaneously to bask in the early morning sun is a most spectacular sight. The functions of sunning behaviour in birds are poorly understood, but the cathartid vultures perhaps use it more than most other groups of birds. It seems to serve two functions. Firstly, some species of cathartid vultures are

Sunning, with the back to the sun and the wings outspread is very typical amongst the New World vultures, in general, and the Turkey Vulture, in particular. Birds habitually sunbathe in the early morning, in sessions lasting half an hour or more. It is thought that the solar energy helps the birds to recover their normal daytime body temperature, which drops markedly at night, as the result of a thermoregulation mechanism that allows them to make considerable savings in energy expenditure. It has also been found that the sun's rays help to bring the plumage back into condition.

[*Cathartes aura*.
Photo: François Gohier/
Ardea]

known to allow their body temperature to fall several degrees at night. This is probably one of their many adaptations to save energy. In the morning, sunning is an effective way to raise the body temperature back to normal daytime levels. Secondly, the feathers of such large birds can become bent when they have spent long periods soaring, because the flight pressure tends to force the feather tips upwards. When the birds land, the feathers retain a rather bent shape, and will take many hours to recover. This may reduce the efficiency of the wing, and birds can speed up the recovery of the feather shape by sunning, as the sun's heat causes the keratin of the feather structure to relax back to the original shape. Most vultures will sun for a short period of time after landing, probably to maintain their flight-feathers in optimum condition.

Heat regulation is assisted by two rather unusual mechanisms. Mention has already been made of the bare areas of skin which are used to radiate excess heat away from the body. The birds also squirt urine onto their legs, and the evaporation of water helps to cool the skin. This strange behaviour is also shown by the storks, and sometimes leads to the legs becoming covered in white powder.

Feather maintenance is extremely important to all vultures, for their whole lives depend on the efficiency of their wings. If this efficiency is lost the birds will need to start flapping their wings more frequently, which uses too much energy. It is, therefore, not surprising that vultures may spend several hours each day at preening, carefully grooming each feather in turn, removing any dirt or food. In rainstorms they hold the wings out to wash the feathers, and then carefully preen them back into shape again.

One feature that all vultures must show is a remarkable ability to withstand bacterial toxins. We know that Turkey Vultures have a high resistance to botulism. Although birds will avoid eating meat that is in an advanced state of putrefaction, there is no doubt that they do regularly need to feed on meat that is far from fresh, and must have evolved mechanisms to detoxify most of the bacterial poisons that are present in decaying food. They have not, however, developed the ability to cope with the toxins with which man today pollutes the environment. Poisons such as strychnine and cyanide which are used in predator control programmes will all kill vultures, and

they seem also to be very susceptible to lead poisoning and other environmental contaminants.

Voice

A strange feature of the cathartid vultures is that they totally lack the syrinx and associated muscles, which form the main mechanism for sound production in other birds. As a result this whole group of birds are almost silent, and they completely lack the ability to produce any normal bird calls or song. They can produce a rather strange variety of hissing, rattling and sneezing noises, none of them very loud. These are probably made by passing air through the air sacs, but even these weird noises are not used extensively. They are at their most "vocal" when breeding, and anyone approaching a nest-site will often be greeted by a warning series of wheezes and snorts.

Food and Feeding

All species in this family are predominantly scavengers, in that they obtain food by finding dead animals, rather than killing prey for themselves. Some obtain virtually all their food this way, refusing to kill even animals that are obviously about to die. But the American Black Vulture does kill a surprisingly wide range of food items for itself, even if most of them are rather defenceless, such as hatching turtles, lizards or small nestling birds. They are also accused of attacking newborn lambs or calves, and undoubtedly wait around domestic stock to snatch the afterbirth. Turkey Vultures have also been reported killing prey, but usually only very sick or young animals. While it is likely that most species will occasionally kill, it is a general feature of the group that they can not, or will not, kill anything substantial, and the majority of their food is undoubtedly scavenged.

It is often assumed that all vultures feed at carcasses of large mammals. In fact the smaller species, such as the Turkey and American Black Vultures will take an extraordinary range of other food items, such as insects, dung, berries and fruits, small mammals, snakes and lizards. The keen sense of smell

of the *Cathartes* species probably enables them to find carcasses of very small animals, such as mice and small birds, as well as catching alive some less active prey, such as insects. Several studies on the food items taken by these species suggest that over much of their range these miscellaneous small prey items probably form a major part of their diet. However, all species will also congregate at the carcasses of large animals, and this is where differences in their feeding behaviour are most obvious.

The various species specialize by taking different types of food from a carcass, and also have a clear dominance hierarchy in the way that they feed. The large condors are the only species which are powerful enough to tear through the skin of large mammals, such as deer, and open up the carcass for the smaller species. In the forests of South America the King Vulture fulfils the same role, and, although it is a much smaller species, it can still open most carcasses, because the food supply in these areas consists of much smaller carcasses, such as monkeys and sloths. American Black Vultures are the main species to feed on the muscle and the viscera, and they have a very large gape for a bird of their size, allowing them to gulp down large amounts of food quickly. Turkey Vultures and both Greater and Lesser Yellow-headed Vultures feed more slowly, and it is these species which clean up any remaining scraps of meat on the bones, picking over the carcass until little remains.

With so many species, and individuals, competing for food around a carcass, it might be thought that there would be endless fighting. But for any bird with such delicate wings as those of a vulture, physical contact is dangerous and likely to lead to injury. Also, fights between vultures waste energy. So instead of having endless physical squabbles with other vultures, these birds have evolved ritualized displays which allow them to recognize more dominant individuals and resolve conflicts quickly. M. P. Wallace has shown that there is a clearly defined dominance hierarchy, in which the larger species dominate over the smaller ones. But most conflicts between species are resolved without physical violence. It is only the three *Cathartes* species which have the ability to smell, and so in woodland or

forest habitats it is almost always these species which find a carcass first. In more open habitats the other species may be first to spot a dead animal, but even here the *Cathartes* vultures are usually the first to arrive. These species feed with a rather quiet dignity, rarely engaging in aggressive encounters, and they will often allow other species to feed alongside them, provided they do not become too numerous. If they are challenged by another bird, they will usually quietly give way without a squabble. Frequently these birds find a source of food, only to have it stolen from them soon after they have arrived by other, more aggressive species. They then withdraw to wait on the sidelines, often coming back to the carcass again when the other species have left, and taking any scraps of remaining food. However, American Black Vultures are far less reticent and seem to enjoy a good scrap! They are generally far more aggressive in their behaviour. They have an elaborate series of threat displays which they use to interact with other conspecifics. One involves a curious form of arm wrestling, in which two birds stand side by side, with wings open, and push against each other until one falls over. Another involves birds leaping at each other and rising into the air, kicking at each other with their feet. American Black Vultures often congregate in large numbers at a source of food, and they can then make massed assaults and overwhelm the carcass, driving all other species away. Even King Vultures can be displaced by an unruly group of American Black Vultures.

The two condor species are today so reduced in numbers that it is difficult to visualize their original role as scavengers. There is remarkable archive film, taken in the 1930's, which shows several dozen California Condors feeding on a donkey carcass, in exactly the same manner as griffon vultures (*Gyps*) are seen today in Africa. Andean Condors were also, in the past, found in large groups at carcasses, although today it is usual to find only a few individuals together. These condors feed mainly on large carcasses. Along the Pacific coasts of North and South America the rich upwellings of the sea currents support a great concentration of marine life. This results in whales, seals and large seabirds being regularly washed up

Flocks of several dozen Andean Condors can form at carcasses, although throughout the species' vast range in the Andes and Patagonia, such congregations are nowadays found only in a few areas of Peru, Chile and Argentina, where the species still survives in good numbers. Juveniles of this species are easily identified by their dull brown plumage, which lacks the prominent white wing panels of the adults. Note also the adult females, which lack the conspicuous comb and neck wattles of the males.

[Vultur gryphus, Ayacucho, Peru.
Photo: Günter Ziesler]

Normally only a few King Vultures can be found feeding together, typically one or two adults and the odd juvenile, although larger numbers occasionally gather at sizeable carcasses. This suggests that the species may regularly feed in family groups, and perhaps also that such groups may maintain feeding territories. Although the King Vulture is dominant over the smaller vulture species, it usually tolerates their presence at carcasses, as in this case, where several American Black Vultures (*Coragyps atratus*) have joined in the feast. Note the all dark plumage of the immature King Vulture on the right.

[*Sarcophaga coragyps*, Hato Masaguaral, near Calabozo, Venezuela. Photo: David Houston]

along the beach. These must have been an important source of food for these birds in the past, and Andean Condors still forage along the seashore today. Inland, their prey was in the past mainly vicuña (*Vicugna vicugna*) and guanaco (*Lama guanicoe*) and any other large ungulates, but today domestic stock are also important sources of food.

It is not always realized that these scavenging birds play important roles in ecosystems. In Neotropical forests, for example, vultures are the major scavenging animals. The remarkable ability of the *Cathartes* species to smell out carcasses on the forest floor enables them to locate virtually all the animals that die. There is real competition for this food, from many scavenging mammals and insects which lay their eggs on carrion. But the superior searching efficiency of the vultures allows them to find almost all carcasses first. They are the major meat-consuming animals in the forests, probably taking more food than that taken by all of the predatory animals combined. They are also, in terms of their biomass, undoubtedly the most abundant "birds of prey" in this ecosystem. Indeed vultures are, in most habitats, so abundant that we tend to take them for granted. Their large numbers reflect how successful they are as scavenging animals, and how much better they are at finding dead animals than any other kind of scavenger.

Breeding

Surprisingly little is known about breeding in most of the cathartid vultures. For the Greater Yellow-headed Vulture no nest-site has ever been found, while only one is known of the Lesser Yellow-headed Vulture, and few of the King Vulture.

One of the curious features of the birds is that, although they share an ancestry with the storks, and might therefore be expected to build conventional tree nests like many stork species, none of the species is known to build any nest structure at all. All lay their eggs on the ground under dense bushes, in among boulder piles, at the back of caves, or in large holes in trees, tree stumps or fallen logs. Occasionally nests may be in tree cavities high above the ground, but this seems to be unusual.

The two large condor species usually select nests in remote sites that are difficult to reach. But the smaller species nest in

positions where they might be thought to be very vulnerable to ground predators. Birds do try to make their movements as inconspicuous as possible, when approaching the nest. In addition, the sites often become rather foul-smelling, which some people have suggested might be a deliberate strategy to prevent predators from taking the young birds, presumably by implying that they will not make a tasty meal. Also, the chicks of some species regularly wander away from the nest-site when they are old enough, and this may be another strategy to deter predators.

But predation of one kind or another does seem to be a major cause of breeding failure, and birds do not show strong nest defence. This even applies to a species as big as the California Condor, which might be thought well able to deal with most potential predators. But N. F. R. and H. A. Snyder showed that one of the main causes of breeding failure in this species was that their eggs were taken by ravens. It seems curious that such large birds are not better able to protect their nests. None of the species, as far as we know, are colonial in nesting. Some species will have a number of nest-sites close together, but there is no clearly developed sharing of defence of the nest-sites between pairs.

The large condors lay only a single egg, but the smaller American Black and Turkey Vultures usually lay two eggs. Eggs are usually an off-white colour, but Turkey Vulture eggs are spotted, maybe because they tend to lay in more open sites than the caves usually chosen by the condors or by American Black Vultures. N. Snyder actually saw a California Condor laying its egg, which was remarkable in that the female was standing upright at the time and the egg was expelled to the ground with some force. In those species which have been studied the eggs are incubated by both parents, and indeed most parental duties seem to be shared.

Incubation periods are rather variable, from about 40 days for the smaller species to about 55 for the larger condors. The chicks are initially covered in fine, fluffy down, which is white in colour in Turkey and King Vultures and the condors, but buff-brown in American Black Vultures. The young birds seem to be able to keep themselves warm from an early age, helped by the thick covering of down, and in Turkey Vultures parent birds only visit the nest-site to feed the chicks for a few minutes each day. Chicks are fed by the parents by regurgitation for the

An American Black Vulture about to feed on the corpse of an American alligator (Alligator mississippiensis). Of all the New World vultures, this is the species with the most varied diet. In addition to feeding on carcasses of almost any kind or size, it is the species that actually kills most prey, including newborn livestock, especially pigs, hatchling turtles, lizards, fish and nestling birds. It also takes the eggs of turtles, iguanas and birds, especially those of colonial nesters, and some vegetable matter, such as sweet potatoes and the pulp of opened coconuts.

Planet Earth]

whole of their growth period. Vultures are unusual among birds of prey in that they do not carry food to the nest in the feet. They do, however, have such large crops that they can transport quite sufficient food in the gut. Very young birds, for the first few days, may be fed food which has been partially digested, but older chicks seem to receive undigested meals. At first the young take the food direct from the parent's bill, but later they may feed from regurgitated food placed on the ground.

From studies on captive birds, it seems likely that the larger condor species do not start breeding until about six years of age. The smaller species probably reach maturity after about three. The California Condor seems to form permanent breeding pairs, and, although we have little information from other species, the close family bonding shown by American Black Vultures suggests that these birds may form long lasting pairs also.

For the condors breeding is a protracted event. The eggs will take about 55 days to hatch, and the young bird will not start to fly until it is about six months old, after which it will remain dependent on the parents for many months. This means that a single breeding attempt in both the Andean and California Condors takes more than twelve months, and so a successful breeding attempt in one year usually results in no breeding attempt the following season.

Movements

The Turkey Vulture is the only species which is truly migratory, and this only applies to some of its races. Both of the North American subspecies travel south in winter, sometimes congregating in roosts of thousands of birds when they reach the winter areas. In Central America, birds moving north or south are funnelled through the narrow strip of land, contributing to one of the most spectacular raptor migrations in the world. They are dependent on following the land route because of their need to use soaring flight during migration, which prevents them crossing the Gulf of Mexico. Counts made in Panama indicate that in some years several hundreds of thousands of Turkey Vultures make this journey, sometimes rising to altitudes of 6000-7000 metres, and apparently without feeding to any substantial extent on the journey. The arrival of the huge numbers

of the North American migrant race into northern South America, where they then co-exist with the resident races of the same species, causes a great increase in the density of Turkey Vultures. There is clear competition between these races at this time, and D. Kirk showed in Venezuela that the migrant race is dominant at feeding sites and causes the resident birds to change their foraging areas and spend more time over the forests.

As far as we know, no other species makes substantial migrations, but many may make short distance movements that are not yet understood. It would be surprising if the arrival of the large numbers of migrant Turkey Vultures into South America did not cause some movement patterns in the resident small vulture species.

Relationship with Man

Vultures are large, spectacular birds, associated with death and cleaning of the body. It is perhaps inevitable that from early times human cultures have recognized vultures as important symbols of burial rituals and the release of the human spirit (see page 91).

Condors regularly appear in the pottery designs, textiles and carvings of the pre-Colombian cultures in the Andes. A condor forms part of the remarkable assemblage of huge designs drawn on the desert of the Nazca Plain in Peru by the Paracas/Nazca civilizations around 1000 to 2000 years ago. Condors were clearly important in mythology and figured in rituals of these early civilisations. Even today the Andean Condor appears on the coat of arms of Colombia, Bolivia, Ecuador and Chile, and so is obviously still a powerful symbol of national identity for the people of the Andes. The Order of the Condor is the highest order of merit in Bolivia. Condors feature in some modern festivals in the Andes, the most famous of which symbolizes the conflict between the Spanish Conquistadores and the native Indians. A condor is tied to the back of a bull, which is sent running through the streets of the town: if the condor survives, it is meant to symbolize the successful resistance of the Indians, and is released back to the wild the next day.

While the three *Cathartes* species all attend large carcasses, they tend to feed far more frequently on a wide variety of much smaller prey items, as in the case of these two Lesser Yellow-headed Vultures. This is undoubtedly connected with the excellent sense of smell possessed by the three species, which enables them to locate even very small carcasses, including those of small rodents and birds.

[*Cathartes burrovianus urubitinga*, Peru.
Photo: Günter Ziesler]

The form of worship of the Mayan culture is poorly known, but King Vultures sometimes appear as god-like figures and appears in manuscripts as the symbol of Cib, the thirteenth day of the month. Many prehistoric North American Indian cultures are known to have held the California Condor in particular respect, burying it with their dead, using its bones for whistles and its feathers for decorative bands, and representing its image on rock paintings.

There is no doubt that modern society views vultures in a very different way from early civilizations. They are now perhaps tolerated as useful, rather than being respected or admired. There is some direct persecution, often on the pretext of supposed damage to livestock, which has rarely been verified, or from thoughtless hunting. The most damaging relationship between vultures and men however comes from indirect persecution. As natural scavengers, vultures are at the end of the food chain. They are therefore likely to accumulate poisons, pesticides, heavy metals and other modern environmental contaminants. Their environment has suffered the addition of numerous modern hazards, such as power lines which provide new dangers to flying birds, as well as the danger of electrocution when birds perch on the pylons. Peril also lurks in the steep sided water troughs which are installed for cattle, and in which the birds can drown. We need to recognize the important role that vultures play in cleaning the environment and minimize the risks to their future survival.

Status and Conservation

Scavenging birds are particularly sensitive to human activity, but a curious aspect of this relationship is that, while some species have been brought to the brink of extinction, others have benefited to a spectacular extent. American Black Vultures and Turkey Vultures are today more abundant in agricultural and developed areas than in undisturbed habitats. These two species feed extensively on road kills, and squashed wildlife is, sadly, one food resource that increases every year. The steady move northwards of these two species in North America in recent years is probably associated with this increase in roadside snacks.

American Black Vultures have suffered persecution, because they are blamed for making attacks on newborn lambs and calves, and some thousands of birds have been trapped in

farming areas in the USA. This species is also blamed for spreading diseases of livestock. Their widespread habit of feeding on garbage dumps and then moving to food markets has also caused them to be suspected of spreading salmonella and other health hazards. This rarely leads to direct persecution, and the solution to this problem is to place better controls on waste disposal. Bigger threats to these two species are probably the chance of being killed by cars while feeding on the roads, and poisoning by eating some of the more bizarre items found on rubbish tips. These smaller vultures species, however, seem well able to withstand the current levels of persecution because of their potentially high reproductive rate.

Very little is known about the status of all the South American species. An indication of how little we know about these birds is the fact that the Greater Yellow-headed Vulture, although it is perhaps the most conspicuous and abundant of all large birds in the rain forest, was only scientifically described as recently as 1964. Direct habitat destruction by forest clearance is an obvious threat to all forest birds, and rightly arouses extreme conservation concern. Less widely appreciated is the extent of human exploitation of remaining forest areas. Any area of forest which has road or river access to human settlement is likely to be subjected to heavy hunting pressure. This rapidly removes the monkey species by shooting, and hunting dogs effectively remove most of the ground mammals. Within a few years primary forests can have much of their mammalian biomass removed by this relentless hunting pressure. This has an obvious impact on scavenging birds, by removing the source of their food supply. It is known that the density of *Cathartes* vultures is well correlated with the density of forest mammals. The King Vulture appears to be one species which rapidly finds it difficult to survive in areas of disturbed forest, presumably because the food supply is no longer able to sustain it. We know absolutely nothing about the population dynamics of this or the other forest species, and how vulnerable they may be to continued loss of mammalian biomass from forests.

But the species which are of most conservation concern are undoubtedly the two condors. The California Condor is one of the most endangered of all bird species. In 1987 the total world population had been reduced to 22 individuals. It is worth concentrating on the story of this species, for the research carried out on this bird gives us a clear picture of the potential threat facing all the other vulture species. Also the recovery programme for the California Condor is including conservation

The presence of two adults and a juvenile on this cliff ledge might suggest at first glance that this is a nest-site, but these Andean Condors are at a roosting site. In any case, both of the adults are males, and unlike many species of Old World vultures, no member of Cathartidae is a true colonial nester. On the other hand, these birds do roost in groups, and on such occasions several dozen condors and even several hundred of the smaller species may gather. It has been suggested that these communal roosts may act as information exchange centres, which, given that the birds depend on a dispersed and unpredictable food supply, would increase their foraging efficiency. Normally condors remain at their roosts for several hours after sunrise, and return to them several hours before sunset. It appears that the amount of time spent at the roost is closely related to the weather conditions, and in the case of the California Condor (*Gymnogyps californianus*) birds will not fly at all during days of thick mist or heavy rain.

action for the Andean Condor, which may also be threatened now.

We should perhaps first ask why these two birds are now so threatened, or, in one case, critically endangered. Some people have regarded the California Condor as being a representative of a past Pleistocene fauna, originally dependent on the rich assemblage of mammal species which became extinct about 11,000 years ago. As such, it is a species which is doomed to extinction. There is no evidence to support this gloomy prospect. All the field evidence indicates that the range of the condor in North America contains abundant potential food and could support a large, viable condor population. The problem for the California Condor, as L. F. Kiff has pointed out, is that it failed to evolve a bullet-proof vest. The cause of the decline of the condor is a combination of direct, and indirect, human persecution. Once these factors are identified and removed there is no reason why condors should not thrive again in North America. In the meantime, conservationists have to fight to hold onto the species until the habitat can be cleaned up and made a fit place for condors to return to.

During the late Pleistocene California Condors occurred over much of North America. Fossils have been found from the west coast across to Florida and as far north as New York. But following the great Pleistocene extinctions, 11,000 years ago, the range of the bird became restricted to the mountains of the Pacific Coast. There the species fed on deer and sheep in the mountains, and on whales and seals washed up onto the beaches.

By early this century, the range had contracted to a small group of remote hills surrounding the San Joaquin Valley to the north of Los Angeles. Nobody knows the cause of this decline, but it was probably a combination of factors: egg-collecting was widespread, as was shooting, but probably far more important was poisoning. At that time, the normal method for farmers to kill wolves, coyotes and other potential predators to their stock was to bait carcasses with strychnine, cyanide or other poison. If condors came to feed at such carcasses, they too would be killed. In addition, widespread hunting un-

doubtedly meant that many deer were wounded, and would subsequently die with lead bullets or shot in their bodies. When condors came to feed on such carcasses they would eat the lead and be poisoned. Condors are birds which are adapted for an environment in which adult mortality is very low. Adult birds would probably have had among the longest lifespans of any bird species. Their reproductive rate was also extremely low, with a maximum rate of one chick every two years. In the undisturbed environments in which the birds evolved, the rate at which young were produced could balance the rate at which adults were dying. But modern man introduced a whole new range of dangers for the condors, and far more birds were dying each year. Unfortunately, the birds could not increase their rate of chick production to compensate, and so were steadily sliding to extinction.

The fight to save the California Condor is a remarkable story, and the accounts given by the Snyders should be read by anyone with an interest in wildlife conservation. Endangered species programmes often involve problems of politics, policy disagreements and bureaucracy that are every bit as important as the scientific research. This has certainly been true for the Condor Programme.

It has always been extremely difficult to collect good field information on the condors, and to identify the cause of the population decline. Despite several excellent scientific studies, by 1980 there was even disagreement over the number of condors still surviving. Several attempts at management of the population had not prevented a continuing decline in numbers. An intensive research programme was then initiated to obtain better information. This included catching birds to attach small radio transmitters, so that their movements could be followed. This was not only to reveal information on their use of the habitat, but also to enable any birds which died to be recovered so that the causes of mortality could be identified. It was also intended to start a captive breeding programme, by catching some immature birds, which, when they started breeding, would provide young birds to release and reinforce the wild population.

The American Black Vulture is the most gregarious member of the family at carcasses. Here, large numbers have gathered alongside many Crested Caracaras (*Polyborus plancus*), and both species are feeding on a heap of capybara (*Hydrochaeris hydrochaeris*) carcasses, all that is left over after one of the traditional round-ups of these giant rodents on the Venezuelan llanos. This is just one of the many examples of how man's activities have benefited the American Black Vulture, which is, for instance, also a regular visitor to rubbish dumps. A direct result of this tendency is that the species is now much more common in habitats altered by man than it is in undisturbed ones.

[*Coragyps atratus*
brasiliensis,

Ardea]

The campaign to save the California Condor must undoubtedly be the most complex and expensive such programme ever carried out for a species of bird. By 1982, the total population had slumped to only 21 birds, and the species actually became extinct in the wild in 1987, as it was decided to bring all the remaining wild birds into captivity. After remarkably successful captive breeding, the species was reintroduced, with the first two birds released into the wild in 1992. Clearly visible in this photo is the inflatable neck pouch, which, as in some storks, for instance the Jabiru (*Jabiru mycteria*), plays an important part in courtship display.

[*Gymnogyps californianus*.
Photo: Ron Austing/FLPA]

These studies revealed that in the early 1980's the total population was around 20 birds and still declining, and contained only four or five breeding pairs. Also of vital importance was the discovery of the cause of death of four birds, recovered because of their radio transmitters. Three had died from lead poisoning and one from cyanide. The few birds which were still breeding, however, seemed to have satisfactory levels of breeding success. Attitudes to the intensive research programme rapidly polarized around two irreconcilable viewpoints. One approach maintained that the condors were extremely sensitive to disturbance, particularly around the nest-site, and that their best hope of recovery lay in minimal disturbance. A second opinion was that the number of birds was now so critically low, and the mortality rate so high, that the species needed active management, including the development of an intensive captive breeding programme. While these arguments were debated endlessly among conservation agencies and through the lawcourts, the condors continued to die.

Finally, the decision was taken to capture all the remaining wild condors, and this was achieved by 1987. The future of the species then lay in the captive breeding efforts of the Zoological Societies of Los Angeles and San Diego, and later also the Peregrine Fund at Boise, Idaho. One of the key pieces of information derived from the field research was that the condors would relay if the first egg was lost. This fact, which was hardly surprising, since it had been known for many years that Andean Condors would relay in this way, had been considered impossible by some people. From the start of the breeding programme, therefore, captive pairs of California Condors have always had their eggs removed for artificial incubation, and in this way two or three eggs can be obtained from each pair. Fortunately for the condors, as well as having had extremely dedicated field researchers to highlight their problems in the wild, they were now entrusted to two outstanding teams of zoo staff. The commitment and skill shown by the zoos in building up the captive population have been really remarkable, and the hatching success and survival of the captive population is extremely high. Equally importantly the Condor Programme has benefited from much recent work on understanding the genetic management of small populations, to minimize the loss of genetic diversity among the birds.

Release of young California Condors back into the wild started in 1992. Already some young birds have been found dead, through collision with power lines and poisoning, which indicates that much work remains to be done on restoring the environment for the birds. Maybe the future for the condors will lie in also releasing birds in other sites in North America where fewer hazards face them. This will give time to correct the obvious problems in their original range. The future for the California Condor is now getting brighter. The numbers are increasing fast, probably for the first time for hundreds of years. Provided the captive breeding programme can be sustained, an increasing number of birds will become available for release each year.

The crisis facing the California Condor has also stimulated much research on Andean Condors. This species was initially used as a model to develop methods of captive breeding, rearing of the young and to develop the best methods for release of birds back into the wild. M. P. Wallace started a programme of releasing Andean Condors in Peru, and then later went on to help develop a release programme for Andean Condors into the former range of the California Condors. This was to study the movement patterns they developed, and find the best ways to support released birds with feeding stations. These birds were later all recaptured, before being replaced by the young California Condors, and taken down to Colombia and Venezuela to reintroduce populations in areas where the birds had become extinct. We have little good information on the status of Andean Condors. There is no doubt that their range has contracted markedly in recent years, and they are now rarely seen in the northern Andes. There appear to be good numbers of birds still to be seen in some parts of Peru and Chile, but we know nothing of the population dynamics of these birds, and there is an urgent need for study of these aspects. It is undoubtedly a vulnerable species, which is likely to need active conservation management in the future.

Genus *CATHARTES* Illiger, 1811

1. Turkey Vulture

Cathartes aura

French: Urubu à tête rouge

German: Truthahngerier

Spanish: Aura Gallipavo

Taxonomy. *Vultur aura* Linnaeus, 1758, Veracruz, Mexico.

Taxonomic status of all three *Cathartes* species rather uncertain: some forms currently considered races of present species may yet prove to merit treatment as full species. N populations of nominate race sometimes placed in separate race, *meridionalis*; those of Falkland Is and W South America sometimes separated off in race *falklandicus*; however, some variation clinal, and in general subject still poorly known (see page 25). Four subspecies usually recognized.

Subspecies and Distribution.

C. a. aura Linnaeus, 1758 - W North America S to Costa Rica; Greater Antilles.

C. a. septentrionalis Wied, 1839 - E North America.

C. a. ruficollis Spix, 1824 - S Central America (from Costa Rica S) and lowland South America; Trinidad.

C. a. jota (Molina, 1782) - Pacific coast of South America (from Ecuador S), E Andes, Patagonia, Falkland Is.

Introduced (nominate *aura*) to Puerto Rico.

Descriptive notes. 64-81 cm; 850-2000 g; wingspan c. 180-200 cm. Size variable. Brownish black, with only slight iridescence on plumage. Head and neck bare, sometimes with whitish warts and patches of bristles. Skin colour variable, from pink to bright red. Juvenile birds are duller brown in plumage, and have dark grey skin colour on head, with short downy feathers. Species shows cline in body size, and distinction between subspecies is largely on size and intensity of colouring of head; race *ruficollis* distinctive, with whitish band across back of head.

Habitat. Found in an extreme range of habitats, from total desert in coastal Peru, through grasslands and savannas, into dense tropical rain forest, and temperate woodland in North America. Does not associate with man in the manner of *C. atratus*; small numbers may collect around rubbish dumps. Wanders up to 4300 m.

Food and Feeding. A more exclusive scavenger than *C. atratus*, rarely killing even small prey items, and relying on finding carcasses. Even attracted by carcasses of small birds, but main prey is medium-sized mammals. In disturbed environments benefits greatly from road kills, and this source of food may account for northern extension of distribution of species that has occurred during present century. Food located by olfaction, and this genus is one of the few among birds in which sense of smell is highly developed and plays major role in locating food. Freshly dead carcasses do not emit strong enough smell to attract birds, but in tropical conditions carcasses one day old are located with great efficiency. Birds tend to ignore carcasses that are many days old, probably to avoid toxic by-products of bacterial action. At carcasses, present species tend to be timid, and usually dominated by both *C. melanobrotus* and *Coragyps atratus*. Usually arrives at carcasses first, withdraws while other species feed, and then returns to clean up after other birds have left.

Breeding. Well studied in North America, very poorly known in tropical areas. Egg-laying in March in Florida, May-Jun further N; Feb-Apr in Panama; Dec-Mar in Cuba. Nests in shallow caves, on ground in dense undergrowth, or in hollow tree stumps and logs; no nesting material provided. 2 eggs; incubation 38-41 days; chicks have white down, and dusky, bare head; fledging at 70-80 days or more.

Movements. North American races migratory, moving to S USA and funneling through Central America into N South America, and possibly S to Paraguay.

Status and Conservation. Not globally threatened. Widespread and abundant. Huge numbers migrate through Central America, with over 230,000 counted over Panama City in Oct-Nov 1973; also c. 1,000,000 recently over Veracruz (E Mexico). Rather common below 2500 m on E Andes, from S.W. Bolivia to WC Argentina, and also in steppe areas of Patagonia. Range has increased recently, and it is known that birds are more abundant in disturbed than in undisturbed habitats. Not seriously persecuted anywhere in range. Introduced to Puerto Rico (from Cuba) in 1880.

Bibliography. Arad *et al.* (1989), Audubon (1826), Bang (1972), Blake (1977), Brown, W.H. 2. Lesser Yellow-headed Vulture

Cathartes burrovianus

French: Urubu à tête jaune

German: Kleiner Gelbkopfgeier

Spanish: Aura Sabanera

Other common names: Savanna (Yellow-headed) Vulture

Taxonomy. *Cathartes burrovianus* Cassin, 1845, near Veracruz City, Mexico.

Taxonomic status of all three *Cathartes* species rather uncertain. Present species has been placed in superspecies with *C. melanobrotus*, but the two are widely sympatric. Formerly called *C. urubitinga* or *C. urubitinga*. Two subspecies sometimes recognized.

Subspecies and Distribution.

C. b. burrovianus Cassin, 1845 - Central America S to C Colombia and NW Venezuela.

C. b. urubitinga Pelzeln, 1861 - lowland South America.

Descriptive notes. 58-66 cm; 950-1550 g; wingspan c. 160 cm. Plumage black. Bare skin on head and neck seems to vary considerably in colour: some birds have pure bright yellow, others also

have orange and blue tones. Immature browner, with dusky head and whitish nape. Races differ only in size.

Habitat. Most records come from flat, grasslands, llanos and savannas. Will enter forests, but usually only at forest edge.

Food and Feeding. Feeding ecology very similar to that of *C. aura*. Has good sense of smell, which it uses to locate food. Probably feeds on wide range of small prey items.

Breeding. Very little information available. Adult seen with two recently fledged young in May in Colombia; in same country, female ready to lay in Aug. Nesting reported in holes

in large trees, Surinam.

Movements. No evidence to suggest any extensive movements, but abundance may vary seasonally in Panama and Venezuela.

Status and Conservation. Not globally threatened. Status and distribution poorly known, but seems to be widespread and relatively numerous. Fairly common to common in suitable habitat in Panama and Colombia, outnumbering *C. aura* at Carimagua, Meta (C Colombia). Common along coastal parts of French Guiana. In Brazil, most common in NE and Amazonia. No threats known.

Bibliography. Belton (1984), Blake (1977), Contreras *et al.* (1990), Houston (1988), Kirk (1988), Koster (1982), Lemon (1991), Monroe (1968), de la Peña (1992), Shuker (1993), Sick (1985a, 1993), Slud (1964), Tostain *et al.* (1992), Wetmore (1964, 1965).

3. Greater Yellow-headed Vulture

Cathartes melambrotus

French: Grand Urubu

German: Großer Gelbkopfgeier

Spanish: Aura Selvática

Other common names: Forest (Yellow-headed) Vulture

Taxonomy. *Cathartes melambrotus* Wetmore, 1964, Kartabo, Guyana.

Taxonomic status of all three *Cathartes* species rather uncertain. Present species very similar in appearance, ecology and behaviour to *C. aura* and *C. burrovianus*. Has been regarded as an allospecies of *C. burrovianus*, but the two have widely sympatric ranges. Monotypic.

Distribution. Poorly known. Amazonia, including S Venezuela and the Guianas. Knowledge of distribution is likely to be conservative.

Descriptive notes. 74-81 cm; 1650 g. Plumage black, with clear iridescence on the back and coverts. Skin colour of head bright yellow, shading to bright orange on neck, and to blue on top of head. Very similar in appearance to *C. burrovianus*, from which not easy to distinguish, but tail noticeably longer; present species has greater wing and tail area.

Habitat. Seems to be confined to undisturbed lowland tropical forest in South America, and does not occur in more open habitats. Not found in disturbed forests.

Food and Feeding. Scavenger on carcasses of forest mammals, such as monkeys, sloths

and opossums. Locates food in similar manner to *C. aura* in forests, flying low over forest at height of tree canopy to detect scent of carrion, then descending to the food by following scent trail. Occurs in some areas sympatrically with *C. aura*, over which it is dominant at carcasses.

Breeding. Virtually no information available, no nest having been found. Copulation seen in Aug, French Guiana.

Movements. No information available.

Status and Conservation. Not globally threatened. Apparently confined to remote areas, and not found where forests have been disturbed. Commonest vulture away from humanized areas in Amazonian Colombia. In French Guiana, common in undisturbed forest, but becoming less frequent in areas where food supply impoverished by heavy hunting pressure.

Bibliography. Bernal *et al.* (1994), Blake (1977), Fjeldsá & Krabbe (1990), Graves (1992), Hero *et al.* (1992), Houston (1994), Shuker (1993), Sick (1985a, 1993), Tostain *et al.* (1992), Wetmore (1964).

Genus *CORAGYPS*

I. Geoffrey Saint-Hilaire, 1853

4. American Black Vulture

Coragyps atratus

French: Urubu noir

German: Rabengeier

Spanish: Zopilote Negro

Other common names: Black Vulture

Taxonomy. *Vultur atratus* Bechstein, 1793, St John's River, Florida.

Affinities unclear. May be better considered monotypic, as validity of races doubtful. Three subspecies sometimes recognized.

Subspecies and Distribution.

C. a. atratus (Bechstein, 1793) - S USA and N Mexico.

C. a. brasiliensis (Bonaparte, 1850) - Central America and N & E South America.

C. a. foetens (Lichtenstein, 1817) - W South America.

Descriptive notes. 56-68 cm; 1100-1900 g; wingspan 137-150 cm. Dull black, with only slight iridescence on wings and tail. Primary feathers have a light grey ventral side, which forms

penetrating far into dense, undisturbed forests.

Food and Feeding. A general scavenger, taking almost any animal food, e.g. insects, birds' eggs, fish; frequents small and large animal carcasses, where collects in large numbers. Has a markedly larger gape than *Cathartes* vultures, and at carcasses specializes in muscle and viscera, which it can gulp down rapidly. Does not have ability to smell, so in forest conditions is dependent on *Cathartes* species to be led to food. Also regularly kills small items of prey, such as nestling birds and hatching sea turtles; can catch live fish, insects, small reptiles, etc. Dominant over *Cathartes* species, especially when present in large groups, and tends to displace them from carcasses. Known to forage in family groups.

Breeding. Laying dates very variable: in Ohio (USA), Mar-May; in Panama Oct-Dec; in Colombia May-Nov. Nest-site variable: in shallow caves; between boulders in rocky outcrops; on ground at base of tree; or in hollow stumps. No nesting material provided. 2 eggs; incubation, by both parents, 38-45 days; chicks have rich buff-coloured down, with head bare; regularly wander from nest-site towards end of nestling period; fledging probably at c. 3 months. Young remain with parents, and continue to forage with them in social groups, probably for many years.

Movements. Unlike *C. aura*, birds in North America seem largely resident. Some birds pass through Panama following the main raptor migration, perhaps suggesting some local seasonal movements. In tropical habitats, birds are probably mainly resident, and marked individuals known to have remained at same site throughout year.

Status and Conservation. Not globally threatened. Widespread and common; has undoubtedly benefited from human activities, and now far more abundant in disturbed habitats than in natural wildlife areas. Suffers occasional persecution, because of suspected transmission of human diseases, e.g. salmonella, and diseases of cattle.

Bibliography. Bang (1972), Bent (1937), Blake (1977), Brown, W.H. (1976), Coleman & Fraser (1987), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Friedmann (1950), Johnson (1965), Lemon (1991), Ligon (1967), McHargue (1981), Monroe (1968), Palmer (1988), Parmalee (1954), Parmalee & Parmalee (1967), de la Peña (1992), Rabenold (1986, 1987a, 1987b), Root (1988), Sick (1985a, 1993), Slud (1964), Snyder & Snyder (1991), Stewart (1974, 1978, 1983), Thomas (1928), Tostain *et al.* (1992), Wallace & Temple (1983), Wetmore (1965), Wilbur & Jackson (1983).

Genus *SARCORAMPHUS* Duméril, 1806

5. King Vulture

Sarcoramphus papa

French: Sarcoramphé roi

German: Königsgeier

Spanish: Zopilote Rey

Taxonomy. *Vultur papa* Linnaeus, 1758, "in India occidentali"; error, Surinam.

Affinities unclear. Monotypic.

Distribution. Tropical forest and savanna regions of Central and South America, from Mexico to N Argentina.

ly over about four years.

Habitat. Lowland tropics, usually associated with undisturbed forest, but also found in open savanna and grassland habitats.

Food and Feeding. A scavenger, usually associating with *C. aura* or *C. melambrotus*. Does not appear to have functional sense of smell, and so is dependent on *Cathartes* vultures to lead it to food. At carcasses, large size and powerful bill enable it to tear open skin of larger mammals that can not be opened by smaller forest vulture species. Dominant over other species, but usually not aggressive when feeding, and will tolerate other species feeding alongside. Usually only one or two adults come to carcasses, together with young birds, suggesting that species may be territorial in feeding. At large carcasses, groups of ten or more adults can be found, although it is unusual for more than two adults to feed together. Comparatively small gape, and feeds rather slowly, taking skin and tougher items of tissue from a carcass.

Breeding. Only a few nests have been found; insufficient information available from the field to describe breeding season or biology, but species breeds well in captivity, from which there is good information on courtship and breeding behaviour. In wild, nests on ground or in stumps of trees, on one occasion perhaps considerably above ground level; no nesting material collected. 1 egg; incubation 53-58 days, in some pairs shared equally by the sexes, in others carried out entirely by female; chick covered in pure white down; regularly wanders away from nest-site as it develops. Development in captivity suggests fledging at c. 3 months, young closely attended by parents long after this.

conspicuous whitish patch on underside of wing in flight. Head bare, with numerous folds of skin, and warty texture. Juveniles similar, but with less skin folding on head and some downy feathers. Races differ in extent of pale area on underwing, and also in size.

Habitat. Closely associated with human activity, and abundant around many cities, feeding on refuse and road kills. Some cities in Central and South America have vast numbers collecting around markets, fish docks and garbage dumps. Otherwise found almost everywhere in lowland habitats, especially along rivers and in open country; rarely found

Family CATHARTIDAE (NEW WORLD VULTURES) SPECIES ACCOUNTS

Movements. Apparently resident in most areas throughout the year.

Status and Conservation. Not globally threatened. Very little information available. Although a very striking bird, it is rarely seen; usually perches high in forest canopy, and flies very high when searching for food, making presence in an area often inconspicuous. Status best determined by laying out carcass baits to attract birds to the ground; using this system, several areas where birds unrecorded for some years have been shown to have healthy populations. Species can survive in areas of cattle ranching, presumably provided it has access to some undisturbed forest areas for breeding. In forests seems to be particularly susceptible to human disturbance, and rarely recorded in areas where mammal populations have been reduced. CITES III in Honduras.

Bibliography. Antas & da Silveira (1980), Berlanga & Wood (1992), Blake (1977), Clinton-Eitnincar (1981, 1987), Contreras *et al.* (1990), Cuneo (1968), Fjeldså & Krabbe (1990), Friedmann (1950), Kirk (1988), Koster & Koster-Stoewesand (1978), Heck (1963, 1971), Houston (1984, 1988), Lemon (1991), Lundy (1957), Monroe (1968), Palmer (1988), de la Peña (1992), Reid (1989), Schlee (1987), Sick (1985a, 1993), Slud (1964), Smith (1970), Thiollay (1985b, 1989b), Tostain *et al.* (1992), Wetmore (1965), Zwart & Louwman (1980).

Genus *GYMNOGYPS* Lesson, 1842

6. California Condor

Gymnogyps californianus

French: Condor de Californie

German: Kalifornischer Kondor

Spanish: Cóndor Californiano

Taxonomy. *Vultur californianus* Shaw, 1798, Monterey, California.

At one time placed in genus *Pseudogryphus*. Monotypic.

Distribution. Extinct in wild from 1987 to 1992. Captive population now being used for reintroduction to former range, in hills around San Joaquin Valley, California. Formerly occupied mountain tops of Pacific coast of North America.

Descriptive notes. 117-134 cm; 8000-14,000 g; wingspan c. 270 cm. Black plumage, with white underwing-coverts. Long ruff feathers also black. Head and neck bare with variable pink-orange and red colours. Immature has bare skin grey.

Habitat. Within recent times range restricted to remote, irregularly wooded hills north of Los Angeles, California. During Pleistocene, species was widespread across much of North America, and must have occupied a wide range of prairie, mountain and hillside habitats.

Food and feeding. Scavenger on carcasses of large mammals. When species was still abundant, large groups of birds could be attracted to feed at a single carcass.

Breeding. Egg laid Feb-May. Nest-site usually in caves or large tree holes; no nest construction. 1 egg; incubation c. 55-60 days; chick has first down white with bare pink to yellow head, then second down grey also covering head; fledging c. 6 months, but still fed by parents for several months afterwards. If breeding successful, pair will not breed in subsequent year. Adult plumage not attained until 5 or 6 years old, and sexual maturity at c. 8 years old. Known to live up to 45 years old.

Movements. Radiotelemetry studies show that most breeding birds travelled about 30 km to reach feeding sites. Not known to undertake long distance movements.

Status and Conservation. ENDANGERED. CITES I. One of the most seriously endangered of all bird species. Population has been declining throughout present century. First detailed study estimated 60 birds alive in 1953; by 1982, numbers had fallen to 21 birds in the wild. Intensive research programme demonstrated that remaining birds had satisfactory breeding output, but that increase in mortality was responsible for the population decline. Causes of mortality were difficult to identify, but shooting, lead poisoning, strychnine poisoning, collision with power lines, electrocution and soilage in tar and oil deposits were probably involved. Disagreement between conservation agencies and consequent legal disputes delayed the implementation of effective recovery programme until so late that captive breeding was the only realistic chance of saving the species. In 1987 it was agreed that all wild birds would be caught and taken into two captive breeding facilities provided by the Zoological Societies of Los Angeles and San Diego. Captive breeding has been highly successful: captive population up to 52 birds by 1991; 15 chicks hatched in 1993; and first 2 young birds released back into the wild in 1992.

Bibliography. (1989, 1991), Wallace & Temple (1983, 1987b), Wallace & Toone (1992), Wilbur (1978).

Genus *VULTUR* Linnaeus, 1758

7. Andean Condor

Vultur gryphus

French: Condor des Andes

German: Andenkondor

Spanish: Cóndor Andino

Taxonomy. *Vultur gryphus* Linnaeus, 1758, Chile.

Monotypic

Distribution. Andes, from Venezuela to Tierra del Fuego, descending to sea-level in Peru and Chile.

Descriptive notes. 100-130 cm; female 8000-11,000 g, male 11,000-15,000 g; wingspan up to 320 cm. The only American vulture to show sexual dimorphism: male has large comb and large neck wattles, lacking in female. Plumage black, with secondaries and upperwing-coverts greyish white. Conspicuous white neck ruff. Bare skin on head and neck variable in colour, reddish pink at base of neck, more mottled greyish pink or yellow on head. Juvenile dull brown, with dark bare skin; over years adopts blacker plumage, with white neck ruff only appearing in adults.

Habitat. Mainly high mountains, including highest peaks, but usually over open grassland and alpine regions, away from human disturbance and where carrion can be found: rare in forested areas. Descends to lowland desert regions in Peru and Chile, especially to forage along the shoreline for stranded whales, seals and seabirds; also on grassland plains of Argentina S of Río Negro.

Food and Feeding. Mainly carrion from large and medium-sized mammals, such as guanacos (*Lama guanicoe*), domestic livestock or marine mammals along coast. Will also take smaller food items, including eggs from seabird colonies. Powerful bill capable of tearing skin and extracting muscle and viscera from carcasses. Up to 40 birds seen together at a large carcass.

Breeding. Poorly known. Laying Feb-Jun in Peru, Sept-Oct in Chile. Nests in shallow caves on cliff ledges. 1 egg; incubation c. 59 days (in captivity); chick grows slowly and is fully-feathered and capable of flight at 6 months, but parental care continues long after fledging, so whole breeding season lasts over 12 months. Breeding probably only occurs in alternate years, and many pairs may not breed at all when feeding conditions are poor. Young birds do not attain adult plumage till 6 years old, and in captivity breeding may be delayed several years further.

Movements. Forages very widely, and must cover great distances. Appears to be resident throughout the year, with no evidence of migrations.

Status and Conservation. Not globally threatened. CITES I. Poorly known, but currently threatened over most of range. Now exceedingly rare in N of range, in Venezuela and Colombia; reintroduction programme using captive-bred birds currently under way in Venezuela and Colombia. Most frequently seen in Peru, Chile, and Argentina, where in some areas species remains common. Still subject to persecution and poisoning over most of range, because of alleged attacks on livestock. Status of remaining population is difficult to determine, because so little known about mortality, breeding frequency and success. Species clearly adapted for exceptionally low mortality and low reproductive output, so highly vulnerable to human persecution. There is serious need for detailed study of population dynamics of this species, to determine its conservation status. Protected under CITES due to pressure from live animal trade.

Class AVES
Order FALCONIFORMES
Suborder ACCIPITRES
Family PANDIONIDAE (OSPREY)

- Large piscivorous birds of prey, with reversible outer toe and spiny foot pads to help grasp slippery prey.
- 55-58 cm.

- Cosmopolitan.
- Shallow waters, both inland and marine.
- 1 genus, 1 species, 4 taxa.
- No species threatened; none extinct since 1600.

Systematics

The Osprey (*Pandion haliaetus*) is generally placed in a monospecific family within the suborder Accipitres, which contains the hawks, the Old World vultures, and the eagles. Still debated is whether this fish hawk is different enough from other birds of prey to warrant such separate treatment, or whether it simply deserves subfamily status within the family Accipitridae. DNA-DNA hybridization studies have suggested the latter, but more work is needed to clarify this.

In essence, this is a hawk that has evolved as a fishing specialist, and its differences from members of the Accipitridae reflect adaptations to its unique way of life. Prominent among these adaptations are: a reversible outer toe and spiny foot pads, which serve as aids to carrying and gripping slippery fish; a long small intestine, as in other fish-eating birds, probably helping it to digest fish, bones and all; dense, compact, oily plumage; long, sharp, curved claws; and nasal valves that help shut out water when the bird dives. In addition, the Osprey has a narrow head and lacks the bony ridges above the eyes seen in many hawks and eagles, giving it an almost feline look when perched. In the air, it both hovers and soars well, but it can also fly long distances directly across water and deserts in steady, powered flight (see Movements). Its wings are relatively long and narrow, a compromise between efficient soaring and manoeuvrability.

The Osprey's fossil record, which dates back at least to the middle of the Miocene, 10-15 million years ago, suggests the species has changed little since then. And later Miocene and Pleistocene fossils from western Europe, North America, and the Bahamas indicate a range essentially unchanged from that of today.

Four Osprey subspecies are recognized nowadays: nominate *haliaetus* from the Palearctic; *carolinensis* from North America; *ridgwayi* from the Caribbean subregion; and *cristatus* from coastal Australia, and a broad arc of islands stretching north and east of the continent, from Sulawesi and Java to New Caledonia. The latter two subspecies are composed of non-migratory, resident populations, while the first two contain both migrants and residents, depending on latitude of breeding (see Movements). The four subspecies differ little, mainly in plumage and size, and sexual differences confuse the issue, as, in all populations, males tend to be paler in their breast plumage and smaller in body mass and wing (see Morphological Aspects).

The lack of speciation among Ospreys is interesting, and contrasts markedly with the *Haliaeetus* sea-eagles (see page 54), which have formed eight distinct species over a range nearly identical to that of the Osprey. These eagles differ from Ospreys, however, in their migration patterns, as most are residents or short distance migrants. Because Ospreys are long distance migrants (see Movements), there is more chance for interchange among populations and thus less chance for subspecies to become isolated as distinctive species.

Morphological Aspects

Ospreys vary in size both geographically and by sex. In any one population, females are larger than males, averaging about 20% larger in body mass, and 5-10% larger in wing length. Some overlap is possible, but this is limited; in North America, for example, nearly all males weigh less than 1600 grams, while nearly all females weigh more. Yet at a distance such differences are obscured and it is often difficult to distinguish between the sexes in the field, even though females tend to have darker breast plumage. Such reversed size dimorphism is typical in birds of prey, but the factors selecting for it are still debated. Large size confers some obvious advantages to a female, for example in terms of nest defence, egg production, and incubation efficiency, but male Ospreys help considerably with both defence and incubation (see Breeding).

In both sexes, Ospreys that breed in tropical and subtropical climates tend to be smaller than those breeding at cooler, higher latitudes. Australasian Ospreys, for example, are 12-14% smaller in wing length than their Palearctic counterparts, while Caribbean Ospreys average about 5% smaller than New England Ospreys. Such shifts along a climatic gradient are thought to have adaptive significance: among warm blooded vertebrates, races in cold climates tend to have larger bodies than those in warm climates, because larger bodies retain heat more efficiently.

In plumage, the sexes are quite similar, although females in any one race tend to be darker on the breast and often on the head. Overall, for both sexes, the Osprey's salient features are its bright white underparts, with a mottled brown breast band of variable intensity, the pronounced crook in its long wings, which in flight are bent back at the "wrists" or carpal joints, its dark carpal patches contrasting with pale underwing-

The Osprey's wings are long and rather narrow, and they are sharply angled at the carpal joints in flight. It flies alternating powerful wingbeats with short glides. Its wing structure allows it to undertake long distance migrations over water and deserts, without showing the dependence on thermals and other natural updraughts that characterizes many broad-winged, soaring raptors. The strikingly white underparts, contrasting with the darker wing feathers and tail, the dense black carpal patches and the broad black line through the eye to the hindneck are the species' most distinctive field characters.

[*Pandion haliaetus*.

Ardea]

coverts, and the dark stripe through its eye. The upperparts of northern birds are a rich dark chocolate brown, the flight-feathers pale grey, and the undertail white with narrow dark barring. The subspecies show only slight differences, mostly in plumage and size, with *haliaetus* and *carolinensis* the largest and darkest, and *ridgwayi* essentially a pale form of *carolinensis*. The Australasian *cristatus* is a small Osprey with a dark breast band and a relatively pale crown. In all races, juveniles resemble adults in terms of plumage, but they are somewhat paler above, the feathers edged with buff, and the breast band less sharply defined. At all ages, the feet are a pale blue-grey, and the bill is black.

The Osprey's adaptations for fishing include relatively long legs for a raptor of its size, and these enable the bird to extend its reach for fish under water. Other such notable developments are spiny foot pads and a reversible outer toe to help grasp slippery prey, dense, oily plumage, and efficient nasal valves that prevent water entering the nostrils when the bird dives. Its wings are relatively long and narrow, much like a harrier (*Circus*), with moderate wing-loading. This is a style of wing evolved for efficient hovering or direct flight, rather than primarily for soaring, although Ospreys can and do soar, especially in the middle of the day. As a result of this structure, the species is an efficient migrant over water and deserts, and is suitably built for long distance travel (see Movements). Unlike many broad-winged raptors, notably those of the genus *Buteo*, this is not a species dependent on landforms, such as ridges that produce updraughts, or thermals, or other features which can play an important part in the migration of soaring hawks.

Among migrant populations, the moult of the primaries proceeds in successive waves, starting from the innermost and working its way outwards. Generally, at least three intact feathers remain between centres of new growth, preserving much of the flight efficiency of the wing. Nevertheless, among migrants, moult stops during both northward and southward migration. Roughly half of the adult birds moult on their breeding grounds, generally in late summer towards the end of breeding, but virtually all adults moult in their wintering grounds. Such wave moult ensures that all the flight-feathers are replaced in one year. Moult of non-migratory Ospreys has not been studied.

Habitat

Breeding Ospreys inhabit a broad array of coastal habitats, along lakes, reservoirs, marshes, bay and sea shores, and to a lesser extent rivers. Shallow water is generally the common denominator here, because fish are easier to find and catch in the shallows than in deep water (see Food and Feeding).

The other key limiting factor for this species is the availability of safe, predator-free sites for the bulky stick nest. Shoreline trees, generally dead ones, occasionally provide good sites, but the vast majority of such trees are unable to support the Osprey's sizeable nest or, just as important, are accessible to climbing predators. Small islands, by contrast, usually have few or no ground predators, and so are favoured nesting habitat. In some places, pairs breeding on small islands will even nest on the ground, for instance in Australia and north-west Mexico. Likewise, trees killed when flooded out by beavers (*Castor*) or by man's reservoirs, natural swamps, and also overwater structures, like buoys and channel markers, provide safety by isolating nests from shore. All these island and overwater situations promote the largest and densest colonies of nesting Ospreys.

The species has several typical habitats, which vary to a certain extent regionally. Salt marshes are commonly used in the north-eastern USA, the birds fishing in the surrounding tidal creeks and rivers, in bay waters, and along the nearby ocean shoreline; in this region, pairs nest increasingly on artificial platforms. Mangrove (*Rhizophora*) swamps are important habitat in southern Florida, Cuba and Belize, and also along the Red Sea and sometimes in Australia, with birds nesting in the tops of mangroves, or on the ground on open islands. In the Carolinas of the eastern USA, in cypress (*Taxodium*) swamps, nests are built over the water in the tops of these trees, while the birds commute to nearby marine bays and estuaries to feed. In Sweden, Canada and Russia, typical nesting habitat comprises lakes with shallow waters and islands in the boreal forest, and also bogs. Scattered pairs nest in tall trees along the shoreline of such lakes, or in smaller trees on islands; in these areas, a late break-up of the ice often delays breeding. In the western USA, birds occupy reservoirs, rivers, often those with anadromous fish, and lakes; fish released by hatcheries often form a key part of the diet. In Scotland, birds breed beside lochs or rivers, with nests in nearby pines, or on small islands; there are a few coastal pairs. Finally, Mediterranean birds occupy cliff nests on rocky islands.

General Habits

For breeding Ospreys can be solitary or form loose colonies. They may nest dozens of kilometres from their nearest neighbours, or, at the other extreme, 30-40 pairs within an area of just half a square kilometre. As many as 200-300 pairs may breed on an island only 700 ha in size, with most of them concentrated in just a few sectors. Such coloniality is unusual for a raptor but typical for a fish-eating bird; fish are a mobile resource, hard to defend, so there is no reason for an Osprey to defend anything but its immediate nest-site.

Defence of nests can be intense, with birds actually striking each other and sometimes falling to the ground, grappling. More often, when an intruder nears, guard calls are given, along with conspicuous, stereotyped posturing: an erect stance, with the back feathers raised, and the wings partially opened, beating slowly, all of which probably serves as a warning. Close approach often brings on an aerial chase. Both males and females will defend the nest against intruding Ospreys, and also against predators, but against a conspecific it is generally only the bird of the same sex that participates. Considerable time can be spent repelling intruders, especially in colonies, suggesting that nest scarcity is a key factor for this species. Intruders can thus be quite disruptive, and eggs are sometimes lost or broken in fights.

Against predators, Ospreys are also formidable defenders of their nests, and they will even strike humans with their

talons, in passing dives. At night, the birds are probably more vulnerable; owls and nocturnal climbing mammals make significant inroads at some nesting colonies. Snakes may be a serious threat at nests in subtropical zones. *Haliaeetus* eagles, especially the Bald Eagle (*Haliaeetus leucocephalus*) in North America, occasionally steal prey from flying Ospreys, and they are potential nest predators. When these eagles move in to nest near Ospreys, the latter often move away.

Male Ospreys breeding in New England spend about 195 minutes per day, on average, getting food for themselves and their family, catching some six to eight fish per day. However, in their wintering grounds, they only require about 30 minutes per day to feed themselves, with an intake of one to three fish per day. For breeders, therefore, 65-85% of each day is spent preening, eating, and resting, which are hardly energy-intensive activities. Yet, both male and female breeders are up against real energetic limitations, and lose weight while feeding young. Raising larger broods than normal can be particularly stressful to them, with potentially serious loss of condition.

Ospreys bathe often, both in salt and fresh water, during the breeding season generally in the morning, after being relieved by a mate from nest duties. They also preen and stretch regularly. When soaked after a dive, a bird will twist in mid-air, shaking itself like a wet dog, before settling down, often with its wings drooped, on a perch to dry.

Voice

Three main types of Osprey calls have been distinguished, guard calls, alarm or courtship calls, and begging. Guard calls consist of a slow series of whistled notes falling in pitch, sounding a bit like a whistling tea-kettle being taken off the stove. This call is an Osprey's first line of defence, usually given at a distance, when an intruder, another Osprey, approaches an individual's nest or favoured perch. Occasionally, more intensive, wavering notes are heard, if the intruder comes closer.

Guard calls can shift to alarm notes when an Osprey spots a human, another potential predator, or a threatening Osprey approaching, especially near the nest. Alarms sound like intense guard calls, but are shorter, quicker, more frequent whistles that

also fall in pitch and can grade into excited, high-pitched squeals ("eeee-eeee-eeee"), as the threats approach. These squeals are the same calls given by males during their aerial courtship displays (see Breeding), so they probably have multiple functions, such as attracting mates, claiming territory, and alerting neighbours and mates to danger. Alarms can grade into a harsh, rasping, guttural "ick-ick-ick", when an individual is highly threatened, for example when a human climbs to inspect a nest.

Nesting females, especially hungry ones, direct begging calls to their mates. These calls start during courtship and extend right through the fledging period. Females depend on their mates for food, so begging often seems to be their way of stimulating males to hunt. Males may or may not respond, apparently depending on their own hunger and how recently they last hunted. Female begging calls mimic those of young fledglings, perhaps making it tougher for males to ignore them.

Food and Feeding

Diet and foraging are well studied aspects of Osprey ecology. Unlike any other diurnal bird of prey, Ospreys depend almost exclusively on live fish. Recently dead and dying fish are scavenged on occasions, but such fish kills are rare enough that Ospreys must depend on live prey; very rarely, other small animals are eaten.

Like most hawks, Ospreys dive feet first and catch prey in their talons. But they are buoyant birds, and, despite their relatively long legs, can penetrate at most only about one metre below the water's surface, probably less. This means that they catch only surface-dwelling fish or those that frequent shallow flats or shorelines, constituting an important limitation and a key fact of Osprey ecology. It explains their preference for living along shallow bays and lakes, and it restricts the species that make up their diet.

Ospreys are generally opportunists, and they will take whatever surface or shallow water fish are most available, usually in the 150-300 g size range although smaller and, rarely, larger fish of 50-1200 g are said to be taken. Nevertheless, they can be selective at times. Along the coasts of Nova Scotia and southern

The Osprey is the diurnal raptor most specialized in catching fish, and these make up its diet almost exclusively. Birds can catch fish of 1 kg or more, but most weigh under 300 g. After a successful plunge, the bird flaps vigorously to gain height, while it grips the fish with two toes forwards and two backwards on each foot. Usually one leg is held behind the other, so that the prey is carried head first, and is thus more streamlined with the body.

After catching fish, the Osprey usually goes directly to a feeding perch, often a dead branch on a tree. Before eating the fish, the bird waits for it to die, in the meantime drying out its soaked plumage, and usually also preening and oiling. Once the fish is dead, the Osprey begins to eat it, starting at the head.

New England, for example, up to half the fish Ospreys eat during the breeding season are winter flounder (*Pseudopleuronectes americanus*), while herring (*Alosa*), menhaden (*Brevoortia tyrannus*), pollock (*Pollachius virens*) and a few other species make up the rest of the diet. But spawning, migratory fish, such as herring and pollock, often arrive in shoals, and, as they are easily caught and are rich in nutrients, Ospreys tend to concentrate on these fish, when available. In northern Europe, freshwater fish such as pike (*Esox lucius*), bream (*Abramis brama*), carp (*Cyprinus carpio*), and trout (*Salmo*) all provide nourishment, with dietary differences depending on the latitude and the size and depth of the lakes fished. On lakes in northern Florida, Ospreys prefer sunfish (*Lepomis*) in spring and summer, when these fish are most available, and shad (*Dorsoma*) in autumn and winter, when sunfish abundance declines.

Even within regions, habitat has a major influence on the size and species of fish Ospreys catch. At least ten different fish species figure prominently in the diet of European Ospreys wintering in West Africa, along the coast of Senegal, although at any one location the birds take just a few species. Mullet (*Mugil, Liza*) represent a particularly important part of the diet in this zone, as they do for most Ospreys feeding along tropical and subtropical coasts. Mullet swim in tight schools, they frequent shallow water, and are rich in fats, an irresistible combination for a fish-eating bird!

Ospreys generally hunt on the wing, actively searching out prey rather than waiting quietly on perches for fish to swim within striking distance. By flying, birds cover more area, thereby boosting their foraging efficiency, despite using more energy for each minute spent hunting. Fishing Ospreys fly slowly, 5-40 metres above the water, sometimes circling back on themselves and often pulling up briefly to hover before moving on again. When a fish is spotted, the dive can be spectacular: the bird tucks back its wings and falls steeply, often manoeuvring subtly with wings and tail to keep on track toward its target; its feet swing forward just before the strike. If unsure

about a fish, the hawk may drop down in gradual stages for a closer look, before making its final plunge or veering off to another area. Occasionally, a bird swoops down to snatch fish just from the water's surface, barely wetting its plumage in the process. After a plunge, an Osprey usually rests very briefly on the water, probably securing its prey, before reaching high with long, fast, almost horizontal wing strokes, using the flexible, outer portion of its wing. Once airborne, it grips its prey with two toes forwards and two backwards on each foot (see Morphological Aspects), and usually one leg behind the other, so that the prey is carried head first. In the meantime, it often shakes water off its plumage with vigorous twists in mid-air. Holding its prey tightly underneath its body, the successful forager flies low over the water if windy, or circles up higher if travelling far on warm, still days.

Ospreys generally hunt alone but small groups sometimes form where prey is abundant. Tides may influence hunting patterns in some areas, but the time of day seems to be a more important factor. Birds tend to hunt most actively early in the morning and in late afternoon or evening, as might be predicted for a bird that does not forage at night. It is not clear how Ospreys determine where to hunt, but a study at one nesting colony in North Carolina (USA) found that individual males hunting for their mates and small young were remarkably faithful to particular foraging sites, even though there were other sites equidistant from their nests, which were equally productive, and just as faithfully used by other males from the same colony. No study has yet shown convincingly that Osprey colonies act as "information centres", with individuals keying in on where their neighbours go to find food. Although such information exchange has been suggested for Ospreys foraging close to a colony, birds in these situations can often see neighbours hovering, so it is difficult to know what clues they are actually using.

Osprey dive success ranges from about 60-70% on fish like carp, which eat slow-moving benthic organisms, to under 40%

on quicker, predatory species like trout. Weather can have a significant influence, at least severe weather with high winds and heavy rain. Most individuals just stop hunting in such conditions, often with disastrous consequences at nests containing eggs or newly-hatched young. Lesser fluctuations in the weather seem to have little effect on breeding success.

Breeding

Ospreys are generally winter to spring breeders in subtropical latitudes, but spring to summer breeders farther north. Pairs along the Red Sea or in Florida, for example, lay eggs from December to March, while pairs in Sweden, Corsica, and New England lay in April and May. Such differences in seasonality probably reflect differences in fish availability, but this has not been well studied. Clearly spring to summer breeding coincides with the arrival of shoals of fish that move into warming rivers and coastal shallows to spawn or feed. The birds arrive and lay as early as spring temperatures and the retreat of the ice allow.

Ospreys are generally monogamous. However, where nests are close together and a male can easily defend more than one site, polygyny can occur, with one male mated to two females; single females are often attracted to empty nest-sites. Very rarely, two females may share a single nest, where sites are limited. Success of secondary nests is poor compared to primary nests, largely because secondary females are neglected by their mates.

Courtship revolves around food and nest-sites. Individuals with established nests tend to return, separately, to those used the year before, especially if the pair has successfully raised young there. Singletons, which may be new arrivals, generally young birds, or alternatively widowed birds, either find an empty nest-site and guard it, or settle in with another single, established bird of the opposite sex. Such birds may also move nomadically through a colony or region looking for an available site, but little is known about this. Where unoccupied sites are plentiful, individuals first breed at three to four years of age, but where scarce, they may delay until they are five or six. Once settled at a site, a female often begs from her mate and sometimes, if hungry, from other nearby males. The males brings fish to the female, generally feeding first himself near the nest, and then delivering the remainder to his mate. A female will copulate often with a mate that feeds her, but rarely with one that does not.

Once a pair of Ospreys settles at a nest-site and starts courtship feeding, mating can occur at almost any time or place, but it is most frequent early in the morning, around the same time as egg-laying. The male mounts female gently, his talons closed and his tarsi resting somewhat precariously along the female's back. Vigorous flapping helps the male to balance. If the female is receptive, she tips herself forward to allow the male's tail to scissor under her own. Young pairs are less likely to copulate successfully than older ones, largely because young males are often reluctant to transfer food to their mates, leaving the female unreceptive for breeding. Pairs average nearly 60 successful copulations per clutch, starting at least two weeks, and peaking a few days, before egg-laying. Because females will sometimes copulate with males other than their mates, males protect their paternity by frequent copulation and by maximizing their time with the female when she is most fertile.

Both the male and the female participate in the building of the nest, and they add material throughout the breeding season. They start with large sticks and then add a lining of softer, flatter material, such as seaweed, dead grass, or leaves. Sticks are forcibly broken off trees or are picked up off the ground. Like the best of pack rats, these birds collect an astonishing array of flotsam and jetsam, including cardboard, bones, hunks of sod, rope, plastic bags and fishing line; these last two items occasionally smother or entangle the young. Nests can become huge, even big enough to support a large man, and in some cases they are reused for generations. Clearly they are much larger than is needed for just a few small eggs, so year to year stability may be one goal, territorial advertisement another.

Copulation is most frequent before egg-laying, when it can occur up to seven times daily, but it continues throughout the laying period and even during incubation. It usually takes place on the nest, although it sometimes occurs on a regularly used perch nearby. The male alights on the female's back, keeping his balance by wing-flapping, and remains there for 7-10 seconds.

Bruce Coleman]

The female lays two to four eggs, generally three, though on average, smaller clutches are laid at lower latitudes. With their pale tan or fawn-coloured background, and their chestnut swirls and splotches, these have long been prized by egg-collectors. On average, eggs measure 62 x 46 mm and weigh about 60-80 g, so a clutch of three represents about 10% of the female's body weight, which is not a significant energetic demand. Indeed, feeding rates during courtship seem to have little influence on clutch or egg size, although lack of food may delay breeding. Late-breeding pairs tend to have smaller clutches and produce fewer young than early pairs.

Eggs are laid one to two days apart. Both sexes incubate, with the female usually doing more, although there is great variation among pairs in the division of this labour. Incubation is often sporadic with the first egg, but is more regular with the second and third. Hatching occurs after about 40 days. Because the first and second eggs are usually larger than the third and fourth, and because they hatch earlier, the first and second chicks to hatch generally have a significant advantage over their younger siblings. This is especially critical in years and regions of food scarcity, when chicks fight for access to the female, when she is distributing food. Larger, older chicks invariably win over their younger nestmates.

To anyone watching a nest, it is obvious when the chicks hatch. After the male delivers food, the female stays at the nest to feed, sharing the fish with her young by breaking off small bits to feed them, instead of flying away from the nest to eat at a nearby perch, as she usually does when incubating eggs. At hatching, chicks are weak, wet, and relatively helpless. Their eyes are open and their bodies are covered with a frizzy coat of white down. Although they can beg food from a parent, they still need to be brooded regularly during both hot and cold weather. By ten to fourteen days of age, the second coat of down, charcoal-like in colour, has replaced the first, and chicks have an easier time controlling their own body temperature, but, even so, they are generally brooded by the female at night and during the heat of day. Chicks are quite mobile by this age, and they quickly approach the female when food is delivered. They also back up, to eject their faeces over the rim of the nest.

Depending on the size of the fish caught, a male parent will deliver three to ten fish per day, rarely more, during the nestling period, and about 30-40% less during incubation. This translates to about 60 g each daylight hour early in the nestling stage, with about 100 g per hour during the period of peak demand, when the chicks are bigger. A fish is usually shared sequentially, but not equally, first by the male and then by the female and her young. Once they are large and are growing actively, the chicks get most of the food, especially in large broods of three or four. The female gets the least because she

Ospreys usually build their nests on trees, rock pinnacles or cliffs. Less often, they use telegraph or power poles and other man-made structures, tall cacti, or small bushes; they will even nest on the ground, especially on islands that are free from predators. The nest is constructed of large sticks, twigs, seaweed, driftwood and miscellaneous items. New material is added throughout the breeding season and, as the nest may be used year after year, it becomes a huge structure, especially considering the size of the bird; some old nests can grow to be as much as two metres deep.

Several studies of populations nesting in trees have shown that the birds apparently select the nesting tree more on the basis of the shape of the tree than on the species. They prefer dead, rather than living, trees, those with broken off crowns, and emergent trees that are taller than surrounding vegetation.

[*Pandion haliaetus*.

Photo: Fritz Polking/FLPA]

The mottled pattern of Osprey nestlings helps them to blend into the nest, and it is actually very difficult to spot them in their nests from above, especially when they are lying flat, as they do in presence of intruders. This, together with the almost constant attendance of female Ospreys at their nests, suggests that there is a significant threat of predation by other birds, probably by *Haliaeetus* fish-eagles. The eggs, well marked with brown blotches and spots, are also cryptic, and this presumably helps to avoid nest predation by crows and ravens (*Corvus*). The large size of the Osprey's nest, and also the fact that it is usually in a conspicuous site, make it an obvious target for other avian predators.

[*Pandion haliaetus*.

must feed begging young. As a result, female parents tend to lose weight during the breeding season, while males rarely do.

Young Ospreys can fly at about 50 days old, or a little later if food is not plentiful. At least in migratory populations, young fledged early in the season survive much better than those fledged late on, probably because they have extra time to gain flight and foraging skills, before leaving on their long migrations. Parents continue to bring food to their young for two to eight weeks after fledging, easing the difficult transition to independence. Once migration begins, however, each bird travels on its own. This is a potentially hazardous journey, especially for young birds. At least 70% of the young that fledge die before they reach breeding age, generally in the first six months after fledging.

As might be expected, there is great variation in breeding success between different regions and even within colonies. Young birds, especially first time breeders, produce fewer offspring than experienced birds. Periods of bad weather, especially heavy rain or high winds, can drastically lower nesting success, because most males either stop hunting altogether or catch very few fish. In addition, Osprey eggs and chicks are vulnerable to predators, especially climbing mammals, and perhaps snakes in subtropical regions; these can take a significant toll at nests that are not isolated by height or water. In migratory populations, to balance the annual mortality of adults, on average roughly one bird must fledge for each nest with eggs. Pairs at coastal colonies tend to reach this level easily in most years, but those nesting inland, at freshwater sites, have more difficulty in attaining this average, which, in part, reflects differences in food availability.

One long-term study that followed a generation of Ospreys in Michigan, USA, showed that: the individuals that lived the

longest produced the most fledglings; many breeders raised no young at all; the number of young birds raised to fledging was correlated with the numbers subsequently recruited to the breeding population; only about 14% of the eggs laid, and 27% of the young fledged, contributed fledgling Ospreys to the next generation; and death before reaching breeding age prevented most individuals (70.5%) from contributing fledglings to the next generation, whereas failure to raise any young, once breeding had been attempted, affected a much smaller proportion of individuals (3.6%).

Movements

Migration is one of the best studied aspects of Osprey ecology. Because these birds have been extensively ringed in several populations, with significant numbers of recoveries afterwards, and because they often concentrate at "hawkwatch" locations, where other migrant birds of prey are studied and counted, their passage south to wintering grounds, and north again to breeding grounds has been followed in considerable detail, at any rate for those populations nesting in Scandinavia and the northern USA.

Not all Ospreys are migrants, only those nesting in regions where winter freezes are regular, as these conditions drive fish into deeper water or make them otherwise inaccessible. In North America, for example, migrants breed north of about 30°-32° N, with the division between the migrant and non-migrant, or resident, populations situated around northern Florida, southern Alabama and Mississippi. In Europe, the cut-off is farther north, at about 38°-40° N. Thus, all middle and northern European populations migrate, as do most of the pairs breeding along Mediterranean shores.

During the fledging period the male does all the hunting for the family. He usually brings three to ten fish per day to the nest, departing each time shortly after delivery. The female remains on the nest for the first 28-30 days after the chicks have hatched. When the fish is brought, she tears it up and feeds the young with a rapid succession of tiny morsels, up to ten per minute, passing the food bill to bill. She continues to feed the young regularly for up to 42 days, and thereafter sporadically, even after the young have left the nest.

[*Pandion haliaetus*.

Photo: Joseph van Wormer/Bruce Coleman]

Although their movements have been little studied, "residents" may wander locally during the non-breeding season, but they tend to remain within a few hours' flight of their nest. One exception may be among Southern Hemisphere breeders, the coastal nesters in Australia, where individuals tend to move farther inland after breeding.

Broadly speaking, migrant Ospreys in the Northern Hemisphere tend to winter south of latitudes where residents are found. Ospreys hatched in the northern USA, for example, nearly always migrate south of Belize or Cuba, where the southernmost populations of New World residents nest. These migrants fly at least to the southern Caribbean, and most go on to the northern coasts of South America, and inland through the vast drainage basins of the Amazon and the Orinoco, or up the Cauca and Magdalena Rivers in Colombia. This separation of resident breeders and wintering migrants suggests that competition between the two groups could be a factor in migration patterns, or simply that food is more plentiful farther south. Many Ospreys from the USA have been recovered south of the equator, although few venture south of 20° S. Ospreys from Scotland, Sweden, and Finland winter at similar latitudes in Africa, especially in West Africa, in an arc stretching along the coast from Senegal south-east to Cameroon. There, the birds are supported by a highly productive network of interlacing ecosystems: rain forest, coastal mangrove, and broad, seasonally flooded rivers.

For North American and Palearctic Ospreys, southward migration starts in late summer or early autumn, and most nests are empty of birds by the first week of September. Each individual bird carries out its migration alone. Some individuals may reach wintering grounds in a month or less, although many, especially young birds, appear to take longer. By mid-November most have arrived in their winter quarters, where they stay for at least three months, rarely moving far and often returning to the same location in subsequent years. By the middle or end of February, northward migration is well under way, with individuals apparently travelling faster than they do in autumn; spring breeding is an urgent business, especially as early breeders fledge the most surviving young (see Breeding).

The Osprey is not primarily a soaring migrant, dependent on thermals and updraughts, like many *Buteo* species (see

page 87). Thus individuals regularly cross water barriers such as the Caribbean and Mediterranean Seas, and likewise the Sahara Desert, a trip of at least 2000 km, taking 40-60 hours. Along the Atlantic coast of the USA, Ospreys are regularly seen at sea, up to 100 km offshore. Most of them, however, migrate along the coast, or inland along mountain ridges.

Ospreys tend to return, as breeders, to their natal areas, especially where nest-sites are plentiful. Where sites are limited, pairs may disperse farther. As with many other birds, females disperse farther than males, probably because this enhances their possibilities in the search for a mate and a nest. Once it has found a nest-site, an individual rarely moves far, although few data are available from colonies with unstable nest-sites, where blowdowns are regular.

Relationship with Man

Few other birds have invoked man's admiration and concern more than Ospreys. Wolof tribesmen in Senegal sing of the Osprey's fishing prowess as they paddle canoes through Atlantic surf to tend their nets. South American tribesmen are known to insert Osprey bones into their forearms to increase their hunting skills.

Modern man, especially in the West, has learned to appreciate Ospreys in different ways and for slightly different reasons, but especially for their drama and rarity. As more and more Ospreys have begun to nest on artificial platforms (see Status and Conservation), certain individuals and organizations have become nearly obsessed with building such nesting sites for them. In Florida, New England, and parts of Scandinavia, for example, people compete for "backyard Ospreys". Entire local populations of Ospreys have been converted to depend on such structures, which provide safe nesting sites in an environment where human commensals, like raccoons (*Procyon lotor*), reach epidemic numbers, and raid all the nests they can reach. In addition, Ospreys nest successfully on duck hunting blinds and on power poles, occasionally shorting out electricity at the latter, when nests become wet. Electric power companies have gone to great lengths and expense to avoid such complications, in some cases actually moving nests to

nearby poles erected specially for the Ospreys. Ospreys are proving so adaptable that they sometimes nest alongside towns and in suburbs; such nests become local landmarks, like those of the storks of Europe. In Sanibel, Florida, one can see what is perhaps the Osprey nest of the future, built on a television antenna!

Ospreys generally fare poorly in captivity, and this is especially true of males, which are more nervous and highly-strung than females. The species is rarely kept as a pet or in zoos, and has never been bred in captivity. Likewise, it is apparently untrainable for use in hawking or falconry, even for its normal business of fishing.

In a few parts of the Osprey's range, its eggs have been prized both for their beauty and for their rarity; indeed, in Great Britain, egg-collectors played an important part in driving the species to extinction in the early twentieth century (see Status and Conservation). In addition, precipitous population declines in the north-eastern and midwestern USA, during the period 1950-1970, were a key factor in the government's decision to ban the use of the pesticide DDT (see Status and Conservation).

Status and Conservation

As with other birds of prey, some people have considered Ospreys a threat and a nuisance, and thus worth shooting or trapping. Although it is difficult to tell for sure, apparently more Ospreys have been shot or trapped in Europe than elsewhere, primarily by fishermen and those who operate fish farms and hatcheries, but also by those so-called "sportsmen" who mindlessly shoot raptors in migration. On the Mediterranean island of Malta, for example, where Ospreys concentrate along with many other birds during autumn migration, a notorious hunt has occurred during September and October each year for decades, with thousands of raptors killed each year, at least 10-20% of which may be Ospreys. This massacre continues today.

In Britain and parts of central Europe, by contrast, Ospreys were shot and pole-trapped regularly near fish ponds and trout hatcheries during the nineteenth and much of the twentieth centuries, but this slaughter has been curbed considerably since the 1960's and 1970's. Both migrants and breeders were killed, but loss of breeders was especially critical and helped drive local populations to extinction. In North America, such killing seems to have been less severe, although certain fish hatcheries have undoubtedly taken a toll locally. Elsewhere, the data are too few to reveal much about shooting. It is noticeable, however, that along the Mediterranean and Red Seas, and the Persian Gulf, Osprey colonies survive only on remote islands or where they are protected.

Although Osprey populations in the USA escaped severe shooting, pesticides, particularly the chlorinated hydrocarbon DDT, hit them hard. Between 1950 and 1970, for example, nearly 90% of the roughly 1000 pairs of Ospreys nesting along the coastline between New York City and Boston disappeared, leaving behind empty nests. Some birds were killed outright; most simply failed to reproduce, their eggs dead due to insecticides concentrated in the fish that laying females had eaten. As with other birds of prey, eggshell thinning aggravated these losses. Other US populations were almost as severely affected by pesticides during those years, for instance those of New Jersey, Maryland and Michigan, although most of the rest of North America's Ospreys escaped relatively unscathed, as did most Ospreys of the Western Palearctic. To be sure, Swedish Ospreys showed some contamination, enough to thin eggshells and reduce hatching rates significantly in a few locations, but not enough to affect population levels overall. Mercury may have been a more critical contaminant in Sweden, killing eggs and perhaps adults, but here again the effects were apparently localized. Overall, Swedish and other Fenno-Scandian Ospreys survived the pesticide era with their breeding numbers relatively intact. By the late 1970's, environmental regulations had banned the use of DDT and its most toxic relatives in nearly

all the countries where Ospreys bred, and had slowed the release of mercury from factories and mining. Although these compounds continue to be sold and used flagrantly in some countries where Ospreys winter, almost no effect on these birds has been demonstrated so far.

As certain Osprey populations dwindled during the pesticide era, one human response was to increase the nesting structures available to the pairs that remained. Such artificial nesting platforms are generally easy to build and provide great stability and durability, boosting local numbers of breeders where reproductive success is adequate. The idea has caught on like wildfire, and variants of these platforms continue to be built throughout the Osprey's North American and Palearctic ranges: in Sweden, trees are topped and platforms wired in; in New England, short poles with platforms nailed atop are dug into salt-marsh islands, and now over 80% of the population nests on artificial structures; and in many countries, hydro-electric poles are modified so that Ospreys can nest atop them safely. Highly adaptable, the Osprey also nests on a host of other artificial sites that are not designed for it, including buoys, windmills, sunken ships, and hides or blinds in marshes used by hunters (see Relationship with Man).

Another way to conserve Osprey populations is to reintroduce birds to regions where they once bred or were more numerous. By bringing young to artificial nests in desired locations, and letting them fledge there, a process known as "hacking", researchers have shown how well these birds will return to their new locations, rather than to the areas where they hatched. Highly successful Osprey reintroduction programmes have been carried out recently in many parts of the USA, most notably Pennsylvania, Minnesota, and New York State. Another is planned for southern Germany. Few birds respond better to reintroductions than Ospreys, provided the new area has suitable habitat.

In central and eastern Europe, Osprey numbers declined drastically from the eighteenth century, particularly after the introduction of firearms, right up to the 1970's, the victims of shooting and egg-collecting. Several of these populations appear to have stabilized in recent decades, with strongholds in north-eastern Germany, in the lake districts of Mecklenburg and Brandenburg, and in Poland; there are also a few new nests in southern France. Still vulnerable are the few small colonies along Mediterranean shores and islands, on Corsica and the Balearic Islands; also those on the Cape Verde and Canary Islands; and others in the Middle East. But these populations have probably always been marginal, at least since human settlement; reintroduction possibly holds the potential for boosting their numbers to stronger levels.

In Scotland, Ospreys were eliminated by gamekeepers and egg-collectors by the early years of the twentieth century. However, they recolonized, probably from Scandinavia, during the 1950's, and since then the growth of this population has been steady. Few conservation success stories have been greeted with more enthusiasm. In 1959, the celebrated nest at Loch Garten, in the central Highlands, was first made known to the general public, and in only seven weeks, some 14,000 visitors came to watch the birds at their nest from a nearby hide. Over 1,000,000 people have now visited the site. The fact that the Osprey has managed to re-establish itself as a breeding bird in Scotland is in large part due to the constant vigilance of nests by a whole host of volunteers, for Ospreys still have their enemies: of 54 nests occupied in 1989, nine were robbed by egg-collectors.

In the north-eastern USA and around the Great Lakes, populations have likewise rebounded dramatically since the ban on pesticides in the 1960's and 1970's. In southern New England, for example, numbers are back to 50-60% of the pre-DDT levels, with population growth rates of 10-20% per year. Recent data suggest that such phenomenal growth may be slowing, in part due to density dependent factors, such as predation, but there is no doubt that these once threatened populations will be there for the long haul, especially given their adaptability in nesting along developed coastlines and adjusting to human disturbance.

PLATE 2

Family PANDIONIDAE (OSPREY) SPECIES ACCOUNTS

PLATE 2

Genus *PANDION* Savigny, 1809

Osprey

Pandion haliaetus

French: Balbuzard pêcheur

German: Fischadler

Spanish: Aguila Pescadora

Other common names: Fish Hawk

Taxonomy. *Falco Haliaetus* Linnaeus, 1758, Europe = Sweden.

Sometimes included within family Accipitridae, but usually in its own subfamily, Pandioninae. Race *melvillensis* often applied to birds from Indonesia to N Australia, but probably not valid; similar to *cristatus*. Four subspecies currently recognized.

Subspecies and Distribution.

P. h. haliaetus (Linnaeus, 1758) - Scandinavia E to Japan and S to Mediterranean, Red Sea and Cape Verde Is; winters S to S Africa, India, W Indonesia and Philippines.

P. h. carolinensis (Gmelin, 1788) - Labrador W to Alaska and S to Florida and Arizona; winters S to Peru and S Brazil.

P. h. ridgwayi Maynard, 1887 - Caribbean, including Bahamas, Cuba and Belize.

P. h. cristatus (Vieillot, 1816) - Australia E to New Caledonia, and N through New Guinea to Java and Sulawesi.

Descriptive notes. 55-58 cm; male 1200-1600 g, female 1600-2000 g; wingspan 145-170 cm. Females slightly larger. Dark stripe through eye; speckled brown necklace, variable in intensity depending on race and sex, generally less marked in males. Distinctive pattern in flight, all white below with blackish brown carpal patches and greater underwing-coverts; wing bends back at carpal joint giving characteristic shallow V-shape. Wings relatively long and narrow. Immature similar to adult but paler brown above, with feathers edged buff; breast band less marked. Races similar, differing mainly in size and plumage: *carolinensis* slightly larger and darker; *ridgwayi* paler above, on head and on breast, than *carolinensis*; *cristatus* smaller, with dark breast band and relatively pale crown.

Habitat. Shallow waters, fresh, brackish and marine. Nests along lakeshores, seashores, marshes and rivers; also on deadwood swamps and reservoirs. Highest densities generally near salt water, especially salt-marshes, mangrove swamps, coastal lagoons and bays. Favours islands for nesting, thereby gaining protection from predators. Becomes accustomed to human activity, so tolerates suburban, even urban habitats. Feeds in rivers, bays, marshes, reservoirs, lakes and ponds, wherever fish are available near water surface.

Food and Feeding. Almost exclusively live fish, mostly of 150-300 g. Takes wide variety of fish species, with some marked local preferences (see page 45). Dramatic dives from heights of 10-40 m, but seldom goes much below surface of water. Secures fish in talons before flying off. Normally feeds alone but can gather in small flocks where fish plentiful.

Breeding. Season varies with region: generally spring and summer in temperate latitudes; winter to spring in tropical and subtropical latitudes. Most pairs monogamous but polygynous trios form where males can easily defend two nest-sites. Nest is large collection of sticks and flotsam, usually wedged high in an exposed tree; also nests on cliffs, power poles, buoys, specially designed platforms, and also on ground, on predator-free islands. Normally 3 eggs (1-4); incubation 35-43 days; chicks tend to hatch sequentially, 1-7 days apart, and youngest chicks disadvantaged when food scarce; chicks hatch with white down, but moult into charcoal-coloured second down after 10-14 days; fledging averages c. 50 days. Sexual maturity at 3 years old; 60-70% die before reaching breeding age; potential longevity 20-25 years.

Movements. Resident in tropical and subtropical latitudes. Migratory elsewhere, generally moving to latitudes near the equator: Amazon Basin and N coast of South America; and coastal W Africa from Senegal to the equator.

Status and Conservation. Not globally threatened. CITES II. Frequent to abundant throughout much of range, e.g. 900-1000 pairs in Finland and at least 2000 pairs in Sweden during late 1980's. Estimated c. 10,000 pairs in Russia, although species redlisted here, categorized rare; figures for 1990's include 3000 pairs in European Russia, and 120-180 pairs in Byelorussia where has apparently increased over last 20 years; extremely rare breeder in Ukraine, with only 2-7 pairs in 1990's; in Azerbaijan, extinct as breeder since 1952, as result of deforestation and also collection of eggs and specimens, although formerly very common in SE. Recovering strongly in NE USA, where numbers reduced by pesticides, especially during period 1950-1970. Also recovering in Scotland, where extirpated in early 20th century, due to hunting and egg-collecting; recolonized in 1950's, and upwards of 80 pairs now breed. Vulnerable populations still found in: parts of Mediterranean, in Corsica (20 pairs), Algeria (6-10 pairs), Morocco (20-25 pairs), and Balearic Is (10-15 pairs); Cape Verde Is (c. 25 pairs) and Canary Is (10-15 pairs); Portugal (2 pairs); Red Sea and Persian Gulf; and Caribbean. Also vulnerable in C and E Europe, where populations apparently stabilizing, perhaps with slow growth, e.g. recent colonization of S France by several pairs. Many birds still shot on migration over Mediterranean, e.g. on Malta. In Australia generally common and secure on coasts, especially in tropics and subtropics. Scarce in S parts of Australia; does not breed in Victoria; now absent from Tasmania; vulnerable in New South Wales, now only breeding on N coast, with population fairly stable at c. 50 pairs. Australian birds generally free from contamination and persecution, although some local disturbance near urban areas. Status of breeders in nearby SW Pacific unknown. Reintroduction techniques can help restore vulnerable populations. Pesticides now reduced to a minor threat.

Class AVES

Order FALCONIFORMES

Suborder ACCIPITRES

Family ACCIPITRIDAE (HAWKS AND EAGLES)

- Small to large diurnal birds of prey, with hooked bill and fleshy cere, powerful legs and feet, sharp, curved claws, and often broad wings; keen vision.
- 20-150 cm.

- All regions except Antarctic; almost all zones support numerous species, but only one occurs in N Arctic.
- All habitats, from forests to wetlands, sub-deserts, tundra, high mountains and urban areas.
- 237 species, 64 genera, 535 taxa.
- 29 species threatened; none extinct since 1600.

Systematics

The first fossil records of raptors date back to the early Tertiary, 30-50 million years ago, notably from deposits in France from the late Eocene and early Oligocene, 35 million years ago, and from the early Oligocene of South America. These birds were buzzard-like in appearance, but they had apparently no phylogenetic connections with today's buzzards, in spite of the probable Gondwanan origin of both. During the Miocene, they were already numerous and widespread in both the Old and the New Worlds.

The relationships of Falconiformes with other birds are still not clear, and even among the Falconiformes, there is no evidence in fossil records that the different families have a common ancestor. It is still possible that the members of this order may be the result of an evolutionary convergence between groups of polyphyletic origin. They have no close relatives among living or fossil species.

According to the most recent classification based on DNA-DNA hybridization, the traditional Falconiformes, or diurnal raptors, would be better placed in the infraorder Falconides within the larger order Ciconiiformes. This infraorder would not include the New World vultures (Cathartidae), which have much closer affinities with the Ciconiiformes (see page 24).

The former geographical distribution and division of the Falconiformes is somewhat confusing. For instance, fossils of Old World vultures (Accipitridae) are known from the early Miocene to the late Pleistocene, alongside New World vultures (Cathartidae), in both Old and New World deposits, but the former group has since disappeared totally from the American continent, whereas the cathartid vultures are now restricted to it.

The Accipitridae are, and have always been, the most numerous family of Falconiformes, and they are also one of the largest avian families. As the Osprey (*Pandion haliaetus*) is nowadays normally placed in a separate family (Pandionidae), there are no subfamilies recognized within the Accipitridae.

The details of any taxonomic list vary a great deal according to the opinions of the authors, and successive major classifications are very rarely identical. Many taxa are converted from species to subspecies or vice versa, while at the same time some species are switched from one genus to another. Thus, the number of species recognized in recent times has ranged from about 212 to 240.

Compared with the classification adopted herein, up to seven genera have been deleted, or up to three more added, in recent lists, and this, without considering several older, outdated names. More than half of the genera, 36 out of 64, are monotypic. The two largest genera, *Accipiter* and *Buteo*, contain 50 and 28 species respectively. Of the total of 237 species, 59% have no subspecies at all, but at the other extreme the Crested Serpent-eagle (*Spilornis cheela*) has 21 subspecies, the Variable Goshawk (*Accipiter novaehollandiae*) has 23, and

The affinities of the Pearl Kite are not altogether clear. It has frequently been considered to belong in the Falconidae, its small size and plumage pattern recalling those found in some falconets. However, its feather lice, as well as a number of anatomical features, indicate that it is a kite, and it appears to be closest to the widespread genus *Elanus*.

[*Gampsonyx swainsonii swainsonii*, Ceará, Brazil.

The Bat Hawk is another enigmatic raptor that shows a certain resemblance to falcons, especially in its flight silhouette. This species appears to be an aberrant kite, with its nearest relatives variously reckoned to be in the genera *Aviceda*, *Pernis* or *Elanus*. However, it is unique in several features, most notably in its large eyes and very wide gape. Both of these attributes are adaptations to its habit of feeding on bats around dusk and dawn, when the bird must make optimum use of the short hunting period available, swallowing bats whole as they move to or from their diurnal roosts.

[*Macheiramphus alcinus anderssoni*, northern Transvaal, South Africa.
Photo: Peter Johnson/NHPA]

seven other species have 10-16 such geographical forms. Some little known island subspecies may still prove to be distinct species, for instance several forms in the Crested Serpent-eagle or the Variable Goshawk complexes, or the form *renschii* of Bonelli's Eagle (*Hieraaetus fasciatus*), which occurs in the Lesser Sunda Islands.

Among the most controversial issues within the Accipitridae, one can mention the splitting of several pairs or groups of species that have frequently been regarded as single species. These include: the marsh-harrier complex in the genus *Circus*, containing the forms *aeruginosus*, *ranivorus*, *spilonotus*, *approximans* and *maillardi*; the Short-toed Snake-eagle complex in the genus *Circaetus*, involving the forms *gallicus*, *beaudouini* and *pectoralis*; the Sharp-shinned Hawk group in *Accipiter*, comprising *striatus*, *chionogaster*, *ventralis* and *erythronemius*; and the Augur Buzzard group in *Buteo*, containing *augur*, *archeri* and *rufofuscus*. However, all of these forms are easily identifiable, even in the field, and have non-overlapping breeding distributions, which, together with other differences, justify their specific status.

Similarly, there are several species pairs which were long regarded as conspecific forms, and which look much alike, but are, in fact, allopatric or parapatric, with breeding ranges which are segregated or contiguous but do not overlap. These forms probably deserve separate specific status too. Among such cases are: the Western Honey-buzzard (*Pernis apivorus*) and the Crested Honey-buzzard (*Pernis ptilorhynchus*); the African Harrier-hawk (*Polyboroides typus*) and the Madagascar Harrier-hawk (*Polyboroides radiatus*); the Eastern Chanting-goshawk (*Melierax poliopterus*) and the Pale Chanting-goshawk (*Melierax canorus*); the Red-chested Goshawk (*Accipiter toussenelii*) and the African Goshawk (*Accipiter tachiro*); the Spanish Imperial Eagle (*Aquila adalberti*) and the Eastern Imperial Eagle (*Aquila heliaca*); and, finally, Bonelli's Eagle and the African Hawk-eagle (*Hieraaetus spilogaster*). Sometimes the two species are sympatric, but are segregated by habitat, as is the case of the Common Black Hawk (*Buteo-*

gallus anthracinus) and the Mangrove Black Hawk (*Buteogallus subtilis*), or by altitude, as in the Crested Serpent-eagle and the Kinabalu Serpent-eagle (*Spilornis kinabaluensis*). Amongst the forms hovering around the borderline of full specific recognition are the races *lineatus* and *aegyptius* of the Black Kite (*Milvus migrans*), and also the race *plagiatus* of the Grey Hawk (*Buteo nitidus*).

Some species have not always been placed in a genus of their own as they actually deserve, for instance the Hooded Vulture (*Necrosyrtes monachus*) which has been included in *Neophron*, the Red-headed Vulture (*Sarcogyps calvus*) which has been placed in *Aegypius* or *Torgos*, or the Gabar Goshawk (*Micronisus gabar*) which is often incorporated in *Melierax*. On the contrary, others are more rightly placed in another existing genus, for example the Chestnut-shouldered Goshawk (*Erythrotriorchis buergeri*) of New Guinea, which has close morphological affinities with the Red Goshawk (*Erythrotriorchis radiatus*) of Australia. The genus *Rostrhamus*, with two species united conveniently on the basis of a striking food specialization, may also be divided. Indeed, the Slender-billed Kite (*Rostrhamus hamatus*) is so different from the Snail Kite (*Rostrhamus sociabilis*) in terms of shape, style of flight, display, calls and habitat that it might well be more aptly returned to its own monotypic genus, *Helicolestes*.

This highly diverse family can be usefully divided into natural groups that bring together species with high morphological or ecological convergence. Such an arrangement may not reflect the actual evolution within the family in a systematic sense, but it does illustrate the multiple radiation that has occurred, from the apparently most primitive forms to the supposedly derived and more evolved species.

The first group is the kites, a heterogeneous assemblage of 33 species, which may be divided into three subgroups. The scavenging or insectivorous habits of most of these species are thought to be primitive traits, from which more predatory species may have evolved. Members of the first subgroup lack the bony shield which projects above the eyes and gives the

other accipitrids their fierce appearance. They feed extensively on caterpillars (*Aviceda*), wasp nests (*Pernis*, *Henicopernis*, *Leptodon*), aerial insects (*Elanoides*), arboreal snails (*Chondrohierax*) or bats (*Macheiramphus*). The second subgroup of kites (*Gampsonyx*, *Chelictinia*, *Elanus*) feed on small insects or rodents, or both, and have the talons flat or rounded, not grooved, as in other accipitrids. The third subgroup contains ecologically diverse species, all of which have the basal joint of the middle toe fused with the next joint beyond it. They include the New World genera *Rostrhamus*, *Harpagus* and *Ictinia*, the Old World *Milvus* and *Haliaeetus*, and the Australian *Lophoictinia* and *Hamirostra*.

The second group comprises the ten species of fish-eagles (*Haliaeetus*, *Ichthyophaga*), which are considered to be derived

from kites, because of similarities in their morphological structure, their display flights, their feeding on carrion and some behavioural habits, notably kleptoparasitism.

The third group of 15 species of Old World vultures share consistent peculiarities related to their scavenging habits. The Palm-nut Vulture (*Gypohierax angolensis*) seems to be intermediate between fish-eagles and vultures in both food habits and anatomy. The Bearded Vulture (*Gypaetus barbatus*) and the Egyptian Vulture (*Neophron percnopterus*) show some similarities, but they may not actually be closely related. All the other vulture genera (*Necrosyrtes*, *Gyps*, *Aegypius*, *Torgos*, *Trigonoceps*, *Sarcogyps*) are more closely related to each other.

The 15 assorted snake-eagles or serpent-eagles are distributed among five genera, *Circaetus*, *Terathopius*, *Spilornis*, *Dryotriorchis* and *Eutriorchis*. They all show relatively primitive structure, bare reticulate tarsi and a high specialization on snakes. They seem to be allied to the kites, and may be convergent forms of polyphyletic origin.

The fifth group comprises the harriers (*Circus*), the harrier-hawks (*Polyboroides*) and possibly also the Crane Hawk (*Geranospiza caerulescens*). The two harrier-hawks are related to the snake-eagles. The Neotropical Crane Hawk shares many morphological traits with the harrier-hawks, including the short outer toe, the narrow head, the weak bill, broad secondaries and a long, double-jointed tarsus, but all of these features may be merely convergent adaptations to the habit of foraging in trees, and the Crane Hawk may, in fact, be closer to Neotropical hawks of the genera *Leucopternis* or *Buteogallus*. The 13 species of harriers are less specialized but they have in common a peculiar ecological niche and also similar morphological adaptations.

The large group of the sparrowhawks and goshawks, often considered the "true" hawks, includes some 58 species with rather uniform characteristics. The genus *Accipiter* is the largest in the family, and its members may range in weight from 75 g, for a small male African Little Sparrowhawk (*Accipiter minullus*), to 1400 g, for a large female of the Northern Goshawk (*Accipiter gentilis*). The genera *Urotriorchis*, *Megatriorchis*

The four members of the Old World genus *Butastur* are so closely related that they are usually considered to form a superspecies. The taxonomic position of *Butastur* is open to debate, but it appears to be intermediate between *Accipiter* and *Buteo*, so it is normally included in the rather jumbled assembly of sub-buteonine hawks. The White-eyed Buzzard is one of the three Asian members of this genus.

[*Butastur teesa*,

Until recently the African Hawk-eagle was usually considered to be merely a rather well marked race of Bonelli's Eagle (*Hieraaetus fasciatus*), but studies have revealed significant differences in behaviour, especially with respect to breeding habits. Most authorities now agree that these forms are more appropriately regarded as two distinct species, although in such a case they clearly form a superspecies.

[*Hieraaetus spilogaster*,

Ardea]

This Rough-legged Buzzard illustrates several of the most typical features of accipitrid head morphology: the characteristic, rather fierce expression, essentially produced by the bony shield which projects over the eye; the large, highly efficient eye; the lores covered in bristle-like feathers; the bare, often brightly coloured cere; and the long, muscular tongue. Most readily apparent is the powerful bill, which has the upper mandible longer than the lower and strongly hooked for tearing flesh; most species lack the tomial teeth found in the falcons, but the tip of the lower jaw is frequently notched.

[*Buteo lagopus*.
Photo: Robert P. Carr/
Bruce Coleman]

and *Erythrotriorchis* are specialized tropical rain forest species and perhaps primitive offshoots of the early *Accipiter*. The Gabar Goshawk is closely related to *Accipiter*, but it is often considered to be congeneric with the larger chanting-goshawks (*Melierax*), which are really more similar to the harriers. Some recent workers have associated the Lizard Buzzard (*Kaupifalco monogrammicus*) with *Melierax*, on the grounds of its plumage, behaviour and yolk colour, although it has more regularly been associated with the following group.

The seventh group, including possibly unrelated tropical genera, consists of 25 sub-buteonine hawks, which may be distinguished by their apparent affinities to any of the following natural groups. They mostly inhabit the New World (*Gerano-spiza*, *Leucopternis*, *Buteogallus*, *Parabuteo*, *Busarellus*, *Geranoetus*, *Harpyhaliaetus*), but the genus *Butastur* ranges through Africa and Asia. Another African genus, *Kaupifalco*, is frequently placed in this group, and the Grey Hawk, sometimes separated from *Buteo* in the genus *Asturina*, may be included in this group too, because of its marked resemblance to *Kaupifalco*.

Of the 28 species of the genus *Buteo*, some can be found almost everywhere, except in Australia. They present considerable evolution of shape, flight and foraging modes, from the small, relatively short-winged, long-tailed *magirostris*, *nitidus* and *platypterus*, to the medium-sized *leucorrhous*, *brachyurus* and *lineatus*, to the largest, long-winged, shorter-tailed forms like *albicaudatus*, *regalis* or *hemilasius*. The genus is sometimes subdivided, normally by placing some of the smaller forms in other genera, such as *Asturina* or *Rupornis*, but, while some kind of subdivision appears to be warranted, as yet there is considerable difference of opinion as to where the dividing line, or lines, should be drawn, so it is probably more appropriate to keep all the forms in *Buteo*, pending further investigation.

The ninth natural group comprises four large eagles from the tropical rain forests of the Americas (*Harpia*, *Morphnus*), the Philippines (*Pithecophaga*) and New Guinea (*Harpyopsis*). These birds have unfeathered tarsi and may be relicts from old lineages. They are among the largest raptors in the world.

The tenth, and final, group contains 33 species of true, or "booted", eagles, which are closely related and occur world-

wide. They are exemplified by the well known, large, generally dark members of *Aquila*. The monospecific genera *Spizastur*, *Polemaetus*, *Lophaetus*, *Stephanoaetus* and *Oroaetus* have been merged by some authors with the larger, widespread genera *Hieraetus* and *Spizaetus*. They are all regarded as the most highly evolved species in the family Accipitridae. The Indian Black Eagle (*Ictinaetus malayensis*) is tentatively placed in this group because of its feathered tarsi, its large size, its nesting habits and its display flight, but it is otherwise very different from the other species. Its very low wing-loading, long wings and short outer toe are all adaptations connected with searching for birds' nests in the tree tops. It has some osteological characters and an immature plumage that are reminiscent of those found in kites.

The business of raptor systematics remains in its infancy, so all classifications must still be considered highly provisional, as new proposals continue to be advanced. One of the most interesting to have emerged in recent years involves a group of seven or eight poorly known species that are endemic to the Australasian Region. These species of the genera *Henicopernis*, *Lophoictinia*, *Hamirostra*, *Erythrotriorchis* and *Megatriorchis*, and perhaps also *Harpyopsis*, have traditionally been scattered out amongst the kites, the "true" hawks and the outsize eagles, but it is now suggested that they are remnants of an old clade.

The Long-tailed Buzzard, of New Guinea and associated islands, has, together with its close ally the New Britain Buzzard (*Henicopernis infuscatus*), traditionally been linked with the honey-buzzards of the genus *Pernis*. However, recent opinion suggests that they may belong to an old endemic Australasian lineage.

[*Henicopernis longicauda*,
New Guinea.
Photo: Brian Coates]

The Red-backed Hawk and its apparently close relative the Puna Hawk (*Buteo poecilochrous*) both show a remarkably wide range of plumage morphs. The fact that similar colour morphs are found in both species causes considerable difficulties in field identification, and has also led to uncertainty regarding the taxonomic status and relationship of the two forms. Pale morph birds appear to predominate in the Red-backed Hawk, the smaller, lower altitude species, and it seems that rufous-backed birds tend to be females, while those with grey backs are usually males.

[*Buteo polyosoma polyosoma*, Falkland Islands. Photo: Annie Price/Survival]

or lineage, endemic to the region. These birds share numerous features, notably in plumage, whereas their relationships with other species are not at all clear. Interestingly, in mammals and also in several other bird groups, there is a similar tendency towards the existence of endemic groups in this Region. Such groups may well have arisen when Australia and South America were both part of the massive southern continent of Gondwanaland.

Morphological Aspects

The family Accipitridae presents a very high degree of diversity, encompassing, as it does, such a wide array of birds, from kites to buzzards, hawks to vultures, and harriers to eagles.

This diversity is amply illustrated by the wide range of body sizes. The smallest species is the Pearl Kite (*Gampsonyx swainsonii*) of South America which barely reaches 25 cm in total length, and 80-100 g in body mass. The males of at least three species, the Tiny Hawk (*Accipiter superciliosus*), the Red-thighed Sparrowhawk (*Accipiter erythropus*) and the African Little Sparrowhawk, also weigh between 75 g and 100 g. At the other extreme, the largest eagles, including females of large *Aquila* species, the Great Philippine Eagle (*Pithecophaga jefferyi*) and the Martial Eagle (*Polemaetus bellicosus*), range between 4 kg and 6 kg, while the Harpy Eagle (*Harpia harpyja*) and Steller's Sea-eagle (*Haliaeetus pelagicus*) weigh up to 7-9 kg; only the largest vultures (*Gyps*, *Aegypius*, *Torgos*) reach 8-12.5 kg. Most buzzards, kites, harriers and goshawks weigh between 250 g and 1300 g. Body length, a measurement little used in practice, usually ranges between 40 cm and 80 cm, and it is only very large species with long tails that reach 100-150 cm. The maximum wingspan just exceeds 3 metres in the Himalayan Griffon (*Gyps himalayensis*), and is almost as huge,

at 250-280 cm, in the Bearded Vulture and the Eurasian Black Vulture (*Aegypius monachus*). In some of the smallest species, wingspan measures under 50 cm.

A characteristic of raptors is their reversed sexual size dimorphism, the female being larger than the male, whereas in most other birds, the male is the larger sex. Many theories have been put forward to explain the evolutionary advantages of this difference. They emphasize the potentially aggressive relationships between mates, the respective roles of the male and the female in displays or brood care, or the segregation of food niches between sexes. The only indisputable argument is that the more aggressive and predatory a species is, and the more it eats birds, the greater the sexual size dimorphism. A female Eurasian Sparrowhawk (*Accipiter nisus*) may weigh up to twice as much as the male. The difference becomes less marked in species that feed mainly on rodents or snakes. It is even more reduced in those kites that eat carrion or snails, and very limited amongst predominantly insectivorous species. There is little or no dimorphism in scavengers, essentially the vultures, in which the male can even be larger than the female. Contrary to most other birds, some hawks have a sizeable right ovary, notably the members of *Accipiter*, but they lack the corresponding oviduct. This may not be related to the larger size of the female. However, in spite of the dimorphism in favour of females, there is no consistent, significant bias in the sex ratios of fledglings or adults, and an excess of males has even been found in a set of 735 broods of the Western Marsh-harrier (*Circus aeruginosus*).

The morphological attributes of accipitrids vary greatly, according to habitat, foraging mode and food type. The bill is hooked and usually strong, for tearing and pulling flesh, skin or feathers. The lower jaw is often notched at the tip to aid in cutting. The upper mandible also has a "tooth" in some kites that may be useful for breaking the neck vertebrae of prey, as

The Variable Goshawk is well named, as it probably shows more marked variety in adult plumage than any other raptor species. Some 23 races are normally recognized, and these are sometimes reckoned to constitute two or even three distinct species.

Most forms show the upperparts paler or darker shades of grey, with or without a rufous collar.

The underparts range from pure white to rich rufous or chestnut, while several races present variable amounts of barring. Just to add to the profusion of different plumages, two races are polymorphic: birds of the nominate race, from Australia, are all white, or grey above with grey and white barring below; those of the New Guinea race *leucosomus* can be all white, all dark, or grey above with rufous and white barring below.

[*Accipiter novaehollandiae*.
Photo: Dave Watts/NHPA]

Juvenile and immature plumages tend to differ conspicuously from the adult plumage, probably a mechanism designed to reduce the risk of young birds being attacked by adults that mistake them for potential rivals. The beautiful colours of the adult Bateleur contrast with the drab brown of the juvenile plumage, a plumage which probably implies a link with the Circaetus snake-eagles. Note the all black secondaries of the adult bird, indicating that it is a male.

in the falcons (see page 221). The Hook-billed Kite (*Chondrohierax uncinatus*), the Snail Kite and the Slender-billed Kite all have a greatly elongated and hooked upper mandible, which is well designed for extracting snails from their shells (see Food and Feeding). In all species, the basal part of the upper mandible is covered by a bare, fleshy, waxy membrane, the cere, which is usually yellow, and through which the nostrils open. Its function is unknown. The lining of the gape is often conspicuous and yellow, especially in species with a wide mouth, notably eagles and the Bat Hawk (*Macheiramphus alcinus*). Vultures have the head almost totally devoid of feathers, in order to avoid staining and clotting with blood when it is inserted into carcasses, and the harrier-hawks, which dig into rotten wood and epiphytes, also have extensive bare facial skin. The lores of honey-buzzards are covered with scale-like feathers, which serve to protect the birds against the stings of wasps, on which they feed.

The tarsi of small, bird-hunting species and harriers are relatively long and thin, whereas those of eagles are stronger and thicker. In the species that kill snakes, the tarsi are covered with thick, imbricated scales that protect them against snake bites. They are feathered in eagles and two buzzard species. The feet have three toes pointing forward and one opposable hind toe, which is usually armed with the longest claw. The curved claws and the rough toe pads provide good grasping ability, especially in the fish- or snake-eating species.

The family exhibits a high diversity of wing shapes and thus a wide range of wing-loadings, the ratio of the surface area of the wing to body weight, and these factors determine the different modes of flight. Raptors have 10 primaries and 11-25 secondaries. A typical hawk's wing is long, broad, and rounded at the tip, with a pronounced chord, and several emarginated primaries, which are important in reducing turbulence and permitting a low stalling speed. Large soaring species, such as vultures, have very long, broad, rectangular wings, which are well suited to making the most of ascending air currents, and allowing the bird to soar effortlessly. The harriers have

long, narrow wings, the small kites have shorter, more pointed wings, and forest hawks have even shorter, but broader and more rounded wings. All of these groups, harriers, small kites and hawks, are adapted to flapping flight and swift pursuit of agile prey in different conditions, helped, as they are, by rather long tails, giving them improved manoeuvrability. The extremely long wings and short tail of the Bateleur (*Terathopius ecaudatus*) enable it to glide fast in a straight line, without a wingbeat, over some considerable distance.

The tail is square, rounded, wedge-shaped or even forked, and is made up of 12-14 rectrices. It tends to be much longer in forest-dwelling than in open country species, and it has become exceptionally long in some tropical forest species which never soar, such as the Long-tailed Hawk (*Urotriorchis macrourus*) in Africa, or Doria's Hawk (*Megatriorchis doriae*) in New Guinea; a long tail greatly enhances manoeuvrability. The species with a slow, soaring hunting flight must decrease their wing-loading, and they also require long tails; good examples of such species are the Red Kite (*Milvus milvus*), the Bearded Vulture and the Indian Black Eagle.

Plumage is varied in the Accipitridae, with many combinations of grey, buff and brown. There are rarely bright red or yellow parts and hardly ever the shining blues or greens found in some other birds. The ferruginous colour of the neck and underparts of the Bearded Vulture is superficial and is caused by staining with iron oxides; it is lacking in captive birds. The most recurrent plumage patterns are underparts usually paler than upperparts, pale patches on the rump, and a barred underwing and tail feathers. This pattern may make the birds less conspicuous, when seen from below. Many Neotropical forest species are either predominantly black, or, more often, strikingly white. The adaptive value of such apparently conspicuous coloration has not yet been explained, and it is interesting to note that it is hardly ever found in Old World species, the exception being the purely white morph of the Variable Goshawk. It may perform the role of signalling to reduce the need for territorial flights, as suggested by the fact that some, at any

The largest members of the Accipitridae, the larger eagles and vultures, have rather long, broad wings, which may be rounded or squarish towards the tips, in stark contrast to the pointed wings of the falcons. This design reflects a more leisurely flight style, usually involving a good deal of soaring and gliding and very few wingbeats. The tail varies from squarish to wedge-shaped, as in the White-tailed Sea-eagle, or rounded, as in Verreaux's Eagle. The rather short tail of the former corresponds to its scavenging lifestyle, while the latter, a more active hunter, requires a longer tail in order to achieve greater manoeuvrability. Note the characteristic rounded wings of Verreaux's Eagle, with the inner secondaries appearing narrow, or "pinched".

rate, of these species spend lengthy periods perched on the tops of dead trees. Light and dark (melanistic), or sometimes rufous (erythristic), colour morphs occur in several harriers and buzzards, and also in some goshawks, small eagles and Neotropical kites.

The juvenile and immature plumages are most often different from those of the adults. Young hawks tend to be streaked vertically, where adults are barred horizontally. Their tails have more, narrower bars than those of adults, and they do not show marked sexual differences in plumage. In species where the adults are predominantly brown, young birds are often paler, whereas if the adults are mainly grey, or black and white, the

immatures tend to be browner. Their wing and tail feathers are often longer, or broader, than in adults, giving them a significantly more massive-looking flight silhouette than the adults, a tendency found from sparrowhawks right up to the Bearded Vulture. The end result of these modifications is probably easier flight, at the expense of reduced manoeuvrability.

That this consistent difference in plumage pattern between adults and young may be adaptive is suggested by some island forms, in which adults retain an immature-like plumage, for example the Madagascar Cuckoo-hawk (*Aviceda madagascariensis*) and the Madagascar Buzzard (*Buteo brachypterus*): some forms of selection are thought to be relaxed on islands.

Large vultures, like the Lappet-faced Vulture, tend to spend much of the day on the wing. This is mainly due to their very limited mobility at ground level, and in particular the costly business of take-off from flat ground. Once airborne, they appear rather reluctant to return to earth, and will often circle around over a located carcass for a long time before eventually descending to feed. They are heavily dependent on thermals in order to rise to any great height or cover more than the shortest of distances.

[*Torgos tracheliotus tracheliotus*,
Masai Mara, Kenya.

Bios]

When there is sexual dimorphism in coloration, the male is the brighter sex, whereas the female tends to resemble the immature bird in plumage. Good examples can be found amongst the *Accipiter* hawks and the harriers, in which the male is often grey, while the female is a drab brown.

The striking similarity between some co-existing, but unrelated, species is noteworthy. It may be sometimes a mere coincidence, as probably exemplified in South American forests by the Rufous-thighed Kite (*Harpagus diodon*) and the Bicoloured Hawk (*Accipiter bicolor*), or the Grey-bellied Goshawk (*Accipiter poliogaster*) and the Slaty-backed Forest-falcon (*Micrastur mirandollei*), which is actually a member of the Falconidae. In addition to the latter case, remarkably, the immature plumage of the Grey-bellied Goshawk closely parallels that of the adult Ornate Hawk-eagle (*Spizaetus ornatus*). In other cases, a potentially dangerous predator may mimic an inoffensive species and thus approach its prey more easily. The Zone-tailed Hawk (*Buteo albonotatus*) thus imitates the scavenging Turkey Vulture (*Cathartes aura*), a member of the Cathartidae, and other classic examples include the Sulawesi Hawk-eagle (*Spizaetus lanceolatus*) and the Barred Honey-buzzard (*Pernis celebensis*), or Wallace's Hawk-eagle (*Spizaetus nanus*) and the Crested Honey-buzzard.

The semi-altricial, nidicolous chicks are initially covered by a first down, which is usually white, growing from the follicles that will later produce the feathers. This is followed by a denser second down that will eventually provide the layer of down under the final plumage. After this preliminary stage, there is one complete moult every year and a progressive change towards full adult plumage over a period of one to five years, according to the age of maturity of the species involved.

Wing moult generally begins with the inner primaries and thence proceeds outwards, whereas the secondaries moult inwards starting from the outermost. In most large species, however, wing moult starts simultaneously at three or four different points, in such a way that adjacent feathers are never missing at the same time. This useful adaptation avoids seriously impeding the flight ability of these species which rely so heavily on soaring. In medium-sized species, immatures moult in the typical descendant sequence, whereas adults show the

irregular moult pattern. In temperate areas, resident birds moult in the summer, the female often doing so quickly during incubation, and the male later and more slowly, when it has been partly relieved of its hunting duties by the female. Long distance migrants, which leave soon after breeding, usually postpone their moult until they have reached their wintering grounds. In large eagles and vultures, a complete moult may extend over a period as long as two or three years, with some, but not all, of the feathers changing each year.

Many species have crests, which are probably used in displays, and these range from the few lengthened feathers of hawk-eagles to the floppy crest of the Long-crested Eagle (*Lophastus occipitalis*). Even in uncrested species, such as members of the genus *Accipiter*, the crown feathers have white bases that are conspicuous when these feathers are raised in alarm or in a threat display. A similar function is probably performed by the bare skin on vultures' heads, which may become dark red during courtship.

The flight performance of each species, along with its ability to soar with more or less help from thermal currents or wind, is controlled by its wing-loading. The heavier the species, the later it gets on the wing in the morning, the earlier it stops flying in the afternoon, and the shorter the distance over which it can sustain flapping flight. Hawks reach their highest speeds of 100-200 km/h, when diving from some height with the wings half-closed, either to catch prey, or at the end of a display flight. Some eagles stooping at prey are said to attain a speed of 300 km/h, but there are no accurate measurements of such observations. At the other extreme, several buzzards and snake-eagles readily use hovering flight to hunt over open areas, where perches are scarce. This enables them to scan the ground beneath more carefully for inconspicuous prey.

Many reactions or forms of behaviour seen in hawks suggest that they have excellent hearing, although even the most nocturnal of them, the Bat Hawk, hunts mostly by sight. The harriers, foraging over dense vegetation, have especially acute hearing which is enhanced by a well defined facial ruff and enlarged ear openings. In contrast, members of this family apparently have a poor sense of smell, and even the vultures are unable to detect a hidden carcass, unlike some members of the Cathartidae (see page 27).

Members of the Accipitridae are to be found in almost all habitat types from dense forest to open steppe. Not surprisingly, Africa, with its wealth of open or fairly open habitats, presents the widest selection of species, and even whole genera, that are adapted to such environments.

The Eastern Chanting-goshawk inhabits areas of rather dry woodland and savanna from Ethiopia and Somalia south to northern Tanzania.

Survival]

Conversely, the keen vision of birds of prey is proverbial. The visual acuity of at least some hawks and eagles has been estimated at 4-8 times that of man, maybe more. The resolving power of the raptor eye is based upon relatively large size, and a high density of cones in the two foveae of the retina; this contrasts with the single fovea found in most other animals. One fovea is directed laterally, the other forwards, and this provides an unusually keen perception of distance and movement, as well as a 35°-50° field of binocular vision. Also, the muscles that control the curvature of the lens are better developed in hawks than in other birds, which allows them to have a long focal length, and the rapid, precise accommodation necessary to stoop and snatch fast-moving prey. Raptors also have the largest pectens of any birds, and these carry fin-like projections that permit a better perception of shapes. The semi-tubular eyes can not move much in their sockets, so that hawks must direct their vision by turning the head, either laterally, up to 180°, or upside down. Night vision and perception of colour are not so well developed. The iris is often yellow, sometimes orange or even red, but usually paler in young birds, and somewhat deeper in males than in females. This has been said to be of great importance for display, although some species, such as the buzzards, have brown eyes. Many hawks have a supra-orbital bony shield that may be useful in protecting the eye when the bird dashes into the vegetation after prey. The well developed transparent nictitating membrane, which can be drawn across the eyes at such moments, is an additional form of protection.

Habitat

The family as a whole has a cosmopolitan distribution. The same is also true of particular genera, such as *Accipiter* and *Circus*, which are found in most parts of all continents, except Antarctica, and on many isolated islands of all three large oceans. At the same time, at least one or two breeding species are found in every major habitat type, except the most extreme, lifeless habitats, such as the northernmost Arctic tundra, above the snowline on the highest mountains, and in the heart of the most arid deserts. Sea coasts, from tropical Asia to the Arctic,

are the home of five species of sea-eagles, and Steller's Sea-eagle sometimes even ventures quite far off the coast into the Sea of Okhotsk and the Bering Sea, to fish from drifting icebergs.

The largest number of species are found in forest and woodland, and up to 18-20 species of Accipitridae may co-exist in a limited tract of primary rain forest in South America, without considering the migrants or vagrants coming from open areas. The poorest natural habitats and the least productive, such as treeless tundras, desert steppes or alpine meadows, can usually support at best only one eagle and one buzzard species.

Open grasslands, dry or wet, flat or mountainous, are inhabited by specialized species such as the harriers, but also by several buzzards (*Buteo*) and the Steppe Eagle (*Aquila nipalensis*), all of which are adapted to nesting on the ground. As soon as trees or woodlands are found, the species richness of raptors increases, and, depending on the continent, many more kites, vultures, snake-eagles, sparrowhawks, chanting-goshawks, buzzards and eagles are added. Only a small number of these species can survive in agricultural areas, unless large tracts of woodland remain. Vast, intensively cultivated plains are now amongst the poorest habitats and the species best adapted to them are the *Elanus* kites and some harriers.

When well wooded and rich in small birds, towns, or at least suburban, residential areas, may have fairly high densities of sparrowhawks, and locally some kites or buzzards. In the tropics, for example in India or Africa, throughout urban areas where sanitation is still poor or rubbish dumps abundant, and where raptors are well tolerated, huge populations of thousands of Black Kites, Hooded Vultures and Indian White-backed Vultures (*Gyps bengalensis*) thrive, as was formerly the case of Red Kites in London, or Black Kites and Egyptian Vultures in Cairo and Istanbul.

More precisely, one must distinguish between breeding, feeding and roosting sites, as well as breeding season and wintering habitats, which may all differ substantially for a given individual. For instance, European or North American buzzards and sparrowhawks in temperate countries usually nest in woodland or forests, but they forage well outside such habitat. The same birds in winter remain mostly in farmland, gardens or lightly wooded areas, coming back to forest edge to roost. The

The Black Hawk-eagle is one of the many species that occur mainly in tropical forests. This habitat is the richest of all in terms of raptor diversity, and in South America up to 20 different species may be resident in the same tract of forest. The hawk-eagles of the genus *Spizaetus* are all essentially forest dwellers, and like the true hawks of the genus *Accipiter* they have rather broad, rounded wings and long tails, attributes that enable them to fly efficiently through the mass of leaves, branches and creepers.

[*Spizaetus tyrannus tyrannus*, southern Brazil. Photo: Luiz Claudio Marigo/Bruce Coleman]

Bald Eagle (*Haliaeetus leucocephalus*), in North America, and the White-tailed Sea-eagle (*Haliaeetus albicilla*), in Eurasia, nest along the forested banks of large lakes and rivers, but they hunt well out into open wetlands, and come back to roost in the most undisturbed forest patches.

Usually temperate migrants choose wintering habitats that are structurally very similar to their breeding habitats. The Western and Crested Honey-buzzards winter in fairly open areas of tropical forest, as does the Broad-winged Hawk (*Buteo platypterus*) in tropical America. The three migratory Eurasian harriers tend to segregate in Africa or India according to the habitat types they preferably select on their breeding grounds, with the Western Marsh-harrier occupying the wettest areas, the Pallid Harrier (*Circus macrourus*) the driest, and Montagu's Harrier (*Circus pygargus*) occurring in intermediate grasslands.

The habitat quality of both the breeding territory, and the home range used outside the breeding season, has a great influence on the density, rate of occupancy, fidelity, degree to which birds are sedentary, and breeding success of raptors. This has been shown in most detail by the long term study of different populations of the Eurasian Sparrowhawk in southern Scotland, but it is suggested for many other species by numerous studies and other, more incidental observations. The quality of a territory primarily depends on the food supply, in terms of its quantity, quality, accessibility, and the extent to which its availability is predictable through time. To a lesser extent, human disturbance, natural predation, availability of suitable nest-sites, foraging perches and shelters are also important factors. In experiments involving the removal of resident individuals, it was shown that the replacement of missing sparrowhawks in Scotland occurred quickly on good territories, but hardly ever on poor territories. Additionally, the newcomers bred less successfully than the original owners, probably because of a lack of experience with the

food resources of the territory in which they settled. Despite overall relative stability of the breeding populations, up to a quarter of the territories of Eurasian Buzzards (*Buteo buteo*) and Eurasian Sparrowhawks in Great Britain and elsewhere in Europe remain unoccupied every year.

General Habits

The daily routine of members of the Accipitridae is highly correlated with their wing-loading, the weather conditions and their food habits. Species of forests or open habitat, which mostly use flapping flight and feed on vertebrates, usually begin hunting shortly after dawn. The more insectivorous species often do not become active until 1-2 hours later, even in the tropics. Species which use soaring flight for hunting are the latest to take off, since they must wait for the building up of warming air currents. A reversed timing pattern is observed in the late afternoon, except for some tropical kites which regularly take advantage of swarming insects at dusk. The heat around midday, especially in the tropics, marks the period of lowest activity for many, if not all, species. During rainy periods, most raptors stop hunting, or at least flying, and long wet periods, such as rainy springs in temperate countries, or the height of the rains at tropical latitudes, act as a limiting factor for many species.

Each species requires a certain amount of time in order to meet its daily food requirements: the smaller the prey, the longer the time that must be spent hunting. On their wintering grounds, large insectivorous species, such as Swainson's Hawk (*Buteo swainsoni*) or the Steppe Eagle, must spend several hours daily foraging actively, whereas similar-sized eagles or goshawks may need only one large prey item every three or

four days, so they may spend much less time hunting. Vultures that have gorged themselves on a carcass may subsequently fast for up to a week or more. During the northern winter, raptors tend to use the relatively short daylight period more fully, and to concentrate more exclusively on hunting than they do during the long summer days. No accipitrid species is really active before dawn, as are the forest-falcons (*Micrastur*) of the Falconidae, and, indeed, very few are even crepuscular on a regular basis. Only the Bat Hawk hunts around dusk, but it too stops soon, once it becomes too dark for it to see its prey. The Letter-winged Kite (*Elanus scriptus*) of Australia is exceptional in that it mostly hunts nocturnal desert rodents and regularly does so not only at dusk, but also well into the night, when there is enough moonlight. Vultures have sometimes been seen feeding on carcasses on moonlit nights.

Probably because flight is costly, many raptor species spend a large portion of the day resting, or at least not moving actively. During these loafing periods, they may watch their territory from a vantage perch, or even wait for an opportunity to catch some easy prey, as it passes by. At such times, a bird will often stand on one leg, with the other drawn up into the belly feathers. Before flying again, a bird often stretches its wings and legs, and this is especially true of the larger species.

Preening is also a time-consuming activity in raptors. Many species like bathing when water is available, but most of them rarely, if ever, drink, at least in natural conditions, except carrion-eating species, which do so regularly. In several species, sunbathing is observed occasionally during the day, but it is frequent in early morning, when birds make a practice of spreading their wings in the first rays of the sun. Similarly, they do so in the wind after rain storms, often drying their wings on an exposed perch. In all these circumstances, tropical forest species use emergent dead trees, and at such moments they become conspicuous.

True playing activities are not often recorded, or at least recognized as such, but they doubtless occur, especially in young birds. Even the vigorous wing flapping and jumps of fledgling hawks on the nests may not only be useful training to develop flight muscles, but also a form of play, as are attempts

to catch flies. When the weather is fine, large-winged species often spend considerable time soaring, without any obvious motivation other than pleasure, even if this may also serve as a territorial display. Nevertheless, in the Chihuahuan Desert of northern Mexico, in summer, Swainson's Hawks regularly spend hours soaring very high in the early afternoon over their territory, apparently to avoid the excess heat at ground level.

One of the most important life history traits of raptors is their territorial behaviour. Predators of vertebrates must have the exclusive use of a sufficient hunting range to ensure a steady food supply. The most typical situation is that of resident pairs spaced out in individual home ranges that are defended almost entirely. In many species, however, the nest and its immediate surroundings are more actively defended than the outer parts of the territory, within which certain areas are much more frequently visited than others. undefended parts of a home range may overlap with similar areas of neighbouring ranges. Hunting home ranges of breeding pairs vary much in size, depending on the density of prey: 50-150 ha in sparrow-hawks and small to medium-sized buzzards; 200-400 ha in harriers and larger buzzards; and 1000-2000 ha in small eagles, the Northern Goshawk, or larger species, like the Crowned Hawk-eagle (*Stephanoetus coronatus*) in a prey-rich forest in Kenya. The large eagles, from Scottish moorlands to African savannas and Amazonian rain forests, have home ranges covering 2500 to 10,000 ha and sometimes more. Intensively studied pairs of Bald Eagles in the United States have mean home ranges of 2200 ha, with extremes of 600 ha and 4700 ha. Under exceptionally favourable conditions, some large raptors may have surprisingly small territories, for instance 100 pairs of African Fish-eagles (*Haliaeetus vocifer*), along the Kazinga Channel in south-central Uganda, had contiguous territories that never exceeded 20-50 ha each.

The maximum hunting range of breeding birds may be somewhat larger than expected from the area known to be used regularly. Eurasian Sparrowhawks have been recorded up to 9 km from their nests, Montagu's Harriers 12-14 km away. Red Kites more than 15 km away, and Verreaux's Eagles (*Aquila verreauxii*) up to 27 km away. Eurasian Griffons (*Gyps fulvus*)

Several birds of prey are to be found mainly in mountainous areas, where they are usually able to take advantage of updraughts and strong winds for soaring flight. The Black-chested Buzzard-eagle is a typical denizen of the Andes, ranging from the foothills up to about 4600 m, although in the south of its range it generally occurs at much lower altitudes.

[*Geranoaetus melanoleucus australis*, Torres del Paine National Park, Chile. Photo: Günter Ziesler]

Some raptors are closely linked with aquatic habitats, most notably the fish-eating eagles of the genera *Haliaeetus* and *Ichthyophaga*. While the eight members of the former are most typically associated with sea coasts and very large inland water bodies, such as lakes and marshes, the two members of the latter are more commonly seen along rivers or even streams. The Grey-headed Fishing-eagle occurs in lowland areas from India east to the Philippines and Sulawesi.

[*Ichthyophaga ichthyaetus*, Corbett National Park, Uttar Pradesh, India. Photo: Günter Ziesler]

in Europe, Rüppell's Griffons (*Gyps rueppellii*) in East Africa, and Cape Griffons (*Gyps coprotheres*) in South Africa are all known at times to search for food more than 100 km away from their nests.

Within the home range, there may be a marked shift of preferred hunting areas between days or seasons, male and female, young and adults. The area used also tends to be larger during the fledging period, when the food requirements are highest, and in winter, when prey density is lower. In the colonial breeders, the *Gyps* vultures, or in occasionally gregarious species, including some kites and harriers, only the nest-site is defended during the breeding season, so that most of the foraging area is shared with other individuals. There, birds may hunt alone, as do the Black, Red and Letter-winged Kites and Montagu's Harrier, or gregariously, as regularly occurs in the American Swallow-tailed Kite (*Elanoides forficatus*), the African Swallow-tailed Kite (*Chelictinia riocourii*) and the Mississippi Kite (*Ictinia mississippiensis*). In resident species, pairs remain on their territory all year round, but in migratory or nomadic species, birds return to take over the same territory every year. Some wintering birds may settle in temporarily defended feeding territories.

Most of the colonial or semi-colonial species tend to spend the night in communal roosts, as do also solitary breeders that become gregarious on winter feeding grounds, for instance the Bald Eagle, Steller's Sea-eagle, the White-tailed Sea-eagle and the Steppe Eagle. These roosts take place in trees, cliffs or marshes, and the same site is regularly used, sometimes involving up to 1000 birds, or more, as is the case of Montagu's Harrier in West Africa. At such sites, when the birds feel secure, they drop into a deep sleep, with the head tucked under the scapulars.

As they are often fierce and aggressive, most raptors exhibit little elaborate social behaviour. The permanently gregarious vultures, which both breed and feed communally, have spectacular aggressive displays around carcasses which are intended to enforce their dominance over conspecifics or other birds.

Gregarious species that flock where food sources are abundant, for example kites or Swainson's Hawks, do not show any form of co-operation between individuals. Nor do the buzzards or eagles, which are so highly gregarious during migration, but which often disperse and remain solitary once they have arrived in their winter quarters, as exemplified by honey-buzzards and the Broad-winged Hawk. Multispecies flocks, or feeding aggregations of up to several hundred raptors of numerous species, commonly occur at concentrations of easy prey, such as swarms of locusts or termites, breeding colonies of queleas (*Quelea*), seasonal bushfires, and the like, but each species forages independently of the others, and rare signs of agonistic

The Black-faced Hawk is one of the many tropical forest raptors about which virtually nothing is known, a reflection of the host of difficulties that complicate the study of shy, inconspicuous species in such an environment. This bird was momentarily disturbed while eating a snake on the forest floor, but it quickly returned to its meal.

[*Leucopternis melanops*, Cuyabeno National Park, Ecuador. Photo: Isabel Martínez]

Bateleurs frequently spend most of the day in flight, but, like this immature bird, they often land at water-holes, where they may stay for several hours, resting, drinking and preening. Sunning is common behaviour in many species, notably vultures, and mainly takes place in the early morning, in the sun's first rays. One of the main purposes of this behaviour, at any rate in some species, is to tone up the feathers and bring them back into perfect shape, after they have been distorted by the considerable pressure exerted during long periods of soaring.

behaviour involve mostly the adults' demonstration of their dominance over immature birds.

Territorial or nuptial display flights are a fundamental component of intraspecific relationships. Primarily during the breeding season, but also in other months in the tropics, pairs of territorial adults, or lone males, perform characteristic, and often spectacular, courtship display flights, mostly above and around the nest-site. This usually takes place in mid- or late morning, or much less frequently in the afternoon. This can be the best way to detect many otherwise secretive tropical forest species, which soar above the forest almost every day, but often only once a day, and for a short period, so as to reassess their territory ownership and signal their presence to their neighbours, or to potential intruders. Curiously, it is only at dawn and dusk that the African Goshawk performs its display flight, with an endlessly repeated, monosyllabic call, quite unlike that of any other raptor.

Open country species soar and display more often, and during a longer part of the day than do forest species. Temperate species tend to perform displays more extensively than many tropical species. Aggressive interactions between a territory owner and an intruder may sometimes end in so-called "cart-wheeling" flights, where the two birds, grasping each other's talons, plummet down, with their feet locked, whirling round together. This may also occur as a form of play behaviour between young birds, or during parent-offspring conflicts, but injuries are rarely reported. Many interactions, however, are resolved by visual signals, thereby averting the need for direct confrontations. Such signals may involve the brightly coloured plumage of adults being displayed at conspicuous perching sites, or, at closer range, an erected crest or showing off the deeply coloured facial skin.

Interspecific competition between raptors may operate through aggressive interference, displacement from the nest-site or mutual avoidance. The Golden Eagle (*Aquila chrysaetos*) often excludes Bonelli's Eagle from small cliffs,

and the latter persistently harasses Eurasian Griffons, if they are near its nest-site. In the Chihuahuan Desert of Mexico, Swainson's Hawks and Red-tailed Hawks (*Buteo jamaicensis*) maintain exclusive territories centred on their respective preferred habitats. In the rain forest of French Guiana, the territories of the Harpy Eagle and the Guiana Crested Eagle (*Morphnus guianensis*) rarely, if ever, overlap, though they may be contiguous. Breeding pairs of Bald Eagles, and probably of other sea-eagles, reduce the number of Ospreys in their territories, maybe because they systematically harass any Osprey carrying a fish, in order to steal it.

Voice

Most species in this family are quite vocal during the breeding season. Usually, loud vocalizations are associated with behaviour related to reproduction, aerial displays, copulation, brood care, the pair-bond, territorial defence and aggression. In contrast, birds are often almost silent outside the breeding period, during migration or in winter. At these times, even among large feeding flocks, or at night roosts of buzzards, kites or harriers, when there are multiple opportunities for interactions between individuals, it is rarely possible to hear more than the occasional, brief call.

Considering the family as a whole, vocalizations are very varied, with screams, croaks, whistles, mews, barks, yelps, cackles, and many more noises recorded. However, any trained ornithologist can easily tell most raptor calls from those of almost any other kind of bird. Moreover, the repertoire of most individual species is rather limited and constant.

Voice characteristics are difficult to describe or render in words. Very roughly speaking one can just say that the usual calls of sparrowhawks, goshawks and several small kites amount to a quickly repeated chattering or clicking vocalizations, sometimes wailing or shrilling, with a perceptibly

different tone between the male and the female. Harriers, especially during courtship, utter either rapid chattering or cackling calls, in the "grey" harriers, or wailing, prolonged, high-pitched calls, in the marsh-harrier group. Kites, at any rate those of the genera *Milvus* and *Haliaeetus*, are often more vocal than other raptors and make various loud mewing, whistling, whinnying and even trilling calls.

The buzzards (*Buteo*) are also quite vocal and their plaintive mewing, screeching or sometimes squalling voice is well known. The large *Aquila* eagles utter repeated harsh, deep, barking or yelping calls in display, but various faint, chirruping calls are also used between mates. The hawk-eagles of *Spizaetus* and associated genera, and also the genus *Hieraaetus*, tend to have clear courtship display calls, that are louder and more musical than those used by *Aquila*, and are not unlike the almost melodious whistles of honey-buzzards (*Pernis*) or serpent-eagles (*Spilornis*). The snake-eagles (*Circaetus*) have both clear, musical whistles, that recall those of orioles (*Oriolus*), and also deeper, harsh, repeated notes that are used during aggressive encounters. Finally, vultures merely emit a series of grunts or croaks, as well as the hisses, screeches and goose-like, or high-pitched, chatters that are typically heard during agonistic interactions around carcasses. Chicks and fledglings of all species make higher-pitched, shrill calls, and chicks still inside the egg will even produce piping or cheeping sounds, sometimes several days before hatching.

Vocalizations play a crucial part in several forms of behaviour. They are primarily important in both courtship and aggressive behaviour, and are associated with the visual displays or postures that are used to attract a mate, to reinforce the pair-bond, to invite mating, to chase intruders, and in nest or territory defence. Accordingly, they may be classified into courtship, contact, advertising, alarm, threat or mobbing calls. Food-related calls are equally important, either when the female solicits food from the male, or when fledglings are begging for food from their parents. When young birds are flying, dis-

persed, around the nest, but are still dependent on prey brought in to them by the adults, their very distinctive persistent, far-carrying vocalizations motivate and help the adults to locate their offspring and provide them with food, while, at the same time, the young birds must remain inconspicuous to any potential predators.

Calls are loud and harsh when alarm or aggression are involved, but much softer during pair-bond interactions at the nest. Some species have a genuine song, with all the characteristics of the classic song of passerine birds, in that it is loud and musical, and is uttered from a prominent perch, mainly during the breeding season, by territorial males only. A good example is afforded by the Lizard Buzzard, which breeds in wooded savannas throughout much of Africa. The far-carrying calls of non-soaring raptor species in the dense understorey of rain forests may also have the same function and significance, for instance the small *Leucopternis* hawks of South America, and the Long-tailed Hawk and the Congo Serpent-eagle (*Dryotriorchis spectabilis*) in Africa. Yet there are several rain forest species that, as far as is known, seem to have neither the loud vocal, nor the spectacular but silent, display flights of many eagles; nor do they produce the resounding song or even the loud calls of the aforementioned species. These include both small and large birds of prey, for instance the Rufous-thighed Kite or several small *Accipiter* species, and, at the other extreme, the Harpy Eagle. The vocal, social and communication behaviour of such species would be well worth investigating.

Food and Feeding

The types of food used by the members of the family Accipitridae are as diverse as the species themselves, and every major group of vertebrates and even invertebrates is included in the diet of at least one species.

The African Little Sparrowhawk is frequently found in the vicinity of water. Like many other members of the Accipitridae, it is not averse to a session of bathing, when it may crouch down, puff out its breast feathers and wriggle its wings vigorously in order to spread the water all over its plumage; this process can be repeated intermittently for about 20 minutes and may be combined with drinking. After bathing, birds sometimes rest in the sun, giving their plumage time to dry out.

[*Accipiter minullus*, Zululand, South Africa. Photo: Nigel Dennis/NHPA]

During the winter, most of the aggressive encounters that take place between Eurasian Buzzards correspond to disputes over food. Rivals threaten each other by adopting the "Angel Posture": the wings are thrown up and sometimes twisted inwards to highlight the striking underwing pattern; the head is thrust backwards, with the bill pointing down; the feathers of the crown and nape are bristled up, and those of the breast puffed out; talons can be presented; and the legs may be stretched too, as each bird attempts to appear larger, bulkier and taller than its rival. Disputes are typically accompanied by calling, and in most cases one bird submits and backs down in response to the threats, but fights can ensue, on occasions even leading to deaths. Larger birds tend to win such disputes.

[*Buteo buteo*.

Danegger/NHPA]

Most species are exclusively carnivorous, but several, such as the American Swallow-tailed Kite, occasionally eat fruit, and this may be more frequent in tropical forests than the sparse records actually suggest. The fruits of the oil palm (*Elaeis guineensis*) are a constant base of the diet of the Palm-nut Vulture, which also frequently takes fish from lagoons and rivers, and many crabs in mangroves, as well as some carrion; the fruits of both larger (*Raphia vinifera*) and smaller palms (*Phoenix reclinata*) are also regularly consumed, and, like the nuts of the oil palm, they are rich and oily, but with a large kernel and little pulp; few fruits, other than those of palms, have been recorded in the diet of this species. Nevertheless, a study of breeding raptors in West Africa, in the wooded savanna at Lamto, central Ivory Coast, showed that two other, rather unexpected species, the Black Kite and the African Harrier-hawk, also included a high proportion of oil palm fruits in their diet, and even brought them in large numbers to their nests to feed the young, a remarkable practice, given that it would seem energetically unprofitable to carry in such largely indigestible fruits, one by one.

Invertebrates are a favourite food, because they are often abundant and are easy to catch. Among the 237 species in this family, 12 are almost exclusively dependent upon insects, 44 are largely insectivorous, at least outside the breeding season, and maybe up to 100 additional species may take some occa-

sionally. Locusts, grasshoppers and other Orthoptera are the most frequently taken insects, along with the flying alates of ants and termites, when they swarm after heavy rains. Alates are so attractive to the raptors that even Steppe Eagles, large birds, when wintering in southern Africa, feed mainly on them, although several hundred individuals of such a tiny form of prey are necessary to supply the energetic equivalent of a single mouse. A sudden profusion of beetles or the pullulations of almost any other medium-sized or large insect are exploited opportunistically by many birds of prey. Huge concentrations of predators, including many hawks, kites and eagles, follow the swarms of locusts in the Old World tropics, or attend bush fires, where they catch far more insects than vertebrates.

Many forest raptors specialize on particular kinds of insects. For instance, the main sources of food for all honey-buzzards in Eurasia are bee and wasp nests, which the birds dig out of the ground or tree holes, and from which they eat some honey and a few adults, but where they carefully pick out the larvae one by one. The African Cuckoo-hawk (*Aviceda cuculoides*), the Pacific Baza (*Aviceda subcristata*) and the Black Baza (*Aviceda leuphotes*) feed largely on insects, especially caterpillars which are taken from in amongst the foliage, as the birds move slowly along, watching intensely, like cuckoos, so as to detect their highly inconspicuous prey. The Double-toothed Kite (*Harpagus bidentatus*), which is less spe-

Concentrations of over 100 vultures can gather around a carcass, and in such cases competition for food is fierce, with a ceaseless string of squabbles. It may all appear to be a wild battle amongst a noisy mob, but, in fact, each individual gains access to the food in a co-ordinated sequence, which is strongly influenced by its hunger, its social rank and its body size. Fighting can be very violent, as vividly illustrated by these two African White-backed Vultures. Note the larger, orange-billed Rüppell's Griffons (*Gyps rueppellii*) in the background.

[*Gyps africanus*,
Masai Mara, Kenya.

cialized, regularly follows troops of monkeys to catch the fleeing insects that are disturbed and thus made visible, when the primates shake the branches. The American Swallow-tailed Kite and the Plumbeous Kite (*Ictinia plumbea*) often almost exclusively hunt high-flying insects above the canopy of Neotropical rain forests.

Other arthropods are occasionally caught, but high specialization occurs only on crabs, notably by the Rufous Crab-hawk (*Buteogallus aequinoctialis*) in the mangroves of South America. Snails are the exclusive food source of the highly specialized Neotropical species, the Snail and Slender-billed Kites, which feed on water snails, and the Hook-billed Kite, which takes arboreal snails, sometimes in surprisingly dry forests. Several species take earthworms when they are easily available; for example Black and Red Kites take them on recently ploughed fields, as does the Eurasian Buzzard on waterlogged meadows in the autumn.

Few species are highly specialized on fish, and they all catch them near the surface of the water. The Lesser Fishing-eagle (*Ichthyophaga humilis*) and the Grey-headed Fishing-eagle (*Ichthyophaga ichthyaetus*), in Asia, and the Black-collared Hawk (*Busarellus nigricollis*), in America, are the typical fish-eaters of tropical inland waters. From African lakes and south Asian sea coasts to the Arctic Circle, the eight species of fish-eagles are primarily piscivorous, but they take mostly dead or particularly vulnerable fish. Spectacular seasonal concentrations occur where such food is abundant, and over 2000 Bald Eagles may gather at the autumn spawning runs of anadromous salmon on the Chilkat River in Alaska, while similar numbers of Steller's Sea-eagles collect in winter to feed on discarded fish and offal, off the north coast of Hokkaido, Japan. Several other species take fish on a regular basis although it only constitutes a part of their diet, as in the case of the Black Kite, the Palm-nut Vulture and the Common and Mangrove Black Hawks.

Amphibians, lizards and their allies are hunted by a wide variety of species that also tend to take insects or higher vertebrates. They are not only caught on the ground, but also on trees by several tropical forest sparrowhawks (*Accipiter*), and likewise by unspecialized canopy dwellers, including *Harpagus*, *Leucopternis* and *Aviceda*; they are also taken from tree

holes and epiphytes by the Crane Hawk and the harrier-hawks. The Eurasian Buzzard regularly eats poisonous toads, just removing the toxic skin off the back.

Snakes are the main, if not the only, prey of the Old World snake-eagles (*Circaetus*) and serpent-eagles (*Spilornis*, *Dryotriorchis*) and also of the ten species of New World hawks of the genus *Leucopternis*; the very limited information available to date does not confirm the presence of snakes in the diet of the Madagascar Serpent-eagle (*Eutriorchis astur*). The majority of these reptile predators are forest or woodland species, which use long periods of quiet perch-hunting to detect their highly cryptic prey. In the American rain forest understorey, the White Hawk (*Leucopternis albigollis*) regularly follows the troops of capuchin monkeys (*Cebus*), to catch the tree snakes that they disturb and that are otherwise very difficult to see. Snake-eagles hunting in open habitats use long periods of hovering flight to search efficiently for cryptic snakes. Many other species occasionally take some reptiles, both arboreal and terrestrial, or even sea-snakes in the case of the White-bellied Sea-eagle (*Haliaeetus leucogaster*). Poisonous species are caught indiscriminately, although no raptor species seems to be immune to their venom. Instead, all rely on their agility, and their ability to grasp and break the head or neck of a victim first, and thus avoid bites. Snake-eagles carry their victims to the nest partly swallowed, head first, with the tail protruding out between the mandibles. In contrast to this, serpent-eagles often carry their prey in the feet, presumably because these species are less exposed to kleptoparasitic attacks in their forest habitat. Even tortoises are eaten, and on several occasions I have seen Golden Eagles in Greece dropping them onto rocks to break their shells.

At least 25 species of sparrowhawks and goshawks (*Accipiter*), several other forest hawks, some buzzards, including the Short-tailed Hawk (*Buteo brachyurus*), and the hawk-eagles (*Spizaetus*) are specialized on birds. Prey species range in size from very small hummingbirds (Trochilidae), which are said to be a common prey of the Tiny Hawk, to large game birds of the Cracidae, Phasianidae or other related families. Birds are also taken in various proportions by a wide range of other raptors, including kites, harriers, chanting-goshawks, buzzards and eagles. Local concentrations of small birds, such as the

dense breeding colonies of granivores and large roosts, regularly attract a number of predators, including bird-hunters, unspecialized nest robbers and some scavengers.

Eggs and fledglings are taken opportunistically by many generalist species, but at least one, the Indian Black Eagle, is a specialist predator of birds' nests, which it searches for carefully in the tops of trees. Even the breeding colonies of large waterbirds are raided by several species of *Haliaeetus*, *Buteogallus*, *Hieraetus* and *Aquila*. In East Africa, Egyptian Vultures have learnt to break the hard shell of Ostrich (*Struthio camelus*) eggs by throwing stones onto them, a classic case of tool use by animals.

Small mammals are a favourite prey of many species, because of their abundance, ease of capture and energetic reward. They are the main prey of a fair number of species from kites (*Elanus*) to buzzards (*Buteo*), and the abundance of voles, mice or lemmings strongly controls the density and breeding success of their main predators. Some such predators are nomadic and breed only where and when there is an outbreak of rodents, notably the Rough-legged Buzzard (*Buteo lagopus*) and the Letter-winged Kite. Larger rodents, such as rabbits in Europe and Australia, susliks in Central Asia, hares in North America, and rock hyraxes in Africa, have the same effect on the density and reproduction of many eagles. The larger eagles commonly kill mammals up to the size of adult monkeys, goats, lambs or small antelopes, but they are unable to fly off with a carcass heavier than their own weight, which is usually less than 4-5 kg. Bats are incidentally caught by some species, but the Bat Hawk has developed a unique specialization, hunting them in flight, at dusk and dawn, and being able to kill and swallow several individuals in quick succession.

The last widespread source of food is carrion. Of course, it is the only diet of vultures, but many other species eat some carrion occasionally, or even regularly, during periods of food scarcity. In winter, White-tailed and Steller's Sea-eagles rely a great deal on dead fish, birds and mammals. Among the vultures, there are specific differences in the use of carcasses, depending on the body and bill sizes of the species involved. The griffons (*Gyps*) primarily eat flesh and viscera, but the

larger species (*Aegypius*, *Torgos*, *Sarcogyps*) also make use of hard parts, including skin, sinews and some bones, while the smaller Egyptian and Hooded Vultures do not have the wherewithal to open large carcasses themselves, and mostly wait for scraps left by the other, dominant species. The Bearded Vulture is a well known specialist of bones, but it does not search only for their marrow. It swallows surprisingly large chunks of bone whole, and breaks the larger bones by dropping them on rocks. Its stomach content is still more acid than that of other raptors, and this helps the bird to digest the bones and use their protein efficiently. Conversely, this species lacks the distensible crop that other vultures have for food storage. Finally, animal dung is commonly eaten by the Egyptian Vulture, and the Hooded Vulture even eats a good deal of human excrement in and around African towns.

Accipitrids use several hunting techniques, in accordance with their habitat structure, prey type and morphological adaptations. The most widely used, and energetically least expensive, is perch-hunting. A bird waits immobile on a perch, gazing intently about, and making short dashes out, usually to catch small prey on the ground a short distance away. Some species also walk for long periods before going back to their perches, for instance the chanting-goshawks, the Lesser Spotted Eagle (*Aquila pomarina*) and the Steppe Eagle. The Black Kite, the Brahminy Kite (*Haliastur indus*), the piscivorous *Haliaeetus* and *Ichthyophaga* eagles and the Black-collared Hawk all detect fish more often from a perch than in flight, and will snatch it from just below the surface of the water, without diving, unlike the Osprey (see page 45). When available, these species prefer dead or stranded fish.

Slow soaring and hovering have similar advantages to perching, as they facilitate the detection of inconspicuous or unsuspecting prey. These methods are practised by a selection of large winged hawks, buzzards, kites and eagles, when hunting over open grasslands. A quite different technique is that of ambush, which involves a hawk waiting, hidden in a tree, whence it can dart forth with surprising swiftness and agility at a passing bird. This is the favourite hunting method of sparrowhawks and goshawks, which rely on the element of surprise

Most members of the Accipitridae are to be heard calling during the breeding season, but they tend to be largely silent at other times of year. A notable exception is provided by some of the large fish- or sea-eagles of the genus *Haliaeetus*, which call far more regularly throughout the year. The voice of the Bald Eagle can be described as a harsh cackling, which is deeper and more raucous in the larger female than in the male, a tendency also noted in some other members of the genus.

[*Haliaeetus leucocephalus*.

The Gabar Goshawk feeds mainly on small birds of less than 80 g. This particular individual has alighted on an Acacia, in which there is a large flock of Red-billed Queleas (*Quelea quelea*), a superabundant agricultural pest species. The goshawk selects a victim and then pounces. The hunting technique used by this species, involving a very rapid, agile chase, contrasts markedly with the far more static perch-hunting system prevalent amongst the chanting-goshawks (*Melierax*). This, together with the fairly short wings, long tail and long toes of *Micronisus*, suggests that it is probably more closely related to the genus *Accipiter* than to *Melierax*.

[*Micronisus gabar*,

Golden Eagles usually prey mostly on medium-sized mammals, such as rabbits, hares and some rodents, although gamebirds can also be important. In some cases, however, carnivorous mammals such as mustelids, cats and even foxes may be taken on a regular basis. The eagle normally catches its prey by striking at it on the ground from a rather low quartering flight. In certain areas, and especially in winter, carrion can make up a significant proportion of the diet of this species.

[*Aquila chrysaetos homeyeri*.

Nature & Travel]

to catch their prey. Quartering, by means of slow, buoyant flight low over the ground, similarly allows the harriers to surprise rodents and birds in open areas. Active hunting in flight is typical of insectivorous kites of the genera *Elanoides*, *Chelictinia* and *Ictinia*, and also of the Bat Hawk, which has a much more rapid, powerful flight. All these species have the rather pointed wings of swift fliers like the falcons.

In order to find carcasses, vultures rely not only on their excellent eyesight, but also on the findings of congeners or other species. Within a radius of several kilometres around it, and while flying about at 200-2000 m, each individual follows the movements of other vultures descending toward potential food.

Social or co-operative hunting has been documented in several buzzards and eagles. It occurs between mates with strong, permanent pair-bonds, and increases the success rate of attacks on large, swift vertebrates. Pairs of White-tailed Sea-eagles succeed in catching wounded waterbirds, which dive repeatedly at each attack of the eagles, but which become exhausted when they can neither breathe nor rest between two dives. Co-operative hunting involving more than two individuals has been described in social groups of Harris's Hawks (*Parabuteo unicinctus*), and it is known to allow this species to take larger prey with more success than if the birds were hunting alone. Groups of two to six individuals gather at dawn, and usually break up into sub-groups which "leap-frog" through the hunting territory, 100-300 m at a "hop", attempting to flush and ambush rabbits. Several birds perch nearby, while one or more birds dive into cover, where prey has gone to ground. Another system used by Harris's Hawks involves relay chases, whereby one bird failing in a capture attempt is replaced by another member of the group. Team hunts with five to six birds are the most successful, and often result in the capture of

sufficient prey to meet the energy requirements of all the individuals in the group.

Piracy, entailing the stealing of food items from other birds, including conspecifics, is common among kites, fish-eagles, the Steppe Eagle and the Tawny Eagle (*Aquila rapax*). Many other species, however, occasionally indulge in kleptoparasitic attempts, and immature birds tend to do so more persistently than adults.

The speed of raptors hunting actively, flying in a straight line, ranges from about 15-30 km/h for harriers, foraging 0.5-3 m above the ground, to 50-80 km/h for the Bateleur, flying at a height of 50-100 m. Vultures and eagles, gliding down over long distances, may reach speeds of 90 km/h or more. Eyesight is by far the most important sense used in hunting, but hearing is also regularly used, as shown by the fact that raptors are attracted by the calls of their prey species, produced naturally or imitated, and sometimes by the noise of distant gunshots, when they may try to retrieve dead or wounded game. The visual acuity of many species (see Morphological Aspects) is an essential part of their hunting skills. Buzzards or eagles, perch-hunting in open country, have demonstrated their ability to detect a grasshopper at more than 100 m, a vole or a lizard at 400 m and a rabbit at least at 1000 m.

Unsuccessful attempts often outnumber successful attacks even by experienced adults, except for birds preying on insects and small rodents. The success rates of attacks on birds by sparrowhawks or harriers usually range between 10% and 50%. On average, young birds show a success rate lower than that of adults, and this rate steadily improves with age and experience.

Killing of prey is achieved mostly using the feet and talons, but large vertebrates are ultimately killed by pecks at the head and neck, while the claws may stab vital organs. The non-

comestible parts of prey, such as large bones, or the legs and wings of birds and insects, are often discarded. Birds are plucked carefully. Curiously, many species first eat the head of any vertebrate caught, especially if the rest of the animal is brought to the nest. The intestines are frequently removed, and the head of a snake will be crushed or ripped off before the body is swallowed whole, at any rate by snake-eagles.

Small prey items up to the size of rats are either swallowed whole or torn to pieces, using the bill. Undigested remains gather to form a pellet of fur, feathers or chitinous pieces of insects that is regurgitated through the mouth. Small raptors cast one or two pellets daily, but larger species may produce less than one per day. Prey is often brought to the nest already partially prepared or eaten, for instance plucked and decapitated birds, or headless mammals. The *Gyps* vultures feed their young with regurgitated, partly digested meat, which is mixed with saliva presumably containing the necessary digestive enzymes.

The diets of unspecialized species vary between seasons, according to prey availability. Young, more inexperienced birds often take smaller or more easily caught prey, either because they still lack the skill of adults, or because they are kept away from the best food sources by the territorial or socially dominant behaviour of adults. Immature African Fish-eagles often eat carrion, whereas adults depend almost entirely on fish. The females of Eurasian Sparrowhawks and Northern Goshawks on average take larger prey than those taken by the smaller males.

The daily food requirements of members of the Accipitridae vary from about 25% of the bird's body weight in small active species during winter in temperate areas, to 10-15% in medium-sized buzzards of 700-1200 g, to less than 5% for large eagles in captivity. Mean consumption is at least 20-30% higher in winter than in summer, and it decreases by about 50% from temperate to tropical species of similar sizes and

diets. In Scotland, the total annual food requirement of a pair of Golden Eagles and their young was estimated, including wastage, at 457 kg, which worked out at about 10-20% of the food available on their home range. The total food consumption of a brood of Eurasian Sparrowhawks during the 32 days of the nestling period works out at 6-13 kg, with about 10 passerine birds per day brought to the nest by the male, to feed the female and the young. In turn, adult Hen Harriers (*Circus cyaneus*) have been calculated to bring in an average of 3.2 voles per nestling per day. At the other extreme, the Harpy Eagle, in the South American rain forests, delivers only one prey item per week to the incubating female, and one item every 3-5 days to its young. The equivalent rates recorded for the Crowned Hawk-eagle in Kenya are respectively one item every 3-5 and 1-6 days. Caching of excess food has occasionally been recorded for several species, but it is much rarer than in falcons (see page 229). When food is abundant, excess quantities of prey are often brought to the nest, where they remain uneaten.

The prey selected is generally the most abundant, the most accessible and the easiest to catch. As is habitual amongst other predators, there is a strong tendency for the birds to take young, sick, odd-looking animals, or those that exhibit abnormal foraging, defence or escape behaviour. There is a fair amount of evidence to indicate that raptors can limit or reduce their prey's numbers locally. This has been demonstrated for Eurasian Sparrowhawks with respect to Great Tits (*Parus major*) and Blue Tits (*Parus caeruleus*) around sparrowhawk nests in English woods, and also in several cases for Northern Goshawks, on drumming male Ruffed Grouse (*Bonasa umbellus*) in North American forests, on corvids in Germany, and on introduced pheasants in Sweden over the winter. More generally, predation pressure is now known to have a long-term influence on the evolution of behaviour, habitat selection, life history and population dynamics of prey species. There is even conclusive evidence that specialized predators, such as the Rough-legged Buzzard, may be responsible for the marked 3-4 year cycle of lemming abundance in the Arctic tundra.

Breeding

One of the basic conditions for the reproduction of many raptors is the existence of breeding territories or exclusive hunting ranges. These are necessary in order to provide a steady source of food throughout the breeding season (see Habitat, General Habits).

Mutually exclusive defended home ranges tend to be the rule, but in some species birds may defend only a portion of their range. At the lowest extreme, scavengers, like vultures and Black Kites, and aerial insectivores, like the two Swallow-tailed Kites and the Mississippi Kite, often have a defended territory that is restricted to the immediate vicinity of the nest-site, while the birds overlap broadly in their hunting ranges.

Territorial behaviour is a fundamental spacing system that limits breeding densities of raptors. Territorial defence is maximum near the nest during the breeding season, and reaches a peak during the nestling stage. Direct physical confrontations between territory owners and intruders are rare. Usually the owner advertises its presence and ownership with a display flight. This warning system informs the neighbours of the continuous occupancy of the territory, and usually prevents them from crossing its boundaries. To repel a persistent intruder, many species, from sparrowhawks to eagles, have a clearly recognizable threatening display flight. It may be the slow, jerky, flapping flight of some sparrowhawks, goshawks and harriers, or the determined gliding approach, with the head fully stretched out in front, of the Short-toed Snake-eagle (*Circus gallicus*). Some species are very aggressive towards potential predators near the nest, and they may actually strike an intruder, even a human; species known to react thus include the Northern Goshawk, some harriers, the Roadside Hawk (*Buteo magnirostris*), the Harpy Eagle and the Crowned Hawk-eagle. In northern Mexico, Swainson's Hawks are frequently not dis-

The Crested Serpent-eagle is the most widespread of the six members of the Oriental snake-eating genus Spilornis. It tends to take up position on a commanding perch in the forest edge, for instance along a stream or in a clearing, and here it keeps a sharp look-out. Once prey is spotted, the eagle stoops and attempts to capture it. Prey may be attacked on the ground or in trees, and indeed arboreal snakes, like this cat snake (Boiga), are frequently taken.

[*Spilornis cheela*, India. Photo: Belinda Wright/DRK]

The largest eagles are capable of killing mammals weighing well in excess of their own body weight, although such prey can not be carried away whole. In areas of rain forest the Crowned Hawk-eagle preys mainly on monkeys, tree hyraxes (Dendrohyrax) and small antelopes, such as suni (Nesotragus moschatus), but in drier parts of its range rock hyraxes (Procavia, Heterohyrax) and viverrids predominate. Most prey is taken on the ground, the eagle dropping rapidly to deliver a sharp blow with its feet. On occasions a monkey can even be knocked off a branch, to fall to its death. Monkeys are normally eaten whole, bones, teeth and all, and in the end only the fur remains undigested. This magnificent adult is feeding on a vervet monkey (Cercopithecus aethiops).

South Africa.
Photo: J. J. Brooks/Aquila]

suaded from violently striking an approaching observer, even if the human turns to face the attacker and waves his arms. Such behaviour is an efficient adaptation designed to minimize predation pressure. At close range, threat displays may involve raising the crest or the head feathers, stretching the head forwards or upwards, or opening the wings; very often the bird calls simultaneously. From an early stage, nestlings exhibit varying forms of defence behaviour against predators. Either they squat down and remain motionless to escape detection, or they lie on their backs and strike upwards with their talons, if

approached too closely. Male-female or parent-young relationships at the nest involve a variety of greeting, solicitation and begging postures or vocalizations that are critical for the maintenance of the bonds uniting the pair or the family.

In spite of the territorial behaviour of resident adults, a substantial floating population of immature or non-breeding birds remains within or between occupied territories. The presence of these surplus, non-territorial birds is difficult to detect, but it is suggested by the classic observations of the rapid replacement of lost mates that occurred when gamekeepers used to shoot females at nests. Such rematings occurred quickly, sometimes within a single day, and up to 3-6 times in succession within the same breeding season. This phenomenon was recorded in apparently healthy populations of Golden Eagles, Eurasian Buzzards and Eurasian Sparrowhawks in different parts of Europe. Even both birds of a pair were replaced sometimes, and an incoming female could take care of the brood left by the previous female. This is, therefore, further evidence that the number of pairs actually breeding may be strongly regulated by their territorial behaviour.

The mean specific densities of breeding raptors in suitable continuous natural habitat range from a minimum of 1 pair/100-300 km² for large eagles, down to 1 pair/1-2 km² for sparrowhawks. Most population studies carried out in Europe and North America over continuous areas of 30-150 km² have given a maximum total of 5-20 pairs of 4-8 accipitrid species per 10 km². Within smaller, more local patches of very rich habitat, densities may be higher, but in most cases and over areas larger than 100 km² the overall densities, with all species pooled, usually reach at most 2-5 pairs/10 km². The highest density ever recorded was in a mosaic of wooded savanna and gallery forest in Ivory Coast, where, within a study area of 27 km², the mean density was 48 pairs of 10 species of Accipitridae actually breeding per 10 km². At the same time, they co-existed with six additional species of non-breeding migrants, which in turn had a mean density of 35 individuals/10 km².

The Western Honey-buzzard is amongst the most specialized of the many insectivorous raptors. It is particularly keen on wasps and hornets, often digging out their combs and then picking out larvae, pupae and also adults one by one. The forehead, lores and legs of these birds are well protected against stings.

[*Pernis apivorus*.
Photo: A. Limbrunner]

*Amongst the most specialized feeders of all accipitrids are the three snail-eating kites, all of which have markedly hooked bills. The Snail Kite and the Slender-billed Kite (*Rostrhamus sociabilis*) both eat mostly apple snails of the genus *Pomacea*, which are regularly found in wetlands. These kites normally hunt from prominent perches, dropping down to snatch up prey with the feet. When flying off to a communal roost in the evening, a bird can often be seen carrying a snail in its bill.*

African White-backed Vultures and Rüppell's Griffons are frequently to be seen together at the same carcass. These species mainly eat the soft muscle and organ tissues, whereas the larger, more solitary species will also consume the harder parts, including skin, sinews and bones. Birds will often thrust their heads and necks deep into a carcass, or will even climb right inside the rib-cage. The bare skin on a vulture's head and neck means it can feed without getting its feathers all clogged up with blood; indeed, feathering on these areas would actually be a liability for vultures.

Breeding density is inversely proportional to mean home range size, and it decreases markedly with increasing body size, though there are often substantial unused, or little used, areas between the regular home ranges of a given species. Densities are highest in scavenging or insectivorous species, intermediate for predators of small vertebrates, and lowest for the specialist predators of larger birds and mammals. The most spectacular concentrations of resident raptors, besides the colonial species, were found, at least formerly, in large towns in West Africa, the Middle East and India, where vultures and Black Kites took advantage of abundant food supplies. In Dakar, Senegal, and New Delhi, India, as many as 170-200 breeding pairs/10 km² of such scavengers were counted.

Habitat quality, nest-site availability and intensity of territorial behaviour are all important proximate factors that control breeding densities, but the abundance of the food supply is by far the most universal and limiting ultimate determinant. There is strong evidence that breeding populations are regulated by prey availability. Spectacular interannual fluctuations in the density of specialist predators of small rodents are directly correlated with rodent densities, whether it be Rough-legged Buzzards on the northern tundra, Hen Harriers on Scottish moorland, Montagu's Harriers on French agricultural land, or Common Black-shouldered Kites (*Elanus caeruleus*) in African ricefields.

Territory size and intensity of defence are lowered, while clutch size and breeding success increase markedly with an improved food supply. Such positive relationships, involving both numerical and functional responses to the main prey species' increase, have been found in almost all of the less specialized and more sedentary species studied, from small sparrowhawks to large eagles. It has been demonstrated that the nesting density of the Golden Eagle in Scotland was correlated with the amount of food, mainly carrion, available in winter, whereas breeding success was related to the amount of live prey available in summer, essentially in the form of grouse, hares and rabbits. A shortage of nest-sites may also limit the

density of a species below the carrying capacity of the habitat, for instance in cliff-breeding species.

Monogamy is the predominant mating system among birds of prey. Cases of bigamy are occasionally reported in some species or particular populations, for example in the Eurasian Buzzard in Scotland (not elsewhere), but these are always exceptions. To date, polygyny is only known to be regular in the Western Marsh-harrier, the Hen Harrier and Montagu's Harrier. In these species, the alpha female is fed more frequently by the male than are the other one or two females, so only the male appears to benefit from this mating system. Polyandry, where one female mates with more than one male and males also feed and defend the brood, is best known in the Galapagos Hawk (*Buteo galapagoensis*), and it has also been reported for the Black-breasted Buzzard (*Hamirostra melanosternon*). It also occurs in Harris's Hawk, where it may be more a case of a co-operative group, with one to five adult or juvenile helpers at the nest. Such groups have a linear hierarchy, and the subordinate birds rarely participate in activities at the nest, limiting themselves to bringing food and helping to defend the nest area. Alpha birds are the breeding pair, beta birds do not seem to be related to them, and gamma birds are probably young from a previous breeding attempt by that same group. It is perhaps surprising that there is no increase in the fledging success of this species for groups as against pairs, but one of the advantages may be that young birds have a longer period in which to learn hunting techniques. Another unusual case is that of the Snail Kite, which may be one of the few vertebrates to practise both serial polygyny and polyandry. In the Everglades of Florida (USA), during periods of food abundance, one bird of a pair frequently deserts a nest 3-5 weeks before the end of the normal period of parental care, leaving its mate to raise the brood to fledging. Females tend to desert small and medium-sized broods, while males leave large ones, and the deserter may go off to renege with a new mate. The remaining parent rarely deserts, and, in fact, has a high chance of rearing the young successfully, as

The eight fish-eagles of the genus *Haliaeetus* are mainly fish-eaters. They also take significant quantities of carrion, although this too is often in the form of fish. Like other piscivorous members of the Accipitridae, they tend to locate their prey mainly from perches, rather than during foraging flights, which are more likely to turn up carrion. In this respect they differ from the Osprey (*Pandion haliaetus*), which typically hovers over the water and then plunges right in. In contrast, having spotted a fish from a perch, the far bulkier, less agile fish-eagles fly over and pounce on the fish in a moment when it is very near the surface, normally immersing only their feet and legs.

75% of the reproductive effort has usually been expended by the time of desertion. However, despite these notable exceptions, most species typically remain mated for life, and even in migratory species birds tend to come back to the same breeding site, and the pair may even migrate together, although there is little, if any, hard evidence for this.

Truly colonial breeding occurs in Rüppell's, the Eurasian and the Cape Griffons. Concentrations of up to 1000 nests are known along the Got escarpment in Tanzania and the Hombori

cliffs in Mali. Several other species may breed in colonies, where food is abundant or breeding sites localized, but they are not obligate colonial breeders, and they are commonly found in scattered pairs. For instance, more than 30 pairs of Montagu's Harriers can nest within a few hectares, whereas over 100 pairs of Black Kites may nest together; other typical examples include the Mississippi Kite and the Snail Kite. Opportunistic concentrations of nests often occur in several species, in areas where there is suitable nesting habitat within rich foraging

Once caught, a fish is carried to dry land or some other convenient perch and consumed.

The heavily built fish-eagles have no difficulty in catching or dealing with sizeable fish, and the very strong bill can quickly tear the fish apart. Fish-eagles are actually quite versatile and will sometimes fish in a style similar to that of the Osprey. Again, they will forage by wading in shallow water, particularly where there are concentrations of dead or dying fish. They are also prone to launch kleptoparasitic attacks on other birds, when their sheer size offers them a good chance of success.

grounds, for example isolated cliffs, woodland or canyons, but these are not considered as true colonies.

Breeding first occurs at the age of 1-2 years in small *Accipiter* hawks and harriers, 2-3 years in buzzards and large kites, 4-5 years in eagles, including sea-eagles, 5 years in griffon vultures (*Gyps*), and up to 6-9 years in the largest vultures and tropical forest eagles. In many cases, the age of maturity is inferred from the age at which adult plumage is acquired or the data come from captive birds, but in the wild individuals

of many species have been seen to reproduce successfully in subadult or even in immature plumage, 1-2 years before the full adult plumage is actually assumed. This tendency is more common in undersaturated populations, which is not perhaps surprising, as it has been shown that when density is high a significant proportion of seemingly mature birds do not breed. Therefore, the mean age of first breeding may be significantly greater than the potential age set by physiology, and it is probably delayed by behavioural factors.

Verreaux's Eagle is a highly specialized hunter, and at least 90% of its diet normally consists of rock hyraxes (*Procavia*, *Heterohyrax*). One of its main techniques consists of flying very low round sunning hyraxes, giving them no time to escape

All species of the Accipitridae build a nest, which is often a solid structure of sticks, with finer material inside the cup. Eagles, as well as large buzzards, kites and vultures reuse old nests year after year, sometimes for several decades, when other sites are scarce or the nest-site is safe. In such cases, the construction may reach enormous proportions. One famous Bald Eagle eyrie was three metres wide and five metres deep. Smaller species build much smaller platforms, and they usually build a new one every year. The *Gyps* vultures, serpent-eagles and snake-eagles build relatively small nests, considering that they are all large birds, and several of them often make a new nest each year.

There is a great deal of variety in terms of nest-sites, and each species has its own preferences as to position, height, orientation, shelter, accessibility and visibility. The nests of most species are in the upper parts of trees. Cliff ledges or caves are almost invariably used by six species of vultures. Seven buzzards, two eagles and the Black-chested Buzzard-eagle (*Geranoetus melanoleucus*) also predominantly use cliffs or low rocks. Only the Steppe Eagle and the harriers nest almost always on the ground, although the Spotted Harrier (*Circus assimilis*) is a tree-nester. Some cliff-nesters, such as the Golden Eagle, build on trees occasionally, and they may even do so regularly in some areas. In turn, several tree-nesters use cliffs, or at least small trees on cliff ledges when they are available. A few species even nest on the ground on predator-free islands, for instance the Eurasian Buzzard in Scotland and the Bald Eagle in the Aleutians, and an increasing number use man-made structures, notably several kites, buzzards and eagles on pylons, or the Black Kite on buildings. There is a fair amount of evidence to indicate that some nesting sites are superior to others, and such sites are repeatedly occupied, even though the owners may change. When Eurasian Griffons were reintroduced to central France more than 40 years after their extinction, they first reoccupied the very same nest-sites that had been used by the last wild pairs.

Many species use old nests, to which they add new material. Changes in nest ownership are commonly observed at the onset of a new breeding season amongst buzzards, kites, goshawks and even eagles, and this strategy can save a good deal of time and energy at the beginning of the season. Resident eagles, buzzards or goshawks often have several nests in their territories and use them alternatively from one year to another. They may refurbish more than one each year, or use alternative sites for roosting, or for preparing prey items for delivery. Whether or not a nest-site is changed from one year to the next is strongly related to the breeding success of the previous year; safety reasons are probably a significant factor affecting this, although it might also be a mechanism to avoid an excessive build-up of parasites. This habit of alternating nest-sites is

found amongst temperate species more commonly than amongst tropical ones.

Twigs with dead leaves or grass are often added to the stick structure, as is wool in the nest of the Bearded Vulture. Black and Red Kites incorporate a mass of rags, paper, dung and other refuse, as, to a lesser extent, do the Egyptian and Hooded Vultures. Several species have the characteristic habit of bringing fresh green vegetation, mostly leafy twigs, to the nest throughout the breeding cycle, especially in the early stages. The purpose of this has been the object of many hypotheses, but there is still no satisfactory and widely accepted explanation for this behaviour; it is not performed by species with small, concealed nests.

The female often seems to select the nest-site and usually does most of the construction, but the male may bring much of the material to her. The duration of nest building varies from 1-2 weeks in small kites and sparrowhawks, or late migrants, such as the Western Honey-buzzard, up to several months in large eagles, when they have to build a totally new nest. Nest construction, as well as other pre-laying activities, tends to be longer in tropical countries than in temperate latitudes, where the duration of the breeding cycle is more constrained. It is shortest at the highest latitudes. Some of the material added to the nest may help to camouflage it, for instance the dead leaves used by honey-buzzards, or sticks festooned with the webs of social spiders brought in by the Dark Chanting-goshawk (*Melierax metabates*).

Apart from such camouflaging, there are many other forms of behaviour that are probably related to anti-predator defence. The nest is always guarded by the female, and she remains on it or close by. While incubating, especially when hatching is near, she squats low, freezing on the nest at the approach of a human intruder, and flying off unobtrusively at the last moment. Once off the nest, she makes loud alarm cries, or attacks the intruder to drive him away. Fledglings tend to move away from the nest as soon as they are able to, coming back to it at night or to be fed by their parents.

In temperate regions, the breeding season is in spring and is related to mild temperatures and maximum food supplies. The laying date is thought to be adapted to the necessary length of the breeding cycle and the growth rate of the young, and ultimately to permit the fledging period to coincide with the optimum availability of the preferred prey. Thus, the Eurasian Griffon and the Bearded Vulture begin to display and even to lay in mid-winter, whereas the Eurasian Sparrowhawk does not do so until late spring. As one moves northwards within the temperate zone, the species start their breeding attempts later on, and they tend to have shorter breeding periods, showing a higher degree of intraspecific synchrony. Laying is also significantly earlier when prey density is higher, after a mild winter

The goshawks and sparrowhawks of the genus *Accipiter* rely mainly on surprise to capture their prey, which normally consists of a mixture of small birds and mammals, amphibians, lizards and the like. The hawk regularly lies in ambush, dashing out with a sudden burst of acceleration, and often, if necessary, with a few dexterous manoeuvres. Once the element of surprise has been lost, only a rather brief chase is likely to ensue before the hawk gives up; its broad, rounded wings are not well suited to the more lengthy pursuits performed by falcons. This African Goshawk has failed in its attempt to catch a Rüppell's Parrot (*Poicephalus rueppellii*), a species probably capable of much faster flight than the goshawk over any but the shortest of distances.

[*Accipiter tachiro*,

Reptiles constitute a major source of food for a number of species. In different habitats, the Martial Eagle specializes on medium-sized mammals or large birds, but in some areas monitor lizards are its main prey. This large, powerful eagle spends long periods soaring aloft on the look-out for suitable prey. Once this has been located, the eagle embarks on a long, steady, usually rather shallow dive, lunging in on its victim on the ground, and braking sharply with its wings and tail spread.

and early spring, and in older, more experienced adults. These same factors of food supply, weather conditions and experience seem to act through the body condition of the female, and they subsequently influence clutch size and, in the end, breeding success, through the female's care of the eggs and young and the amount and quality of the food provided by the male.

In tropical areas, where the seasons are based on the rainfall regime, raptors tend to breed during the dry season. The large species begin early in the dry season, the smaller ones in the second half, both timed in order that the young may fledge early in the wet season, when there is a plentiful flush of new food, but before the vegetation cover reaches its full development, and also before the rains become too troublesome. Near the equator, with two marked wet seasons, raptors breed during the longer of the dry seasons or during both, as is known to be the case of the Gabar Goshawk, where marked birds have been found breeding twice a year. In more aseasonal or unpredictable environments, some species may lay eggs in almost every month, for example the Galapagos Hawk. In arid central Australia, the nomadic Letter-winged Kite may breed at any time, following the irregular rains that constitute the major determinant of rodent outbreaks.

In partial migrants, the male either arrives first or remains on the territory. In some other migrants, such as *Accipiter* hawks, the female more often returns first, whereas in at least a few late arriving migrants, the two sexes appear simultaneously, as if they were already paired. Pair formation and copulation are mostly performed at the nest-site or in the immediate vicinity. Copulation sometimes occurs several hundred times during the pre-laying period, for instance in the Northern Goshawk, often following aerial displays, nest building bouts or courtship feeding. The female stays at the nest throughout the pre-laying period, when the food brought by the male is crucial

for the number and quality of the eggs that are to be produced. The female invites the male to mate using particular attitudes, such as bowing the head, dropping the wings, crouching, or showing off the conspicuous uppertail- or undertail-coverts.

Besides intensive nest defence against intruders, mate guarding and regular courtship feeding, the male also performs spectacular display flights, to reaffirm his ownership of the territory, to attract a mate or to strengthen a pair-bond. Eagles, including some snake-eagles, and also some harriers and buzzards, perform undulating "pendulum" flights, diving with the wings closed, then rising with the wings spread, swinging round and over, and retracing the course repeatedly; cuckoo-hawks and bazas (*Aviceda*) sometimes even roll and loop, or tumble about. The birds may remain silent, but for some, such as the hawk-eagles, loud calls are a prominent part of the display. In mutual displays, the two sexes can cross their flight-paths, or the male descends towards the female with his wings raised, and the female turns over and presents her claws, as occurs in several buteos and the Black-chested Buzzard-eagle. In Eurasian Griffons, mates glide very close to each other, their wings fully stretched. Other notable displays include those of honey-buzzards, which have characteristic wingbeats that involve clapping over the back, while the Crested Goshawk (*Accipiter trivirgatus*) and the Grey-headed Kite (*Leptodon cayanensis*) have rapid, fluttering, downward wingbeats. Simple soaring and calling are common in many raptors, as are temporary groupings of several birds calling together. The simplest form, used by small or non-soaring tropical forest raptors, is an advertising posture in which the bird perches on a prominent tree top. The loud calls of perched or flying African Fish-eagles are particularly striking and well known.

The eggs have a rather rounded oval shape, and are mainly white in ground colour, often with a blue or green tinge, and

The tarsi of the African Harrier-hawk can bend 70° backwards and 30° sideways; its head is small and narrow. These peculiar adaptations are connected with its habit of foraging in cracks or holes on vertical tree trunks or amongst palm fronds. It also specializes in taking nestling chicks from weaver colonies, clinging onto a nest or a branch and tearing open the nests.

[*Polyboroides typus*.
Photo: M. C. Wilkes/
Aquila]

often marked with brown, reddish or grey. The inside of the shell is greenish or pale bluish. Most large species of eagles and vultures, as well as tropical species of any size, especially in rain forests, lay 1-2 eggs. Small and medium-sized temperate species of kites or buzzards lay 3-4 eggs, whereas a normal clutch size of 5-6 is found in small accipiters and in harriers. Clutches of over six eggs are exceptional, and sometimes result from two females laying in the same nest. However, such large clutches are laid by rodent specialists, such as the Rough-legged Buzzard, Montagu's Harrier and the Common Black-shouldered Kite, at the peak of vole or lemming cycles, since their clutch size is greatly affected by food availability and may vary from no eggs, and consequently no breeding, in

poor years, to five or more, in years of rodent outbreaks. As with other birds, mean clutch size tends to increase with increasing latitude: it doubles in Eurasian Sparrowhawks between North Africa and Scandinavia, or in the Broad-winged Hawk between Caribbean islands and southern Canada. Eagles in temperate zones lay two eggs, or sometimes three, except the Short-toed Snake-eagle, which is a determinate single egg layer. Comparable species in the tropics lay only one or two eggs. The full clutch represents 4-8% of body weight in small species, to less than 3% in the largest species.

Eggs are laid at intervals of two days in small species, or three to five days in larger species. Since incubation begins with the first or second egg, the young of earlier eggs hatch quite some time before those of later eggs, and thus have a significant size advantage over them. This asynchronous hatching gives rise to intense sibling competition, and the youngest chicks often die of starvation or due to aggression by their nest mates. In some eagles, for instance the Lesser Spotted Eagle, the oldest chick always kills the smaller one, even when food is not in short supply. This so-called "Cain and Abel" conflict has been tentatively explained by several theories, but none of them is fully satisfactory.

The incubation period varies considerably between the different groups, lasting about: 28-38 days in harriers; 28-36 days in sparrowhawks; 35-38 days in larger goshawks; 28-38 days from the smallest to the largest buteos; 36-48 days in *Aquila* eagles; 47 days in the Short-toed Snake-eagle; 48-56 days in the largest tropical forest eagles; and up to 52-60 days in the largest vulture species. In accipiters and harriers, the female incubates alone. In larger species, however, from kites and buzzards to eagles, the male relieves the female for short periods, or sometimes, as in Verreaux's Eagle, shares a significant part of the incubation, a tendency more common with clutches of two eggs than of one; the male almost exclusively takes his turn during the daylight hours. The incubating female is fed by the male, but sometimes she also hunts for herself. In vultures, the sexes share the incubation duties more or less equally, and

Many accipitrids sometimes perform a "Mantling-display", spreading their wings over a prey item to create a sort of canopy. This behaviour is most commonly employed to guard the food from pilfering attacks by conspecifics or other species, and it may be accompanied by the puffing up of feathers and threat calls. The same display can be seen in well grown chicks on the nest, when warding off siblings from food that has been appropriated. This Northern Goshawk has killed a Common Moorhen (*Gallinula chloropus*).

[*Accipiter gentilis*.

Like most of the buzzards or hawks of the genus *Buteo*, the Red-tailed Hawk is something of a generalist in terms of its feeding habits. Overall, it feeds mostly on small to medium-sized mammals, birds and reptiles, but in some areas snakes make up approximately 50% of all the prey taken (by biomass), and these can include venomous species, as illustrated here by an immature bird, which is in the process of killing a fairly large eastern diamondback rattlesnake (*Crotalus adamanteus*).

[*Buteo jamaicensis*.
Photo: L. Lee Rue/FLPA]

the female leaves the nest to do all her own feeding herself. During incubation, all species frequently turn the eggs and shift their position. Infertile eggs regularly occur in the clutches of most species, even in healthy and uncontaminated populations of both temperate and tropical countries. In Ivory Coast, Nigeria and Kenya, research showed that up to 20% of all eggs were infertile in two-egg clutches of eagles, Hooded Vultures, African Harrier-hawks, Lizard Buzzards and Black Kites.

The nestling period, from hatching to the young bird's first flight, again varies a great deal, especially with size, lasting: 24-30 days in small sparrowhawks; 29-46 days in harriers; 40-45 days in goshawks; 42-49 days in *Buteo*; 60-77 days in temperate eagles, such as the Golden Eagle, the Eastern Imperial Eagle and the Short-toed Snake-eagle; 95 days in another *Aquila* of the tropics, Verreaux's Eagle; 95-130 days in large vultures; and 105-148 days in the largest tropical forest eagles, notably the Harpy Eagle. The chick's first contour feathers appear during the second third of the nestling period as wing and tail quills. The body feathers quickly follow, first on the upperparts. The growth rate of chicks is spectacular, but it draws to a halt near fledging time, when the young bird may even start to lose weight, because of reduced feeding rates.

During the last third of the nestling period, the young bird ceases to require parental protection, and it becomes increasingly active, even starting to feed for itself. Prior to leaving the nest, it indulges in bouts of vigorous wing-flapping exercises. The first flight out of the nest is usually made without any parental coaxing, but, in some cases, it may be under the close surveillance of the adults, and in response to their forceful encouragement. After leaving the nest for the first time, young birds are often unable to make an upward flight back to the

nest, and they must be fed out of the nest for several days, until they are stronger on the wing, and able to come back to the nesting platform.

In dimorphic species, males grow faster than females, and in sparrowhawks and goshawks a male often spends 3-4 days less at the nest than a female, and this may be eight days less in the Crowned Hawk-eagle. This compensates for the smaller size of male chicks, and their resulting competitive disadvantage. Even in species where the Cain and Abel battle always eliminates the younger chick, there is no conclusive and generalized evidence of a significantly skewed sex ratio in fledglings. On the whole, the mortality rate during the nestling stage does not differ between the sexes. It is normally in the range of 20-40%. This mortality is mostly associated with food shortage, acting through the dominance of the elder members of the brood, which are strongest and which are always fed first, until they become satiated. This is an adaptive mechanism whereby breeding success is controlled by food availability.

Except in vultures, where the two sexes share the duties of brood care equally, the male does not normally feed the young, but only brings prey to the female, leaving it to her to dispense the food. However, if the female disappears, the male may sometimes be able to feed the young efficiently, at any rate if the chicks are already roughly half-grown. In the Snail Kite, one adult often deserts the nest at an early stage, in order to renege elsewhere, leaving its mate alone to care for the eggs and young, often successfully. In most species, the male provides almost all of the food for the female and chicks, from the pre-laying stage to about half way through the nesting period. The high rate of energy expenditure that this implies often induces weight loss in the male. Towards the end of the nestling period, the female hunts progressively more and more, so as to

help meet the increasing food requirements of the growing young.

Wing and tail quills continue to grow for some time after fledging, even up to 3-4 weeks more in kites and goshawks. At this stage, young birds tend to follow the adults about persistently, but they return to be fed at the nest, where prey is delivered at least for several days and for up to 2-4 weeks in eagles. They slowly begin to hunt for themselves, first trying to catch easy prey, such as insects, before turning to more difficult quarry. Their poor success is compensated for by the prey brought by their parents. Definite examples of actual training by adults have been reported more rarely and more inconclusively than in falcons. The development of hunting skills is very variable between individuals. In Europe and North America, young buzzards may still be fed 2-6 weeks after fledging, and they may stay in their parents' territory for one to several months more.

Usually the adults do not drive their offspring away from the territory until just before the beginning of the next breeding cycle, but in many cases the young birds leave the territory, even while they are still being offered food. The young of late breeding migrants, notably the honey-buzzards, must be able to leave the breeding area only 2-3 weeks after fledging. They may do so before or after the adults, but there are several records of whole family groups departing or migrating in close association. Otherwise the young often disperse at random in any direction, for instance in the Eurasian Buzzard. Young Bald Eagles in Florida, however, regularly migrate northwards up to southern Canada in late summer, before returning in winter. When the period of dependence is relatively short, mortality tends to be rather high, partly because young birds still require plenty of time to perfect their hunting skills. The evolutionary strategy of tropical forest eagles, which are K-selected (with low productivity, but a long average lifespan), involves lengthening the learning period, and thus reducing first year mortality to the minimum. In the Harpy Eagle and the Crowned Hawk-eagle, and also in the Martial Eagle of more open habitats, post-fledging dependency can last 11-12 months, which means that the adults can breed successfully only every second year.

Overall breeding success, measured in the mean number of birds raised to fledging per successful nest, ranges in temperate countries from 2-4 for accipiters and harriers, to 1.5-2.6 in buteos, 1.2-1.8 in kites and honey-buzzards, and 1.1-1.6 in eagles, except the Lesser Spotted Eagle and the Short-toed Snake-eagle which never raise more than one youngster to fledging. In a West African savanna, the productivity levels recorded were 0.66 young per nest for two large species, the Palm-nut Vulture and the African Harrier-hawk, and 0.9-1.3 for two medium-sized species, the Black Kite and the Lizard Buzzard, and also one small species, the Shikra (*Accipiter badius*). However, in many populations, the proportion of all territorial pairs that do not breed at all, or that fail to fledge any young, is usually 10-40%. Indeed, the actual mean productivity of large vultures, such as the Lappet-faced Vulture (*Torgos tracheliotus*) in Africa, or of the large tropical forest species, including the Great Philippine Eagle, the Harpy Eagle and the Crowned Hawk-eagle, is below 0.4 young fledged per pair per year.

Whereas starvation and sibling competition are the major causes of brood reduction, nest predation is often a significant factor. Even formidable forest eagles, such as the Crowned Hawk-eagle in Africa, or Blyth's Hawk-eagle (*Spizaetus alboniger*) and the Mountain Hawk-eagle (*Spizaetus nipalensis*) in south-east Asia, often build their nests on surprisingly isolated trees, as if they were trying to avoid the attentions of monkeys or other dangerous nest predators. Chick mortality due to the effects of parasites, cold or rainy weather or excessive heat has been recorded in a fair number of species, but the overall significance of these factors is not well known. A seasonal decline in productivity, which is typical amongst many birds, has also been found in the Eurasian Sparrowhawk, the Eurasian Buzzard and the Bald Eagle, but it should be remembered that late breeding pairs are often younger or inferior breeders.

The overwhelming influence of food supply determines a species' breeding success at a whole series of different levels: the proportion of pairs actually breeding; the age of first breeding; clutch size and the quality of the eggs, and thus hatching success; the growth and survival rates of chicks and fledglings; and, finally, their subsequent dispersal patterns. Once again,

The mainly African genus *Circaetus* feeds heavily on reptiles, in particular snakes. Prey is mainly sought from a perch or by means of quartering flight, often interspersed with hovering. Once captured, snakes may be killed on the ground or in mid-air, depending on their size, and larger snakes have their heads crushed or severed prior to being swallowed. If necessary, the largest snakes are torn up, but birds are frequently seen flying back to the nest or to a suitable perch with the tail end of the snake still sticking out of the bill. This Short-toed Snake-eagle has caught a young ladder snake (*Elaphe scalaris*).

[*Circaetus gallicus*.

Nature & Travel]

Bones constitute up to 85% of the diet of the Bearded Vulture, in the form of both bone marrow and the bones themselves. Large leg bones are particularly favoured, and remarkably large bits of bone can be swallowed whole. However, when the bones are unmanageably big, either for swallowing or for crunching up, the bird resorts to a well known, but unique, solution. It takes to the air, carrying the bone, or even the whole skeleton, and rises up some 20-80 metres or more before dropping its load onto flattish rocks at a regularly used site, known as an ossuary. The bird quickly spirals down after the bones, in order to avoid losing them, and will repeat the process several times, if necessary, until the bones are sufficiently smashed for consumption.

Apart from the large carrion-eating species, relatively few of the Accipitridae are known to drink, at any rate on any sort of a regular basis. Indeed, some species that are frequently kept in captivity have never been recorded drinking. The replenishment of body fluids to balance the losses sustained during excretion and pulmocutaneous evaporation is probably achieved mainly by the bird assimilating those of its prey.

this influence is most patently demonstrated, and also most marked, in birds specialized on cyclical rodents. From years when voles are scarce to those of pullulation, the Rough-legged Buzzards in Norway may fail to breed at all, or lay small clutches but not rear any young, or, at the other extreme, produce clutches of 4-7 eggs and rear 4-5 young to fledging. Golden Eagles and Ferruginous Hawks (*Buteo regalis*), in western North America, or Golden and Bonelli's Eagles from Scotland to Spain, are also very sensitive to the density of hares and rabbits. Breeding success rates vary widely with geographical area, latitude, habitat quality and altitude, but in all cases food seems to be a central factor.

Similarly, within a given region, different territories produce more or less young consistently over the years, as has been demonstrated for the Eurasian Sparrowhawk in Scotland. Cold wet springs affect breeding success through hunting time and efficiency, and the reduced presence of the female at the nest. In South Africa, heavy rains improve the productivity of Verreaux's Eagle, through an increase in its prey density. On the other hand, increased density of breeders affects their overall reproductive success due to the frequent interactions between territorial pairs, as shown in Verreaux's Eagle and the African Fish-eagle.

A very small proportion of species may exceptionally raise two broods in the same year. This has been documented in White-tailed Kite (*Elanus leucurus*) and the Common Black-shouldered Kite during periods of rodent pullulation. Social groups of Harris's Hawks, with the assistance of helpers, may also succeed in raising two successive broods, after good rains, in the semi-deserts of the south-western USA. Laying a replacement clutch, when the first one has been lost at an early stage, is not uncommon in small species, and is more regular when food is plentiful;

replacement clutches are normally laid about two weeks after the loss of the first clutch. Such replacement laying is less frequent in medium-sized species, and is rare or almost unknown in the wild in large species, although it can easily be induced in captive birds by the removal of the first eggs laid.

Mortality rates are well known for a few species only, and many estimates are biased, because recoveries of ringed birds are more frequent in densely populated areas, where human-related causes of death are prominent. The period of heaviest mortality is during the first months of a young bird's independence. Small species, such as the Eurasian Sparrowhawk, suffer 50-70% mortality during the first year, and 30-35% thereafter. This compares with a mean annual mortality of adults of about 20% in the Eurasian Buzzard, but only 2.5-5% in the much larger Golden Eagle and Eurasian Griffon. Overall mortality between fledging and the acquisition of adult plumage has been variously estimated at between 60-90%, and 79% of Eurasian Buzzards and 83% of Red-tailed Hawks are reckoned to perish within their first two years. Starvation, predation and, to a lesser extent, disease are the major causes of natural mortality, as also are accidents, in those species that are active hunters.

Documented longevity records in the wild are of over 15 years for Eurasian Sparrowhawks, and 24-26 years for Eurasian Buzzards and Red Kites in Europe. In captivity, several individual Golden Eagles, sea-eagles, Bateleurs and vultures have lived 48-60 years.

Movements

As an adaptation to seasonally fluctuating food supplies, many, perhaps most, species in temperate areas, and also in open

Many raptors perform spectacular aerial courtship displays. Amongst the most widely used and impressive is "Mutual Soaring", in which both sexes soar aloft together and the upper bird, usually the male, periodically dive bombs its partner, which rolls over and presents its talons. In some species the display is taken further, and the birds may actually grasp each other's talons; some species, including harriers, also perform a remarkable "Food-pass", the upper bird dropping or lowering a prey item into its partner's talons. During territorial defence, intruding conspecifics are occasionally repelled by means of similar, though more genuine, attacks, although a warning is usually enough to drive off most interlopers.

habitats at tropical latitudes, perform seasonal movements of one kind or another.

The most typical kind of migration is the regular long distance shift of the whole population of a species between non-overlapping northern breeding grounds and tropical wintering areas, and this can be seen in many groups, for instance amongst Eurasian breeders; the honey-buzzards; the Black Kite; the Short-toed Snake-eagle; Pallid and Montagu's Harriers; the Levant Sparrowhawk (*Accipiter brevipes*), the Chinese Goshawk (*Accipiter soloensis*) and the Japanese Sparrowhawk (*Accipiter gularis*); the Steppe Buzzard, the race *vulpinus* of the Eurasian Buzzard; and the Lesser Spotted and Steppe Eagles. Examples of typical migrants from North America are the Mississippi Kite, and Swainson's and the Broad-winged Hawks. The migrations of such species involve hundreds of thousands of individuals moving at specific and relatively constant dates over considerable distances. The longest migrations include those of the Steppe Buzzard between Siberia and the southern tip of Africa, of the Western Honey-buzzard between Scandinavia and Central Africa, and of Swainson's Hawk between southern Alaska and northern Argentina, and each of these mounts up to a flight route of about 30,000 km per year. Most of these species are diet specialists and their food supplies are largely unavailable on their breeding grounds in winter.

More species are partial migrants with northern populations almost completely migratory and southern ones more sedentary. The Eurasian Sparrowhawk and Eurasian Buzzard are typical examples, as are the White-tailed Sea-eagle, the Bald Eagle, the Western Marsh-harrier and the Hen Harrier. These species migrate over shorter distances, the northernmost breeders going the farthest south, but even these individuals barely reach the northern tropics. Thus, in the Northern Hemisphere, the proportion of migrant species increases from south to north, and in Eurasia there is a similar gradient from the south-west to the north-east. Some northward movements of raptors breeding in southern South America have been recorded, but as yet they

remain poorly documented. The particular movements of partial migrants may actually change from one year to another, according to winter conditions. Immature birds are generally more migratory, and tend to disperse over longer distances and in higher proportion, than do the more sedentary adults.

Some populations or species remain within their breeding ranges while the food supply is still abundant, but move southwards in large numbers when it is scarce. These so-called invasions or periodical irruptions are typically performed by Northern Goshawks and Rough-legged Buzzards, because their prey, tetraonids and small rodents respectively, fluctuate cyclically. At middle or low latitudes, migrant populations often co-exist with the resident ones, and, in some cases, by the time they leave their winter quarters, the local residents are already breeding.

Immature birds first disperse in any direction whatsoever, in summer and early autumn, sometimes even moving northwards, as do young Bald Eagles from Florida, but even these birds resume a normal southward movement in late autumn. In species that do not breed until they are two or more years old, a substantial proportion of young birds remain on their wintering grounds or near them, at least during their first summer. This practice is common amongst young Western Honey-buzzards and Short-toed Snake-eagles, which stay on in Africa. Irregular, opportunistic or nomadic movements, involving breeding or non-breeding populations, occur in the rodent specialists, for instance the Rough-legged Buzzard of the Arctic tundra, and the Letter-winged Kite of Australian deserts, and also in the locust predators of the Sahel, such as the African Swallow-tailed Kite. Within their wintering ranges, several species wander about over large areas, concentrating at abundant food supplies. This is typical of gregarious insect-eaters, like Montagu's Harriers feeding on locust swarms in West Africa, Steppe Eagles tracking emerging termites in East Africa, or Swainson's Hawks catching insects in South American *pampas*.

Whereas there are no movements known among tropical rain forest raptors, many species in African savannas perform

Copulation normally takes place at the nest-site or very nearby, but not actually on the nest itself. It tends to be repeated a great many times even before the female is ready for fertilization, and probably serves as a form of courtship behaviour to strengthen the bond. It is typically preceded by courtship feeding, nest building or an aerial display, and the female will adopt certain standardized postures that invite the male to mate with her. The Galapagos Hawk is one of very few bird species found to operate an apparently stable polyandrous mating system, in which up to four or even eight males are associated with a single female.

seasonal migrations. Within West Africa, five species perform erratic movements, thirteen are partial migrants, and six undertake regular, long distance migrations, at least of several hundred kilometres, along a north-south axis between the rain forest and the edge of the Sahara. In highly migratory species, there is little overlap between the ranges occupied during the rainy and dry seasons. The northward movements are closely related to the onset of the rains, and the southward return follows the beginning of the dry season. The birds invariably occupy the latitudinal range where food availability and accessibility best meet their requirements, in terms respectively of the abundance of locusts and small vertebrates, and the grass cover. Typical migratory species are the Black Kite in its race *parasitus*, the Shikra, the Grasshopper Buzzard (*Butastur rufipennis*) and the Red-necked Buzzard (*Buteo auguralis*). Similar movements are known to occur south of the equator, and two species are known to cross the equator during their annual movement, Wahlberg's Eagle (*Aquila wahlbergi*) and the Ovambo Sparrowhawk (*Accipiter ovampensis*). In Africa, as in tropical America and southern Asia, the temperate wintering migrants are ecologically segregated from their most similar counterparts. They tend to occupy secondary, marginal or seasonal habitats that are little used by residents of comparable niche, and they mainly exploit seasonally surplus food sources, such as swarms of locusts or termites, breeding colonies of queleas, bush fires or drying wetlands. Thus, there is little or no real competition between the migrant and resident species.

Broad-winged species migrate by soaring in updraughts created by wind, or in thermals, rising currents of warm air. They climb as high as possible, and then glide down, sometimes over a long distance, towards the next air current, where they can regain the lost height. They try, as far as possible, to avoid highly costly flapping flight and also sea crossings, as there are only weak thermals in special conditions over water. Consequently they tend to fly almost exclusively over land and in good weather conditions. They make frequent detours to search

for good updraughts, and they can go a long way round coasts or mountain ranges, to avoid the sea crossings or to use the lowest passes.

Such species are also strongly gregarious, and multispecies flocks of several hundred birds are not rare. This is a necessary adaptation as the birds need to share the best air currents available for energy saving. When they come together in a thermal, different birds will often leave it at different times and heights, depending on their specific and markedly different flight speeds and abilities. Highly gregarious species include hawks, kites and eagles, but also the smaller Levant Sparrowhawk in the Middle East, or the Grey-faced Buzzard (*Butastur indicus*) in the Far East. When conditions are favourable they can fly very high, and radar tracking and also migrant searching with powerful optical devices have shown that, in the midday heat, many of them may pass undetected, well above the range of visibility of the naked human eye. The highest altitudes recorded above ground level generally range from 2000 to 4000 m, with a maximum of 5000-6400 m for Broad-winged and Swainson's Hawks over Panama. More usual altitudes, however, are 200-1000 m above the ground. A Rüppell's Griffon, not a migrant, is said to have hit a plane at more than 10,000 m above sea-level, but this is probably an exceptional case.

The smaller species, mainly harriers, sparrowhawks and goshawks are more lightly built, and have a much more active style of flight. Although they are able to use thermals very efficiently, they are less dependent on soaring flight than the larger species, and they may use powerful flapping flight over long periods. This allows them to follow much broader migration routes, to fly during a longer period of daylight, to cross larger expanses of water more readily, and often to travel alone.

These different flight powers have important ecological and physiological consequences. Large soaring species of kites, buzzards, hawks, eagles and vultures, have constrained routes, on which over very long distances the habitat below may be unsuitable for stopping and feeding in, and especially to sustain the huge gatherings of birds that concentrate along such routes.

Very few birds of prey are colonial breeders, and the maintenance and defence of territories play important roles in spacing out the different pairs and also the non-breeders in any given population. Territorial defence is most intense around the nest itself, and is not surprisingly more vigorous during the breeding season. In most cases a mere threat display is sufficient to drive off an intruder, but some species regularly launch an attack against any potential predator that approaches the nest, and will deliver sharp blows with the feet, even against humans.

This is why at least several of these species have evolved some of the typical adaptations of long distance migrants, such as pre-migratory fattening. Their ability to cover a large part of their migration without feeding is now well documented, and it is commonplace to see huge concentrations of Western Honey-buzzards, or Swainson's or Broad-winged Hawks, stopping for the night; yet not one bird attempts to hunt or casts a pellet.

Even some smaller species, such as the Mississippi Kite and the Levant Sparrowhawk, also have the habits of using thermals extensively, travelling in large groups, and carrying out a speedy migration by covering long distances without interruption. In contrast, species that readily use flapping flight, such as harriers and many sparrowhawks, are better able to choose suitable habitats for stopping over in, sometimes for long periods, with the result that they can hunt almost every day. These species do not accumulate a substantial amount of body fat. The migration of Eurasian Sparrowhawks is often closely associated with the simultaneous movements of flocks of passerine birds, upon which they feed.

Almost all raptors travel only by day. Nevertheless, there is a fair amount of evidence that at least Montagu's and Pallid Harriers can migrate by night, with a series of observations from lighthouses, and the arrival of birds on sea coasts at dawn; recently, convincing data, gathered through radar tracking, have shown that Levant Sparrowhawks may do so regularly.

Where migration routes are channelled along mountain ridges, through narrow passes, and especially across straits at the narrowest sea crossings, the concentrations of migrants can be spectacular. These well known sites are used by teams of enthusiastic birdwatchers for counting the migrants, and thus following year after year the population levels. The most impressive sites are in Central America, where birds coming from the huge North American continent are funnelled into a narrow isthmus. In autumn, 2.6 million raptors have been counted over Panama, and recently in Veracruz, eastern Mexico, where the full flow of migrants has not yet become concentrated, 2.5 million were recorded, including 900,000 Broad-winged Hawks and 400,000 Swainson's Hawks, as well as one million Turkey Vultures.

Other famous concentrations of migrants occur along the south-west coast of the Black Sea and through the Bosphorus, and also around the eastern Black Sea coast in Turkey. These two fluxes join in Israel and go on through Suez, whereas more eastern populations follow the Red Sea coast along the Asir Mountains, to cross at the Bab al Mandab straits. Spring passage at Elat, at the head of the Gulf of Aqaba, the north-eastern branch of the Red Sea, has reached 1.2 million raptors of 28 species. The Mediterranean Sea is crossed at the narrowest straits, at Gibraltar and between Tunisia and Sicily, but numerous migrants also appear on Malta. Migration is studied at several concentration points in Europe, from Falsterbo in southern Sweden to the

Trees and cliffs provide nest-sites for the vast majority of species, although some nowadays use man-made structures, such as pylons and buildings, and a few even nest on flat ground, notably most of the harriers. The various different Old World vulture species tend to prefer one or other of these substrates, and only a few species will use either, depending sometimes on local availability. Tree-nesters, like the Lappet-faced Vulture, tend to be solitary, or at most loosely colonial. In contrast, cliff-nesters, like the Cape Griffon, habitually form sizeable colonies, sometimes holding around 1000 pairs.

Unlike the falcons, all accipitrids build a nest, or at least refurbish an old nest. In the Common Black-shouldered Kite, material is mostly brought in by the male, while the female occupies herself more in the business of construction. Some material is collected from the ground, but often the male procures the necessary sticks from nearby trees, selecting and grasping hold of suitable twigs, and then snapping them off.

[*Elanus caeruleus caeruleus*, Nile Valley, Egypt. Photo: Oriol Alamany]

Alps and the Pyrenees, and likewise in North America, from the Great Lakes to Hawk Mountain. In Asia, similar localities are also well known, such as Beidaihe in China, the Korea Strait between Korea and Japan, the southern peninsula of Taiwan, and the Straits of Malacca at Cape Rachado, between Malaysia and Sumatra. To reach the Indian Subcontinent, raptors cross the Himalayas and the Hindu Kush at surprisingly high altitudes. In the upper Kali Gandaki Valley between Tibet and Nepal, many are seen well above 5000 m, and a Steppe Eagle has been found dead on Mount Everest, at over 8000 m.

Each species has its own seasonal and daily patterns of migration. For instance, in Europe, Black Kites are the first to leave, in August, and the first to come back, in March. In late summer, they are followed by honey-buzzards, which are the latest to come back, many of them not arriving until early June. Partial migrants are usually among the latest to depart in autumn, and the earliest to reappear in spring. There may be a certain segregation in time between different age classes. In Europe, for example, adult Black Kites and Steppe Buzzards leave about 3-4 weeks before the juveniles. The reverse is usually true in shorter distance migrants, and more adults are liable to stay put; this is the pattern in the Eurasian Sparrowhawk, the Eurasian Buzzard and the Northern Goshawk. Sometimes there is also segregation between adults and younger birds in the winter quarters, for instance in the Steppe and Lesser Spotted Eagles in East Africa. In the Western Marsh-harrier, the proportion of adult males present in winter decreases markedly with decreasing latitude.

Adult raptors usually show high fidelity to their breeding sites, and immature birds too demonstrate a strong tendency to settle in the same area, or to disperse over relatively short distances, often within less than 100 km from the natal area in most temperate species. Many incidental observations suggest that they may present similar fidelity to their wintering areas

year after year. This has been clearly demonstrated in marked adult Bald Eagles. The rate of return to the same territory or nest-site is positively correlated with previous breeding success, as is known for Eurasian Sparrowhawks, Eurasian Buzzards and Golden Eagles in Europe, and it may be equally associated with food conditions.

Relationship with Man

The attitude towards raptors of most, if not all, ancient civilizations and present day tribal populations throughout the world was, or still is, either neutral or rather positive. Only in modern societies has it been hostile.

In Ancient Egypt, a falcon was a god, and some hawks were also portrayed with religious significations; indeed, raptor representations abound on bas-reliefs in the temples and tombs of that civilization. Eagles and vultures figured prominently in the Aztec and Maya cultures, and both divinities and kings were represented with an eagle's head. Eagles were also present as emblems of power in old Chinese dynasties. Accounts and references to raptors are plentiful in the Bible, as well as in Greek mythology, and countless citations in the literature of the last centuries serve as reminders both of the old traditions themselves and also of the persistence of these old beliefs in the religious or cultural significance of raptors. Eagles were the emblems of the Roman legions, and, up to the twentieth century, of emperors and czars. They have been chosen as the national emblems of countries, such as Poland and the USA, by the German Reich and by European armies.

In Australian aboriginal and other primitive cultures, raptors were considered as totem symbols, and they featured in religious rituals and legends. Bald Eagle and Golden Eagle feathers were used by most Indian tribes throughout North America in decorative head-dresses and armbands. Alongside

Some accipitrids, especially the smaller species, tend to build a new nest each year, and in such cases the structure tends to remain relatively small. The basic nest design is a stick platform with a central cup, which may or may not be lined with softer materials. The Grey-faced Buzzard builds a fairly small nest of twigs and sometimes sedges, and lines it with pieces of bark, grass and green leaves. In this species, as in many others, fresh sprigs of green leaves can be added throughout the breeding attempt; the purpose of this behaviour is not clear, but one of the many suggestions is that it may help to camouflage the eggs and young.

[*Butastur indicus*,
Russian Far East.
Photo: Yuri Shibnev]

the more colourful feathers of parrots, macaws or birds of paradise, eagles' feathers, in particular, are still used in various ornamental dresses for religious occasions or hostilities. They are also used in arrows, by some of the forest-dwelling native tribes of South America and New Guinea. In the past, Indians of the Xingu (Mato Grosso) would keep a Harpy Eagle in captivity, as a periodical source of feathers, and Indians in French Guiana rarely miss an opportunity to kill Harpy Eagles or other rain forest eagles, mainly for their feathers. The frequent use of eagles and other large raptors in modern publicity is a proof that they have not yet lost their symbolic power in popular traditions.

Different body parts of vultures and other raptors, from eyes, or whole heads, to feet, feathers and bones, are still used in traditional medicine or sorcery by healers and witchdoctors in many parts of Africa, from Senegal to Ethiopia and South Africa, and also in the Caribbean. Traditional Chinese and other oriental medicines sometimes make use of raptors. Buddhists in Tibet allow Himalayan Griffons and Bearded Vultures to dispose of human corpses, and these are intentionally exposed on rocks near the villages. Parsees in India follow a similar religious custom, and leave their dead at the tops of special towers for ecological disposal by Red-headed and Indian White-backed Vultures.

Falconry has been one of the most intense relationships between man and raptors. Although mainly falcons (Falconidae) are involved in this sport, sparrowhawks, goshawks and eagles are also used regularly. Falconry originated in Asia, maybe in India and China as early as 2000 BC, and probably at first as a method of hunting for food. It is illustrated on an Assyrian bas-relief dated to 722 BC. It was already practised in the first centuries AD almost throughout Asia, from Persia to Japan, and it flourished in the feudal societies of Europe and the Middle East between AD 500 and 1600. It was then often a part of everyday life, not only for the nobility and the gentry, but also for the middle classes, who hunted with "second-rank"

species, including Eurasian Sparrowhawks and Northern Goshawks. Many kings, czars and emperors in Europe, as well as Arab sheikhs, Indian maharajahs, Mongolian khans and Japanese shoguns were all avid falconers, and the tradition is kept alive today by a few thousand dedicated people in Europe, North America and Japan.

However, only in Arabia does falconry remain an institution, with all the state and passion of the royal courts of old times. Nevertheless, it is still used traditionally in central Asia, from Iran to Mongolia, for hunting hares, gazelles, foxes and wolves with Eastern Imperial and Golden Eagles. Similarly, in eastern Turkey and northern Tunisia, at Cap Bon, large numbers of Eurasian Sparrowhawks are trapped during their migration in early spring, then quickly trained and used to hunt quails that pass through later in the season. They were formerly released after the quail hunting period was over, but many are now retained in captivity, because migrants are becoming much less numerous than before.

In the past, when falconry was mostly reserved for fairly few, high ranking people, in order to assure an abundant supply of birds for these falconers, several raptor species received strict protection. Today, despite the development of captive breeding, and the involvement of many falconers in raptor conservation, nest robbing and the trade to provide raptors to inexperienced or unscrupulous falconers is locally a severe additional cause of loss for some raptor populations. On the other hand, escaped birds sometimes settle successfully in the wild, and the breeding population of Northern Goshawks in Great Britain, that was once considered extinct, is said to have been re-established from birds originating from falconry. Accipitrids used today in Europe and North America are mostly Northern Goshawks and, to a much lesser extent, Eurasian Sparrowhawks and Golden Eagles. Occasionally, some other species may be trained, and Harris's Hawk has now become a popular species with falconers in the USA. Quails, partridges, pheasants, rabbits and hares

Given the considerable variation in body size within this family, it is not surprising that there is also a fair degree of variety in clutch size, and while most of the large species lay only one or two eggs, the smallest accipiters and the harriers can lay five or six. The Eurasian Sparrowhawk, probably the best known member of the family, normally lays three to six eggs at intervals of two to three days; up to five chicks can eventually be raised to fledging. If its eggs are lost or destroyed, this species is capable of laying a smaller replacement clutch once or even twice during the same season.

[*Accipiter nisus*.
Photo: B. Speake/Aquila]

are the most favoured game. For the large-scale expeditions that Arab falconers still mount to hunt bustards in North Africa and Pakistan, it is almost exclusively falcons that are used.

The unprecedented reverence offered to raptors through falconry in Europe's Middle Ages was suddenly and dramatically replaced towards the end of the eighteenth century by an obsession, at least as strong, to destroy these same birds which were soon to be labelled "vermin"! This change in human attitudes towards raptors occurred as early as the sixteenth century in parts of England, and overseas emigrants carried with them this new and hostile approach to predators. Prior to this, they had mostly been regarded with indifference, and had been eliminated only locally, when they did persistent damage to free-range poultry, which is still the way they are treated today in many Third World countries. But now they were regarded as enemies, because of their supposed competition with human interests. With the changes in people's ways of thinking, they were also increasingly considered as rapacious and cruel beings; few people knew them enough to admire their beauty or to appreciate their usefulness. Human hunting pressure mounted rapidly, and economic concern led to an increase in the value placed on, and consequently the artificial management of, game populations; at the same time, livestock farming was intensified. Any apparent damage to small game, chickens or lambs became intolerable for many people. The potential benefits brought about by the predatory activities of raptors, such as their controlling of agricultural pests, checking the spread of diseases, and maintaining the balance in nature, were ignored or thought greatly to underweigh their grossly exaggerated or misinterpreted depredations.

Systematic, indiscriminate persecution of raptors was undertaken mainly by hunters, gamekeepers and locally by farmers,

in the belief that this was the only way to prevent the predation of hawks and eagles on lambs, poultry and game species. Persecution was officially encouraged in many countries by the payment of bounties by state or local authorities, and also by land owners, for every "pest" killed. The supposed merits of this widespread policy were so unanimously accepted that even the first people to call for the protection of birds and the ornithologists of the early twentieth century still did not oppose this attitude. Destruction peaked between 1860 and 1960, but then, between 1960 and 1980, birds of prey became partly or totally protected in most developed countries. This legal protection did not completely halt the persecution, especially amongst a significant proportion of hunters who still oppose the official bans and continue to shoot, trap or poison hundreds of raptors even in countries with highly developed conservation movements, such as Britain, France and the USA. Even in northern Scandinavia, eagles and their nests are still destroyed because the birds are blamed for killing young reindeer.

The magnitude of the slaughter sometimes defies the imagination. Considering only the rewards paid for birds actually recovered and officially reported, 88,476 Golden Eagles and White-tailed Sea-eagles, as well as 135,000 other raptors, were killed in Norway alone during the second half of the nineteenth century. Similar huge numbers were eliminated elsewhere, including 128,273 Bald Eagles killed in Alaska in the period 1917-1952, and 147,237 Wedge-tailed Eagles (*Aquila audax*) destroyed between 1928 and 1968, in Western Australia alone. In a relatively small country like Austria, 15,000-22,000 raptors per year were still officially killed between 1948 and 1968. There is a good deal of solid evidence to show that between 1950 and 1970 several million raptors were killed in Europe by hunters and gamekeepers, at a time when numbers had

already been drastically reduced by pesticides. Some species are not yet protected locally, and in Finland, for instance, about 6000 Northern Goshawks are still killed annually by the hunting community.

This persecution led to dramatic declines or even the local extermination of some species over large areas, even before the Second World War. The decline first became apparent from the decreasing numbers of rewards paid. It was especially noticeable for eagles, but such relatively common species as the Red Kite, the Eurasian Buzzard or the Northern Goshawk disappeared from large parts of Britain, Denmark and the Netherlands. Further evidence for the strong influence of this persecution of raptor populations comes from their marked increases, notably in Western Europe, first during the two World Wars, when few gamekeepers remained active, and then later when birds of prey were finally protected in the 1970's. The reduction of population levels also affected their age structure and breeding success. The increased occurrence of birds in immature plumage among breeding pairs of Golden Eagles in Scotland, White-tailed Sea-eagles in Norway or Spanish Imperial Eagles in southern Spain was correlated with the reduction of surplus adult birds and intraspecific competition. Decades of persistent shooting also affected the behaviour of species, and they became much less tame than they are naturally in areas with little or no hunting. This wariness often prevents them from using otherwise suitable habitats that are too close to human habitation or activities.

The most widely used methods of killing included shooting, trapping and poisoning. Raptors were shot anywhere, but particularly destructive methods involved shooting birds at the nest, or from a hide near a live, or mounted, Eurasian Eagle-owl (*Bubo bubo*), a very effective way of attracting birds of prey that come to mob the owl. Thousands of raptors are still shot or caught in nets in southern Europe when they attack the live decoys of the numerous trappers of passerine migrants. Pole traps set in the open were extremely deadly, but their use, now

legally prohibited, has fortunately become marginal. Leg traps placed on the nest, or on a small mound in treeless tundra, or baited with a carcass, are still widely used, even if they are not always primarily intended for raptors. The cage trap, with a live pigeon as a decoy, is a favourite trapping method in Germany and Scandinavia, where it is used to take Northern Goshawks. Shooting eagles from cars along roads, or from aeroplanes, was also widely practised in North America and Australia. The poisoning of carcasses is a widespread cause of mortality among scavengers, such as vultures, eagles, buzzards and kites, even though they themselves are not always the prime targets; strychnine and 1080 (Sodium monofluoroacetate) are among the notoriously infamous products that have frequently been used.

If gamekeepers and shepherds have been, and still are locally, responsible for some of the most serious persecution of raptors, this does not, by any means, account for all of the persecution that these birds have suffered. Shooting for fun at particular points where migrants concentrate is a hobby practised on a large scale. The well known story of Hawk Mountain in Pennsylvania, USA, must be cited. Migrant hawks were regularly slaughtered there in autumn, but the site became a focal point for raptor conservation in the USA, and then an important tool for research and education. Other black points still exist, where tens of thousands of raptors are killed every year, notably in Europe in the Straits of Messina, on Malta, in Lebanon, and along the east coast of the Black Sea. Birds were formerly killed, and still are to some extent, for food, and fat migrants, especially Western Honey-buzzards have been considered a delicacy. Raptors were also used as food for Eurasian Sparrowhawks, themselves caught in large numbers, notably in Turkey and Tunisia, to be trained for quail hunting. Similar large-scale trapping and shooting, mainly for food, occurs in Taiwan and the Philippines, primarily affecting Grey-faced Buzzards. Many migrants are also killed in China for use in traditional cuisine.

Incubation is usually carried out mostly, or entirely, by the female, and males often lack the median brood patch found in females. When the male does actually take an active share of the incubation duties, he nonetheless almost always leaves the female to take the overnight spell. Incubation usually starts with the laying of the first or the second egg, and can last anything from about 28 days in fairly small species, such as the Australian Black-shouldered Kite, to about 60 days in some of the large vultures.

Ardea]

Egg-collecting, which was a highly respectable occupation for more than a century, is now dying out, but it has accounted for thousands of raptor clutches. Sometimes the incubating female and the alarmed male were shot together, just so that the collector could check the identification of the eggs with greater certainty! Today, disturbance of nests or nesting activities by forestry activities, road building, cross-country vehicles, recreation, cliff climbing and hang-gliding, as well as low-flying aircraft and military exercises, bird photographers and many other kinds of human-related disturbances, almost certainly cause a considerably greater loss of broods than the old-fashioned egg-collecting ever did. Predators take advantage of nests left unguarded by disturbed females. The sensitivity of breeding raptors to disturbance is intensified by their shyness, induced by decades of heavy persecution. The sprouting

up of holiday cottages in many previously undisturbed areas, in conjunction with the promotion of camping, boating and fishing, means that raptor habitats are steadily encroached upon, and few species can readily adapt to this invasion of their habitats. Bald Eagles and White-tailed Sea-eagles are amongst the species most notoriously affected, and most prone to nest desertion. Nest disturbance increases the expenditure of both time and energy in adults, reduces the level of parental care, and affects the nutritional condition of nestlings.

Trade is also locally of great concern. In Europe and North America the trade is mostly limited to providing zoos, exhibitions and falconers, but in Latin America, pet or stuffed raptors are sought by many people as decorations for their homes. The situation is even worse in south-east and eastern Asia, from Indonesia to China and Japan, where birds of prey are much

On hatching, the semi-altricial chick is covered in a thick coat of down. It can clamber about the nest with the aid of its stunted wings, but can scarcely support the weight of its big head; however, it can already see. During the early days it is brooded, almost invariably by the female, to help it combat the intemperances of the climate, such as rain, or excessive heat or cold. The Square-tailed Kite's chick remains in the nest for about two months.

[*Lophoictinia isura*, Australia.
Photo: Michael Morcombe/
NHPA]

The roles of the sexes during breeding are usually quite different, especially in the more aggressive predators. At first, the female remains on the nest most of the time, brooding and guarding the chick or chicks, while the male faces the onerous task of supplying food for both the female and the chicks; he tends to deliver the prey to the female, and she feeds the chicks. About half way through the fledging period, the youngsters are large enough to be left alone, and the female's help is required in order to meet the ever-increasing demand for food. The female Black-breasted Snake-eagle remains with her chick most of the time during 28 days or so, after which time both adults spend long periods hunting and both may feed the chick.

[*Circaetus pectoralis*.

prized, not only as pets or as stuffed birds, but also for food and medicine. The scale of the uncontrolled trade within and between Asian countries is little known at present, but there are certainly some cases in which it constitutes a serious problem.

Status and Conservation

Outside human spheres of influence, raptor populations are usually highly stable. Long-term studies of territorial species show that resident populations vary by no more than 15% of their mean level over many years, even though there is higher variability in the breeding success and overall production of individuals; these results have been found in studies of the Golden and Verreaux's Eagles, the Eurasian Sparrowhawk and the Eurasian Buzzard. Experimental studies provide much evidence that this stability comes from the limitation of density by territorial behaviour, the quality and reliability of the food supply, the availability of nest-sites, and the buffering surplus population of non-breeders. As long as their habitat remained unchanged, whole communities studied in Germany, France, the USA and Kenya retained similar overall population densities and species composition for many years. When populations have been reduced for any reason, they are usually able to recover to about the same levels as previously. Thus, any wide fluctuation in the number of breeding birds is a warning that some unnatural factor may be involved, and that careful research must be undertaken to identify it.

Raptors can play an important part in general conservation strategies for a number of reasons. First, they can take on the role of "umbrella" species, because of their large home ranges, which encompass larger populations of most other species. Second, they are "flagship" species, that are very suitable for arousing public interest and support. Third, they are sensitive bioindicators of environmental changes, particularly in terms

of habitat quality and pollution; they are already used to help monitor forest degradation in the tropics. Finally, their biological role as top predators may be critical for the balance and functioning of ecosystems. Their predation pressure may contribute to the maintenance of high species diversity, by reducing the numbers of dominant prey species, and thus allowing marginal species to survive.

Overall, the worldwide situation of this family is not encouraging. Indeed, the status of few species can be considered well known, and we can give a reliable world population estimate for no more than 20 species (8%), most of them inhabiting temperate zones. From the very scant information available on their past abundance, it appears that many of them had much higher populations one or two centuries ago, and that they are still globally decreasing, if only because of habitat loss. Very few species are actually increasing. Some species may undergo range expansions, but their densities within the range do not increase: the Common Black-shouldered Kite having colonized parts of the Iberian Peninsula, is now spreading towards southern France; the White-tailed Kite is similarly expanding in North and Central America.

A species may increase locally but not elsewhere: the Spanish and French breeding populations of Eurasian Griffons have increased more than fivefold in recent decades, but this may merely be a recovery following protection, and in the meantime other populations are vanishing, for instance in the Balkans and the Middle East. A similar, probably related, increase of Eurasian Black Vultures occurred in Spain, which now holds up to 900-1000 breeding pairs, with a twofold increase over the last five years, but again the species is disappearing from the Balkans and the Middle East, and it is already extinct in several countries. The Eurasian Sparrowhawk and the Northern Goshawk are also recovering, sometimes spectacularly, from recent population crashes in Western Europe, but the eastern population that migrates through Tunisia has declined enormously since World War II.

During the first three weeks of the nestling period, the male of the Pale Chanting-goshawk has to meet all the food requirements of the female and young, in addition to his own. He does not usually visit the nest, but simply leaves the prey for the female to pick up and deal with. She will first feed herself and then pass on food to the young. Although this species regularly lays two eggs, the younger chick normally perishes just a few days after hatching.

[*Melierax canorus*.
Photo: Peter Steyn/Ardea]

Some apparent increases may be only the result of improved knowledge: over 150,000 Lesser Spotted Eagles were tallied during autumn counts of migrants in Israel, when the species was previously thought to number only a few thousand pairs. Because of human-related habitat changes, some species increase numerically, but without expanding their ranges. For instance the Crested Serpent-eagle, the Changeable Hawk-eagle (*Spizaetus cirrhatus*) and the Roadside Hawk, all tropical species of the forest edge and open woodlands, benefit from deforestation, and they are certainly much more widespread and abundant in partially cleared and cultivated areas than they are in primary forest. Hen and Montagu's Harriers probably augmented their ranges and numbers in Europe during the large-scale deforestation of the Middle Ages. Tree planting and the erection of windbreaks in the Great Plains of North America have allowed the spread of species that nest in trees, as have *Eucalyptus* plantations in open areas of South Africa.

Fortunately, at least 50 species throughout the world may be considered globally stable, or even locally increasing, or recovering. Nevertheless, it is difficult to imagine how large their populations were in the past. Many descriptions of various authors from the sixteenth century to the nineteenth suggest massive declines in European populations, in the number of migrants at the Bosphorus, in Egypt, Syria, India and other countries. Sharply declining populations and shrinking distributions are somewhat better documented. A total of 37 species are currently listed as threatened by ICBP/BirdLife International. However, these include species with widely different population sizes, conservation problems and levels of threat.

Several Palearctic species have undergone huge declines in both numbers and breeding distribution. For instance, the Red Kite still occupies most of the countries in which it has been known to breed, but its current estimated total population of 10,000-15,000 pairs is probably a tiny fraction of its former numbers. The White-tailed Sea-eagle is still distributed from Greenland to Kamchatka and south to Algeria, and it may number several thousand pairs, but it has disappeared from large areas within this vast range, especially in western and

southern parts of Europe, and the large, undisturbed wetlands with which it is associated are among the most threatened habitats today. By way of comparison, the Madagascar Fish-eagle (*Haliaeetus vociferoides*), with about 50-100 pairs, may still retain a more substantial fraction of its former population, but, nonetheless, a population which is more fragile, because of its very small size and limited range.

A very patchy distribution, and a low density over a large range with little protection should not be considered a more secure situation than a hundred pairs in a relatively small area, but with higher densities, a good level of monitoring and pertinent conservation measures; such a comparison can be made between the status of the Eastern Imperial Eagle, which ranges from central Europe to western China, and the Spanish Imperial Eagle, endemic to the Iberian Peninsula. A restricted distribution may, in itself, be a great threat when it is associated with moderate density, a patchy distribution and habitat loss, as is the case of the Kinabalu Serpent-eagle of northern Borneo. In contrast to this species, the Andaman Serpent-eagle (*Spilornis elgini*), a congener with a comparable range comprising merely the Andaman Islands, occurs at surprisingly high densities over most of the archipelago, as is often the case with birds of small islands; it may easily number several hundred pairs, a much higher figure than the total population estimated for the threatened Kinabalu Serpent-eagle.

Different populations or subspecies may also have widely divergent status. For example, the nominate race of the Bald Eagle, which breeds in the southern USA, has declined dramatically during the last 150 years, and it is now much smaller than that of the northern race *washingtoniensis* that breeds in Alaska and Canada. The Hook-billed Kite is unevenly distributed and sometimes rare, but it ranges all over Neotropical rain forests. However, its island races *wilsonii* and *mirus*, endemic to Cuba and Grenada respectively, both have extremely small populations which are endangered.

Maybe the most serious concern lies in the tropical rain forests. A total of 109 species of Accipitridae (46% of the world total) are closely associated with dense, wet tropical forests, and at least 40 of these species should probably be considered

Many species are unable to rear more than one chick, even though they may lay a second egg, as a form of insurance policy. The weaker chick, usually from the second, later-hatched egg, is likely to die of starvation after only a few days, but in some cases it is actually killed by its sibling. The reduction of the brood to one means that there is a better chance of the single chick surviving to fledge successfully. Wahlberg's Eagle normally only lays one egg, but on the rare occasions when two are laid, the elder chick invariably kills its younger sibling.

[*Aquila wahlbergi*,
South Africa.

threatened. The richest tropical forest genera are *Accipiter* with 37 species, *Leucopternis* with 10 species, and *Spizaetus* with 9 species. The current status, ecology and population trends of most of these species are extremely poorly known and inclusions on the Red List of threatened taxa are likely to be very conservative. Moreover, some species, mostly from India to the Philippines and the Solomons, have island populations of relatively restricted range, and numerous well differentiated subspecies, some of which may prove to be full species. The raptor species considered to be the most severely endangered are all tropical forest species: the Madagascar Serpent-eagle, recently rediscovered in north-eastern Madagascar; the Great Philippine Eagle and the Javan Hawk-eagle (*Spizaetus bartelsi*), both of them thought to number roughly 50 pairs, surviving at widely scattered localities; the White-collared Kite (*Leptodon forbesi*) of north-eastern Brazil, only recently confirmed as a valid species; and Gundlach's Hawk (*Accipiter gundlachi*) of Cuba, which is thought to number about 150-200 pairs.

It must be also remembered that the early colonization of many islands by man, well before their discovery by European explorers, resulted in waves of bird species extinctions. In New Zealand, New Caledonia, Hawaii and Reunion, just to mention a few examples, at least seven raptor species are known in subfossil form, and all of them disappeared in the wake of human occupation of their habitats, well into historical times. Among them was the largest eagle known, Haast's Eagle (*Harpagornis moorei*) of New Zealand, which preyed upon the large flightless moas, and disappeared with them, perhaps less than 1000 years ago.

Historically, human persecution has been the most prominent factor in the declines of different raptors (see Relationship with Man). Farmers and hunters, hoping to reduce losses of livestock and game species by the systematic elimination of predators, were powerful agents in the decline of many raptors. However, legal protection of most, if not all, raptors has now been adopted in almost all developed countries, and, as a result of protective measures, deliberate killing has been greatly reduced in recent years in Europe and North America. Nevertheless, ringing recoveries have shown that shooting,

trapping and poisoning, though illegal in most cases, are still significant causes of mortality among raptors in many temperate areas, and legal protection, where it exists, is poorly enforced in Mediterranean and Arab countries. In most inter-tropical regions, raptors tend to be ignored both by law and by the public, but they are killed fairly often for fun, food or feathers, or when attacking poultry. A general trend towards official protection comes from changing attitudes, a better appreciation of the role of predators and a growing concern about the loss of biodiversity.

Poisoning is still widespread, sometimes deliberate, but most often incidental, arising from poisoned baits or carcasses intended for other predators. Vulture populations have particularly suffered from this type of accidental poisoning, and have been virtually eliminated in Greece, the former Yugoslavia, Romania and South Africa.

Pesticides constitute another major issue, one which has been extensively publicized. In the 1950's, the rapidly increasing use of DDT and other persistent organochlorines to control agricultural pests and mosquitoes, or in seed dressings, resulted in the extensive poisoning of insectivorous and granivorous birds, and consequently of their predators. Raptor breeding success was severely affected. Besides cases of acute poisoning and direct mortality, pesticide contamination and the magnification of residues up the food chain, resulted in the accumulation of sub-lethal levels of chemicals, and in the breeding failure of raptors through eggshell thinning, egg breakage and embryo deaths. This led, in turn, to widespread and serious population declines. One of the best examples among the Accipitridae is that of the Eurasian Sparrowhawk, which was very common in Europe, but which almost disappeared from intensively cultivated areas, notably in England and the Netherlands. Its already considerably reduced breeding success was probably further exacerbated by extra mortality, associated with the substantial use of cyclodienes in seed dressings. The species reached its lowest population levels in the early 1960's, but recovered spectacularly, at least in some Western European countries, after the progressive ban of most organochlorines from the late 1960's onwards. These pesticides

are still manufactured and used in developing countries, where temperate migrants, on their wintering grounds, are known to become contaminated.

Many other pollutants, including toxic industrial waste, still affect raptors, at any rate in industrialized or intensively cultivated areas, and significant concentrations of such pollutants may be found locally in individual hawks or eagles; pesticide residues are still found in the tissues of most raptors collected, even sometimes in apparently remote areas of Africa or South America. Polychlorinated biphenyls, or PCB's, are particularly widespread. Heavy metals, such as lead, mercury and cadmium, kill or incapacitate raptors when they reach high concentrations in prey species. Lead poisoning is a significant cause of mortality in Bald Eagles and probably in some populations of Western Marsh-harriers, as both of these species feed extensively on dead or wounded waterbirds that have been shot by hunters, and from which they ingest lead pellets. Organophosphates (formerly parathion, now fenthion) that are used for killing granivorous birds, notably in Africa, often kill huge numbers of raptors, when they concentrate around the roosts or breeding colonies that have been sprayed. Long after the spraying operations, raptors still feed on the highly tempting sick or dying birds. Mass mortality has been reported on numerous occasions after large-scale treatment with highly toxic

rodenticides, such as zinc or thallium sulphates, used in Israel, Malaysia and West Africa. Still now, the widespread application of dicoumarin and other anticoagulants also causes the death of a significant number of kites and buzzards. Molluscicides, used in rice fields, have also killed many Snail Kites, at any rate in Surinam.

Other human-related forms of mortality include electrocution on pylons and collisions with electric powerlines. The importance of both of these as significant factors in overall mortality was long unsuspected, but it now appears to be serious in many areas. For instance, at least 15% of the young Bonelli's Eagles fledged in southern France are found dead under powerlines in their first year. Many raptors are killed by cars, usually when they are attracted onto roads by carrion or voles. Accidents causing injury during the pursuit of prey form a natural cause of mortality, especially among young, inexperienced birds. Many buildings, or other human structures, offer the added risk of collisions, entanglement, drowning in tanks, and so on; for instance, crashing into window panes is a significant cause of mortality for Eurasian Sparrowhawks in some suburban residential areas, as it is for a surprising number of their avian prey.

It is difficult to assess the real impact of direct persecution, poisoning, pesticides, electrocution, collisions and other

The chicks of the Australasian Goshawk hatch with a covering of white down. The first contour feathers are acquired at about two weeks old, and by three weeks old the birds are extensively feathered, although at this stage they are still unable to feed on their own. The complete fledging period in this species ranges from about four to five weeks, after which the young remain dependent on their parents for another five or six weeks.

[*Accipiter fasciatus*, Australia.
Photo: Hans & Judy Beste/Ardea]

human-related mortality, compared with natural mortality rates due to starvation, predation, disease and so on. Although detailed demographic studies have rarely been performed, a simple glance at proportions amongst recorded causes of deaths indicates that man-induced mortality is often dominant in densely populated and cultivated areas. The spectacular recoveries of the Eurasian Sparrowhawk and the Eurasian Buzzard in Western Europe, after the banning, but not the complete elimination, of pesticides and shooting, also show how much these factors were limiting their populations.

Today, and in the long term, the major problems faced by raptors in most parts of the world are the loss, degradation and fragmentation of their habitats, and the associated decrease in quantity and quality of hunting areas, nesting sites and food supplies. Extensive modifications of the landscape have occurred since the beginning of agriculture and early deforestation, but they are now changing the whole face of most countries, far more than ever before, at the same time creating new habitats, thereby eliminating many species, while favouring only a few others. For instance, intensive agriculture, driven on by drastic international policies, is rapidly eliminating the grassland, hedges, woodland, orchards and fallow fields, where passerine birds, rodents, insects and other favoured prey used to thrive. The carrying capacity of the new,

open fields is dramatically reduced, as is the mean density of the breeding populations of raptors traditionally associated with those habitats, such as the Eurasian Sparrowhawk and the Eurasian Buzzard in Europe. Although these two species have recovered well after the pesticide and persecution eras, they have been much more successful in diversified and well wooded areas, where the carrying capacity of the habitat is still much the same as it used to be.

The extensive afforestation of Scottish moorlands with dense, uniform, monospecific pine plantations is said to be detrimental to the Golden Eagle, and, at a later stage, to the Hen Harrier. The drainage of wetlands, which has accelerated in recent decades, has been an important cause of the decline of harriers everywhere, of Bald Eagles in the USA, and of White-tailed Sea-eagles in Europe. Large-scale agricultural schemes in Kazakhstan, in the south of the former Soviet Union, have eliminated or highly disturbed huge areas of steppes that were the breeding habitat of the Pallid Harrier and the Steppe Eagle. Modern forestry often impoverishes the forest fauna and may reduce the density of prey for forest raptors, and ultimately their own density, due to the resultant increase in mean territory size; this is certainly the case in Northern Goshawks. Through increased disturbance and loss of prey, intensive silvicultural management of Central European forests

The chicks grow very quickly, and, once the wing and tail feathers have sprouted, the contour feathers of the body soon follow. The chicks are left alone for increasingly lengthy periods, and the adults' visits to the nest become steadily briefer, as the young birds are able to feed by themselves. They now start to exercise by flapping their wings vigorously on the nest, in preparation for their maiden flight. Young Spotted Harriers fledge at around 36-43 days old.

[*Circus assimilis*.
Photo: Hans & Judy
Beste/Ardea]

Steller's Sea-eagles fledge at about ten weeks old. Up to three eggs may be laid, but usually only one chick is reared, and overall annual average productivity is approximately one chick fledged for every two breeding pairs. A significant proportion of chicks die as a result of falls, either from the nest or with it.

[*Haliaeetus pelagicus*, Kamchatka.

Survival]

may lead to the local extinctions of Lesser Spotted and Eastern Imperial Eagles.

Finally, sprawling urbanization, industrialization and road construction are significant causes worldwide of almost total habitat loss. Among the Accipitridae, only some sparrowhawks and goshawks, in both tropical and temperate zones, as well as vultures and Black and Brahminy Kites, can adapt successfully to densely urbanized areas, and even these, only when enough large trees remain for nest-sites. Where birds are not molested, even large raptors may survive in surprisingly populous towns, for instance the White-bellied Sea-eagle in India and south-east Asia.

The widely publicized deforestation of the tropics is a major threat, and it may be the single most important problem for raptor conservation in the years to come, because of the large number of species it affects. Three detrimental factors are operating, often concurrently. First, deforestation itself involves the conversion of forests to open, cultivated habitats or tree plantations, where very few species can survive. The second factor is the disturbance or degradation of the forest cover through logging, firewood collection, forest management or agroforestry, road building, and the shifting cultivation of indigenous people. Detailed studies in the Neotropics, Africa and south-east Asia have all shown that some primary forest raptor specialists are unable to withstand a high level of disturbance, and soon disappear. Other species have a wider range of tolerance and can survive, at least locally. Another category of species, inhabiting natural gaps and forest edge, are favoured by the openings created, and actually increase in logged or secondary forest and in clearings. Thus, the overall result of degradation is a loss of some species, and a change in the relative numbers of the remaining species. The third component of deforestation is the fragmentation of forest tracts, which threatens the survival of small, isolated populations, which cease to be viable. Species adapted to living within the dense rain forest have proved very reluctant to cross open spaces

between small patches of forest, and they are thus among the least likely to survive. Even hunting pressure alone may eliminate large forest eagles, such as the Harpy Eagle and the Guiana Crested Eagle, in tropical America, probably by lowering prey density below a critical level, and also because of the occasional killing of the eagles themselves.

In the face of such a wide variety of threats, conservationists are using a no less wide array of methods and programmes to slow up the decline of raptor populations. Very active international or national organizations, and also local associations, usually with more enthusiasm than money, are now working in most countries.

In view of the importance of direct persecution, improving and enforcing the protective legislation is still one of the main aims of organizations devoted to raptor protection. The education of the public, to dispel popular misconceptions, through pamphlets, conferences, museum exhibitions and sometimes live displays of raptors in zoos, or demonstrations by falconers, are also an integral part of these activities. It is also essential for such groups to reduce incidental threats of human origin, for instance by fitting up powerlines so as to reduce the risk of electrocution, and also to campaign for restrictions in the use of pesticides, poisons, lead shot and other environmentally damaging substances. More biologically orientated interventions include habitat management, brood manipulation, reintroductions, artificial feeding and population monitoring.

Landscape ecology, metapopulation dynamics and conservation biology provide general rules for maintaining high biodiversity, and rare or patchily distributed species like raptors, on a regional scale. The study of species ecology and minimum viable population size has provided guidelines for the designation of protected areas of suitable size. The conservation of viable populations of all 21 species of true rain forest accipitrids that breed in French Guiana would require the preservation of a continuous tract of undisturbed primary forest of at least 1 million hectares, and preferably much more. Complex

The fates of large numbers of harrier clutches, especially in Western Europe, are tied closely to man's agricultural practices, because several species normally nest in fields of cereals. With the large-scale mechanization and intensification of agriculture, the whole process of the harvest has changed radically: for example, in many areas harvesting now occurs much earlier in the year, some time before the harriers' young have had time to fledge; similarly, a process that formerly took a team of labourers several days to complete is now polished off in a few hours by machines that do not see the nest they are on the point of destroying. In order to combat these problems, many bands of volunteers search out the nests and, often with the assistance and collaboration of farmers, work out various different ways of saving the nests and their contents, without undue disruption to the farmers' interests. Montagu's Harrier is one of the species most seriously affected by the modernization of agriculture.

[*Circus pygargus*.

NHPA]

networks of forest patches linked by forest corridors have been proposed in Australia and North America, where large continuous areas of natural habitat are no longer available.

On a more local scale, conservation plans often include a zoning of recreational activities to reduce disturbance in areas critical for the breeding of eagles, for example restrictions on fishing and boating in nesting areas of the Bald Eagle. The elimination of shrub encroachment followed by grazing by sheep, to maintain open grasslands, has been successfully used to improve the hunting habitat of Bonelli's Eagle in southern

France. Promoting more natural forestry policies, and leaving undisturbed areas around nesting trees, during logging operations, has helped to maintain pairs of Bald Eagles or White-tailed Sea-eagles. Providing safe nest-sites and keeping stretches of water open have been instrumental in the recovery of the Snail Kite in Florida. Controlling agricultural development, cattle ranching and military training activities on range lands in Idaho have been critical in the management of the rich breeding community of raptors of the Snake River Valley. Planting hedges and woods and leaving patches of fallow land amidst the vast cultivated croplands of North America have increased the distribution and density of several species of raptors. The construction of large reservoirs has created many new breeding or wintering habitats for Black and Brahminy Kites, Bald Eagles, sea-eagles, and fishing-eagles among others. Finally, management of powerlines, by providing platforms on pylons or alternative nest-sites nearby, has allowed eagles in western North America and also in South Africa to colonize treeless plains.

Habitat management often improves prey diversity and density, but direct feeding is also used to reduce winter mortality, or to provide uncontaminated food, for instance for the White-tailed Sea-eagle in Sweden. Providing carcasses for vultures has been extremely successful in Europe and South Africa. These "vulture restaurants" are also used for ecotourism and education, as well as to reduce the risks of shooting and poisoning, by attracting vultures into safe areas. Feeding previously unsuccessful pairs of Bonelli's Eagles and Egyptian Vultures in southern France has spectacularly increased their breeding performances, thus demonstrating how a scarce food supply was limiting their breeding success.

The unintentional introduction of rats, mice, rabbits, sparrows and starlings to Australia and North America has provided abundant food sources for several raptor species and has led to an increase of the populations involved. The fact that domestic pigeons or released pheasants appear very attractive to Northern Goshawks in Europe, probably increases the survival rate of immature birds, but is, at the same time, perhaps the cause of their persecution by pigeon-fanciers and gamekeepers, despite official protection. Scavenging raptors in many tropical towns, and formerly in Europe, obviously

Very little is known about the Semiplumbeous Hawk, which inhabits humid forests from Honduras south to north-west Ecuador. Its current listing as a near-threatened species is more a reflection of this absence of hard data, rather than of any decline. The species is fairly common in parts of Colombia, where it is also known to occur in mature second growth.

[*Leucopternis semiplumbea*, Tortuguero National Park, Costa Rica.
Photo: William Grenfell]

Formerly more widespread in Spain and also occurring west into Portugal and south into Morocco, the Spanish Imperial Eagle has declined considerably over the last 80 years, to become one of the rarest of all raptors, now numbering only about 150 pairs. It is currently the object of a major conservation campaign, which aims to increase the extent of its habitat under protection and reduce the alarming amount of mortality caused, often indirectly and accidentally, by humans. A captive breeding programme has recently been launched.

[*Aquila adalberti*.
Photo: José Luis González Grande/
Bruce Coleman]

The Black Harrier, a species that breeds only in South Africa, is currently considered near-threatened. Within its specialized fynbos breeding habitat it is still widespread and locally common, but this habitat type is already fairly restricted and it has been severely degraded. The species will also breed in fields of cereals, but here it faces the additional threat of contamination from pesticides.

[*Circus maurus*,
Stanford, Cape Province,
South Africa.

benefit from the superfluity of rubbish, offal from slaughterhouses and excrement, but these species disappear rapidly when hygiene and urban sanitation improve. Similarly, a crash in the population of a prey type, such as that due to myxomatosis in Europe, may result in a substantial decrease in rabbit predators. The rarefaction of swarming locusts in the Sahel zone of Africa, after many years of systematic spraying operations, has probably been influential in the decline of the Montagu's Harriers that used to exploit this superabundant resource in their winter quarters.

The settlement of breeding populations of some raptors in urban or suburban areas is a recent phenomenon that may help the survival of the species involved. A growing number of cities in Europe, North America and Australia have significant populations of an increasing number of species. Sparrowhawks and even goshawks are the most frequent colonists, and they may reach high densities in the centre of large towns, for instance the Eurasian Sparrowhawk population studied in Prague, where breeding success was shown to be better than that of rural breeders. The Mississippi Kite, in south-eastern North America, has also now established several colonies in urbanized areas. Other highly artificial habitats are regularly exploited by some raptors, for instance the wide grassy embankments along highways, which are often much richer in rodents than the surrounding agricultural areas.

A wide variety of techniques have been used to prevent local extinctions, to halt declines, or to help species to recover. The permanent protection of nesting sites is not always feasible, and must be superseded by active nest guarding, to avoid disturbances, and to prevent eggs or chicks being stolen by collectors or falconers. In France, nearly 1300 volunteers watch over more than 1800 nests of threatened raptors each spring, to prevent human interference which can often cause the loss of whole broods. Safe artificial nest-sites are occasionally provided, mainly in reconstructed or rehabilitated ecosystems, for example sites for the Ferruginous Hawk in strip-mined areas of the north-western USA. A considerable proportion of harriers in Western Europe now breed in cereal fields, and consequently their nests are destroyed at harvest time, which usually arrives before the young have fledged. It is a time-consuming activity, for scores of volunteers, to locate the nests and shift them

before the harvest, or persuade the owner to maintain a patch of unharvested crops around the nest, or take out the nestlings and replace them after the harvest in the original nest, fenced off against potential predators; such dedicated steps are taken for over 1500 nests in France each year.

Brood manipulation is used to increase the productivity of several depleted populations. It was first used in Central Europe for the Lesser Spotted Eagle, as the chick that hatches second is always killed by its elder sibling. With the manipulation, the younger chick is removed just after hatching, placed in an active nest of a common foster species, for instance a Eurasian Buzzard, and then returned to its original nest 1-2 weeks before fledging, by which time sibling aggression is almost suppressed, and the adults may still accept the newcomer. The transfer of eggs from threatened clutches, from healthy populations, from captive birds, or from wild broods with abnormally low success, is another way of improving the breeding success of populations, when lack of food is not the limiting factor. Double-clutching, the removal for artificial incubation of the first clutch to induce a female to lay a second one, is used in captive pairs, and sometimes in the wild, in order to raise more young, and perhaps allow transfers.

An increasingly popular conservation measure is the reintroduction of a species to an area from which it had been previously eliminated, usually due to human persecution or pesticide contamination. Two main techniques of release are used. For solitary species, the most appropriate way is to put well grown nestlings on a specially prepared nest, and feed them until they are able to fend for themselves. This system was used to re-establish breeding populations of White-tailed Sea-eagles and Red Kites in Scotland, and also for Bald Eagles in several areas of the USA. Similar projects are under way with the aim of reintroducing the Bearded Vulture throughout the Alps, and the Eurasian Black Vulture in France. The same technique, or the release of birds already able to fly, is also used to strengthen small or declining populations, such as that of Eurasian Black Vultures on the Mediterranean island of Mallorca.

The most successful reintroduction project of any member of the Accipitridae has been that of the Eurasian Griffon in south-central France. It has been achieved by a technique

adapted to the highly social behaviour of this species. Birds were kept in aviaries at the site where they had last been known to breed, until they were released in groups of adults at the beginning of the courtship period. This minimized the risk of dispersal, and ensured that the birds would breed there, if anywhere, soon after release. From 1982 to 1986, altogether 61 birds were released. In 1993 the colony comprised 132 birds, and 34 pairs fledged 22 young, with a total of 117 already fledged in the wild. The individuals used for reintroduction came in varying proportions from three sources: young taken from the nests of healthy populations elsewhere; moderately

injured birds, treated and rehabilitated, before being returned to the wild; and birds produced by captive breeding programmes and donated by zoos.

Captive breeding programmes are now being developed for more and more species in several different countries. They most often use falconers' birds or those that are permanently injured, and serve to provide birds for release in the wild, for educational displays by falconers, and to increase expertise in raptor manipulation and veterinary medicine. Captive breeding must only be used as a last resort, to save or re-establish a wild population in conjunction with habitat conservation, population management, improved and enforced legislation and, if necessary, public education to eliminate hostile attitudes towards birds of prey and minimize human disturbance.

Raptor conservation programmes in tropical countries currently encompass global management plans, including forest conservation, economic incentives for sustainable use of forest by local people, hunting regulations, improvement of agricultural practices, development of ecotourism and training of local students and rangers. The Peregrine Fund, of Idaho (USA), has been extremely active in this field, and has launched the following successful programmes, amongst others involving temperate species or other Falconiformes.

The Harpy Eagle Conservation Programme works co-operatively with Latin American governments, organizations, logging companies and local people to conserve forests and breeding sites of Harpy Eagles. At the same time, it develops captive breeding and release techniques, with the aim of re-establishing the species in areas where it has been lost, but where suitable habitat remains, and also for the management of small, isolated populations. More than ten nests are monitored in Venezuela, Panama and Guyana, and surveys are being carried out in Colombia, Ecuador and northern Central America. Flying young have been fitted out with satellite-monitored radio transmitters, to permit the study of their dispersal, and adults have been equipped with standard ground-read transmitters, so that their habitat use can be monitored. A dozen birds are kept for captive breeding and for the subsequent release of their offspring.

The Philippine Eagle Project is aimed at preventing the extinction of what is perhaps the world's largest and most spectacular eagle, and restoring a self-sustaining population of

During the 1980's the total population of the Javan Hawk-eagle was estimated to number only some 50-60 pairs. A special project was launched in 1990 with the initial aim of obtaining a clearer picture of the overall numbers, and these are now reckoned to be very slightly higher than was thought, but still perilously low. In addition to the major factor of deforestation, the capture of birds for sale appears to be contributing to the decline of this species, although the Indonesian government has recently taken steps to toughen the measures against such illegal trade.

[*Spizaetus bartelsi*, Jakarta, Java.
Photo: Michael Riffel]

Although it has a very limited range, the New Caledonia Sparrowhawk occurs at surprisingly high densities, with almost six birds recorded per square kilometre in areas of optimum habitat. Recent survey work suggests that the total population of this species is likely to be in excess of 5000 pairs, and at present there is no evidence to suggest any decline.

[*Accipiter haplochrous*, New Caledonia.
Photo: Thierry Petit/Bios]

The plight of the Great Philippine Eagle is desperate, with total numbers reckoned to be under 200 individuals in the wild. Populations are now highly fragmented, and, with relentless human encroachment on the few remaining patches of suitable forest, together with continued shooting and capture for trade, very drastic measures are now required, if this magnificent species is not to disappear in the wild within a few decades.

[*Pithecophaga jefferyi*,
Mindanao, Philippines.

this endangered species to one of its last remaining strongholds on the island of Mindanao, in the southern Philippines. Two chicks have been bred in captivity, and an important education and socio-economic programme is in progress. This includes reforestation operations, finding, monitoring and protecting nest-sites, with the help of settlers and villagers, and also an exchange between local and North American schools.

The Maya Project in Guatemala uses raptors as an environmental focus for the conservation of tropical forests and for building up local conservation capacity in Central America. It is unique in the amount of new information that has been accumulated on secretive tropical forest raptors, and in the training and participation of a large number of Latin Americans.

The scarcity of field work carried out in the Andaman Islands has probably been mainly responsible for the Andaman Serpent-eagle being classified as a threatened species. As the human population of these islands is rapidly growing, the bird's forest habitat may well come under threat in the future, but for the time being the species remains common.

[*Spilornis elgini*,
Andaman Islands.

Within an area of some 2.2 million hectares, in the contiguous border parks of Guatemala, Mexico and Belize, it conducts studies of as many species as possible in natural habitats, and also those altered by humans, in order to find out how various forms of land use affect the forest and its raptors. It tests and improves methods for monitoring tropical forest species. Sixty permanent 1 km² plots have also been established and census work carried out, as a basis for long-term monitoring of the populations and the effects of deforestation, habitat fragmentation, hunting and other potentially significant factors.

The Madagascar Fish-eagle Project also fits into this general strategy of broad integrated conservation and development programmes, aimed to provide local people with sustainable alternatives to habitat destruction, while protecting natural areas to conserve biodiversity and especially valuable species. A wetland area of western Madagascar has been selected, as up to half of the entire population of the endemic eagle breeds there. The project is carrying out ecological and conservation studies, in addition to experimental management, but it is also involving the local Sakalava people, who, with their knowledge and their traditional use of the wetlands, help to contribute towards the selection of areas for special reserves that will protect the area's natural habitats and endangered species. These reserves will integrate conservation with the traditional customs and use of resources by the local people, and will enable them to become guardians of the wetlands and their threatened fauna.

PLATE 3

inches 10
cm 25

Genus *AVICEDA* Swainson, 1836

1. African Cuckoo-hawk

Aviceda cuculoides

French: Baza coucou **German:** Kuckucksweih **Spanish:** Baza Africano
Other common names: (African) Cuckoo-falcon, African Baza

Taxonomy. *Aviceda cuculoides* Swainson, 1837, Senegal.
Forms superspecies with *A. madagascariensis*, and possibly also with *A. jerdoni* and *A. subcristata*.
Three subspecies recognized.

Subspecies and Distribution.

A. c. cuculoides Swainson, 1837 - woodland from Senegal E to SW Ethiopia and S to Nigeria and N Zaire.
A. c. batesi (Swann, 1920) - lowland rain forest from Sierra Leone E to E Uganda and S to N Angola.
A. c. verreauxii Lafresnaye, 1846 - woodland and coastal, riparian and montane forest from Kenya S to N Namibia and South Africa.

Descriptive notes. 40 cm; 220-296 g; wing-span 91 cm. Perches horizontally on short legs, often with wings slightly drooped. Small nuchal crest and rufous patch at all ages. Juvenile, brown above with large brown spots on white underparts, similar to juvenile *Accipiter tachiro*. Subadult plumage with rufous wash to chest and finer grey barring on underparts. Brown eye in juvenile turning pale yellow in subadult; in adult, bright yellow in female, red in male. Races separated by size, extent of barring and intensity of plumage colour.

Habitat. Interior and edges of evergreen, riparian and coastal forest, patches of dense deciduous woodland or exotic plantations in more open savanna, up to 3000 m.

Food and Feeding. Lizards, especially chameleons, and large insects, including grasshoppers, mantids and caterpillars. Also beetles, wasps, termite alates, crabs, fish, small birds and bats. Perches for long periods, usually within cover, then swoops slowly down to take prey from foliage or branch, or by hopping along the ground. Occasionally hawks aerial insects, or courses low over open vegetation to drop on prey, flying with relaxed kite-like flight or soaring to display chestnut underwing.

Breeding. Mainly in rainy season: laying Jun-Jul in Sierra Leone; Jun in Nigeria; Feb in Gabon; Mar, Aug-Nov in E Africa; Apr, Oct-Nov in C Africa; Sept-Mar in S Africa. Whistling calls and rocking-and-rolling flight displays distinctive. Builds typical flimsy and untidy platform of twigs with leaves still attached, placed high in the canopy. Usually 2 eggs (2-3); incubation 32-33 days; chicks have white down; fledging 30-42 days; sexes share care of the young, but male does not usually provision female.

Movements. Resident in most areas but some seasonal movement into coastal Kenya to breed in Apr-Nov and into Transvaal highveld after breeding in May-Aug. May move locally within deciduous woodland in response to fluctuations in chameleon and insect numbers, leading to irregular influxes in areas of E and S Africa. Small-scale seasonal movements have also been detected in W African savannas.

Status and Conservation. Not globally threatened. CITES II. Generally common around forest edges, less common in woodland. Easily overlooked, and so may be found to be more common, especially as a breeding species. Affected by loss of prime habitat through cutting of forest and woodland, but uses many secondary habitats including suburban gardens. Subject to predation by sympatric raptors, some of which also colonize secondary habitats or plantations. Not known to be affected by pesticide use.

Bibliography. Ade (1985), Benson & Benson (1975), Brown & Bursell (1968), Brown *et al.* (1982), Carlyon (1987), Chittenden (1984), Dewhurst *et al.* (1989), Finch-Davies & Kemp (1980), Ginn *et al.* (1989), Grimes (1987), Hall *et al.* (1991), Jeffery (1977), Jones, J.M.B. (1985), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Searle (1993), Tarbuton & Allan (1984), Thiollay (1978c), Vernon (1979), Weaving (1977).

2. Madagascar Cuckoo-hawk

Aviceda madagascariensis

French: Baza malgache **German:** Lemurenweih **Spanish:** Baza Malgache
Other common names: Madagascar Baza, Madagascar Cuckoo-falcon

Taxonomy. *Pernis Madagascariensis* A. Smith, 1834, Madagascar.

Forms superspecies with *A. cuculoides*, and possibly also with *A. jerdoni* and *A. subcristata*. Monotypic.

Distribution. Madagascar.

Descriptive notes. 40-45 cm. Pale rump distinctive; dull brown without bright colours of plumage or soft parts of African congener *A. cuculoides*. Sexes similar. Juvenile has brown eyes, but other differences not described. Resembles sympatric *Buteo brachypterus*.

Habitat. Evergreen and dry deciduous forest from sea-level to 1600 m; clearings within forest, e.g. around villages and towns, and some palm plantations.

Food and Feeding. Mainly small reptiles, e.g. chameleons and geckos, and large insects, including grasshoppers. Hunts from a perch, gliding down to take prey from foliage. Usually perches within canopy, often on the edge of a clearing. May be active at dusk.

Breeding. Laying Oct-Dec. One nest 1.4 m up in crown of tree. Pair recorded feeding chicks with insects; chicks have white down. No other details recorded.

Movements. None recorded.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Occurs throughout Madagascar and is fairly common in all forest zones, least so in the dry S and deforested central plateau.

Bibliography. Benson *et al.* (1976), Dee (1986), Langrand (1990), Langrand & Meyburg (1984), Milon *et al.* (1973), Rand (1936), Salvan (1971).

3. Jerdon's Baza

Aviceda jerdoni

French: Baza de Jerdon **German:** Hinduweih **Spanish:** Baza Oriental
Other common names: Blyth's/Legge's/Crested Baza, Brown/Crested Lizard Hawk

Taxonomy. *Pernis Jerdoni* Blyth, 1842, no locality = Bengal.

Probably forms superspecies with *A. cuculoides*, *A. madagascariensis* and *A. subcristata*; all four sometimes considered conspecific. Five subspecies recognized.

Subspecies and Distribution.

A. j. ceylonensis (Legge, 1876) - SW India and Sri Lanka.
A. j. jerdoni (Blyth, 1842) - NE India through Burma, S China (SW Yunnan, Hainan), Thailand and parts of Indochina to N Malay Peninsula; some movement S for winter.
A. j. borneensis (Brüggemann, 1876) - Borneo.
A. j. magnirostris (Kaup, 1847) - Philippines.
A. j. celebensis (Schlegel, 1873) - Sulawesi, Banggai Is and Sula Is.

Descriptive notes. 41-48 cm; 350 g; wing-span 117 cm. Medium-sized brownish kite with long crest; dark crest feathers have white tip; flies with soft wingbeats of paddle-shaped wings. Female fairly similar to male in size and plumage, but lacks grey on head and upperparts. Juvenile like female, but head darker and breast streaked; has one more, narrower tail band. Races generally differ mainly in size and intensity of coloration, ranging from dark and strongly patterned in Sulawesi to pale in Sri Lanka.

Habitat. Moist deciduous to evergreen tropical forest, forest edge and clearings, in foothills from 200 m to 1100 m; also around quiet backwaters; typically in rain forest, but in Sumatra mostly recorded in swamp forest; occurs over mountain grassland in Sulawesi. Nests in forest in canopy of large trees, occasionally in tea plantations.

Food and Feeding. Chiefly insects, but also lizards (e.g. *Calotes*) and frogs; one record of small snake. Hunts from perch, making short sallies to ground when prey sighted. Reports of crepuscular activity not verified.

Breeding. Poorly known. Season Apr-Jun in NE India; Feb-Apr in SW India; Nov-May in Sri Lanka. Small, compact nest usually in crotch or in crown of large tree, 7-20 m up; lined with green leaves. Spectacular display flights over nest area in forest include mutual soaring and undulating flight, accompanied by vocalizations. Usually 2-3 eggs. Juveniles dependent on parents for some time after fledging. No further information available.

Movements. Sedentary; recorded throughout year in virtually all of range. Some birds, possibly juveniles, from N of range apparently disperse or migrate S into Thailand, where movements recorded, and into Malay Peninsula, where only records are in winter.

Status and Conservation. Not globally threatened. CITES II. Appears to be relatively uncommon to rare throughout range; might even be threatened, as rare almost everywhere and largely restricted to undisturbed or only slightly disturbed forest, which is fast disappearing. Nevertheless, may be commoner than thought, and simply not detected due to unobtrusive habits. Widespread in Kalimantan; uncommon in Philippines. Status uncertain in Sumatra, where may be resident, with recent records from E coast in May and Aug. Several recent records from N & S Vietnam; also known from S Laos, suggesting species may be resident throughout Indochina. Also reported from E Ghats of SE India.

Bibliography. Ali & Ripley (1978), Betts (1953), Bishop *et al.* (1995), Cheng Tso-hun (1987), Dickinson *et al.* (1991), Goodman & González (1990), Henry (1971), Holmes & Burton (1987), King *et al.* (1975), Lekagul & Round (1991), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Rand & Rabor (1960), Riley (1938), Smythies (1981), Stresemann (1940a).

4. Pacific Baza

Aviceda subcristata

French: Baza huppé **German:** Papuaweih **Spanish:** Baza Australiano
Other common names: Crested/Lizard Hawk, Crested/Lizard Baza

Taxonomy. *Lepidogenys subcristatus* Gould, 1838, New South Wales.

Probably forms superspecies with *A. jerdoni*, *A. cuculoides* and *A. madagascariensis*. Populations of Solomon Is now regarded as single race, thus possible races *proxima* and *robusta* now included in *gurneyi*. Race *njikena* of NW Australia doubtfully separable from nominate *subcristata*. Thirteen subspecies currently recognized.

Subspecies and Distribution.

A. s. timorluensis (A. B. Meyer, 1894) - islands off Sulawesi, Lesser Sunda.
A. s. pallida (Stresemann, 1913) - S Moluccas.
A. s. reinwardtii (Schlegel & S. Müller, 1841) - C Moluccas.
A. s. stresemanni (Siebers, 1930) - Buru (C Moluccas).
A. s. rufa (Schlegel, 1866) - N Moluccas.
A. s. waigeuensis Mayr, 1940 - Waigeo I.

- A. s. obscura* Junge, 1956 - Biak I.
A. s. stenozona (G. R. Gray, 1858) - W New Guinea, Aru Is.
A. s. megala (Stresmann, 1913) - E New Guinea.
A. s. coultasi Mayr, 1945 - Admiralty Is.
A. s. bismarckii (Sharpe, 1888) - Bismarck Archipelago.
A. s. gurneyi (Ramsay, 1882) - Solomon Is.
A. s. subcristata (Gould, 1838) - N & NE Australia.

Descriptive notes. 35-46 cm; 227-448 g; wingspan 80-105 cm. Resembles most others in genus, particularly *A. cuculoides*. Adult grey with crest and bold ventral barring, unmistakable within range. Female slightly larger than male. Juvenile brown, not grey, with bold face pattern and rufous patch on breast. Slight regional variation in size, colour and nature of ventral barring.

Habitat. Rain forest, open forest, woodland and edge, including farmland and urban trees; from sea-level to 1000 m in Australia, and to 1700 m in New Guinea. Nests in forest and woodland, often in riparian woodland.

Food and Feeding. Omnivorous. Mainly eats foliage insects and tree-frogs; also lizards, small birds and nestlings, and small fruits. Forages by low quartering of tree canopy, or still-hunting within canopy, inspecting foliage; sometimes clambers about among branches. Glides or drops to snatch prey from foliage.

Breeding. Sept-Jan in Australia; season apparently longer, extending into early dry season (austral autumn) in New Guinea. Solitary. Nest is small platform of twigs 25-40 cm wide, 12-15 cm deep, lined with green leaves, within tree canopy, 6-35 m above ground. Usually 2-3 eggs (2-4); incubation c. 29-33 days; chicks have white down; fledging 32-35 days. Age at first breeding at least 2 years. Storms sometimes destroy nests and eggs or young.

Movements. Mostly sedentary. Extreme SE populations (Australia) partly migratory, making some local altitudinal and N-S movements, and wintering on subtropical coasts.

Status and Conservation. Not globally threatened. CITES II. Common in tropics, uncommon at extremities of Australian range. Probably benefits from fragmentation of continuous dense forest, as it prefers edges, although absent from extensively cleared areas. Possibly affected by pollutants such as lead in heavily urbanized areas.

Bibliography. Andrew (1992), Beehler *et al.* (1986), Bell (1984), Bowler & Taylor (1989), Coates (1985), Cupper & Cupper (1981), Czechura (1993), Hollands (1984), Ley (1990), Marchant & Higgins (1993), Olsen & Maples (1993), Olsen, Crome & Olsen (1993), Schodde (1977), Schodde & Tidemann (1988), White & Bruce (1986).

5. Black Baza

Aviceda leuphotes

French: Baza huppard **German:** Dreifarbenweih **Spanish:** Baza Negro
Other common names: Black-crested Baza, Black-crested Lizard Hawk

Taxonomy. *Falco leuphotes* Dumont, 1820, Pondicherry, India.

Race *wolfei*, based on single specimen, doubtfully distinct from nominate. Birds from Burma and Thailand may belong to race *syama*, as opposed to rather similar nominate *leuphotes*; these birds sometimes awarded separate race, *burmana*. Four subspecies normally recognized.

Subspecies and Distribution.

A. l. wolfei Deignan, 1948 - Sichuan (C China).

A. l. syama (Hodgson, 1837) - NE India and E Nepal E to S China (Guangdong, Hainan); winters S through Indochina and Malay Peninsula to Sumatra.

A. l. leuphotes (Dumont, 1820) - SW India, S Burma and W Thailand; may also breed in parts of Indochina.

A. l. andamanica Abdulali & Grubb, 1970 - South Andaman I (Andaman Is).

Descriptive notes. 30-35 cm; 168-224 g; wingspan 66-80 cm. Small black kite with long crest; in flight, appears pied, and looks more like corvid than accipitrid. Female similar to male, but lacks white on secondaries. Juvenile also similar, but duller with white streaks on throat. Racial differences rather slight: *syama* has longer primaries, and barring on underparts probably averages blacker; single specimen of *wolfei* seems identical to many individuals of previous race and also nominate; both specimens of *andamanica* show only two bars on upper belly, and also differ from other races in unbarred flanks.

Habitat. Open deciduous or evergreen tropical forest, especially around clearings and wide streams, from sea-level up to 1000 m. Gathers to spend night at communal roosts in winter.

Food and Feeding. Mainly large insects, especially grasshoppers, but also lizards and frogs; occasionally small mammals and birds. Hunts from perch, making short sallies to take insects in flight; also takes prey from leaves or ground. Sometimes hunts in small flocks. More active when overcast and at dawn and dusk; at times gregarious.

Breeding. Breeding accounts scarce. Season Mar-May in Burma; Feb-Jun in SW India; Apr-Jun in NE India. Small, compact nest built by pair, 20-30 m up in large forest tree, often near water, lined with grass and green leaves. Usually 2-3 eggs; both sexes incubate. No further information available.

Movements. Migrants from N parts of range move S through Malay Peninsula in Nov-Dec to winter in Sumatra, returning in Feb-Mar. A few migrants recorded in SE India and Sri Lanka.

Status and Conservation. Not globally threatened. CITES II. Generally uncommon, but probably passes undetected due to unobtrusive habits, and may be commoner than thought. Seen in large numbers on migration in Malay Peninsula. Widespread destruction of forest throughout much of range is only known threat.

Bibliography. Abdulali & Grubb (1970), Ali & Ripley (1978), Andrew (1992), Chong Tso-hin (1987), Deignan (1948, 1948), Biechocup & Hue (1978), Henry (1971), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Riley (1938), Smythies (1986), Tikader (1988).

Genus *LEPTODON* Sundevall, 1836

6. Grey-headed Kite

Leptodon cayanensis

French: Milan de Cayenne **German:** Cayenneweih **Spanish:** Milano Cabecigrís
Other common names: Cayenne Kite

Taxonomy. *Falco cayanensis* Latham, 1790, Cayenne.

Apparent affinity with old world honey-buzzards (*Pernis*) and bazas (*Aviceda*). In past, alternatively known as *Odontriorchis palliatus*. Until recently considered to include *L. forbesi*, which was thought to represent another variant on immature plumage of present species. Two subspecies recognized.

Subspecies and Distribution.

L. c. cayanensis (Latham, 1790) - S Tamaulipas and Oaxaca (Mexico) S to W Ecuador, Amazonia, Guianas and Trinidad.

L. c. monachus (Vieillot, 1817) - C Brazil to E Bolivia, N Argentina and Paraguay.

Descriptive notes. 46-54 cm; 416-605 g. Short, broad wings and long tail. Grey head, black back, tail black with three whitish bars (uppermost concealed) and white tip. Below white with slight greyish wash; black underwing-coverts contrast sharply with generally pale underside of remiges. Iris blue-grey to blue-black; cere, facial skin and legs blue-grey. Sexes alike, but female averages slightly larger. Three distinct immature colour morphs: pale morph all white below (including underwing-coverts) and on head, (including forehead and area above eye) with narrow black cap and nape, broad white collar, dark

brown or blackish back, and brownish bars on tail, recalling much larger adult of *Spizastur melanoleucus*; dark morph similar, but has all dark head, and heavy dark streaking ventrally; intermediate morph lacks white on sides of head and collar, and is whitish ventrally with narrow streaking on breast; cere, facial skin and legs yellow in all immature morphs. Race *monachus* somewhat larger.

Habitat. Rain forest up to 2000 m, but mainly in lowlands, especially in vicinity of water. Regularly soars over the forest, but not for extended periods. Uses gallery forest, forest edge and disturbed, fragmented habitat.

Food and Feeding. A broad diet, including many insects, honeycomb, wasps and hornets and their larvae, birds and their eggs, snakes, lizards (especially arboreal geckos), frogs and molluscs. Often hunts from an exposed perch, especially in early morning or late evening. Observed feeding in association with marmosets in Minas Gerais, Brazil, catching cicadas flushed by the monkeys.

Breeding. Display flight involves rapid, fluttering, downward wingbeats. Two clutches (of 2 and 3 eggs) purportedly of this species. One from twig nest high in tree: eggs greyish white, with reddish brown scrawls and dots. Two unmarked eggs from Trinidad.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Rare to uncommon throughout extensive range, but not threatened at present. Estimated average density of at least 3 individuals/10,000 ha at one forest site in French Guiana. In Colombia, commonest in Amazonian zone. Does not persist in heavily cleared areas.

Bibliography. Albuquerque (1986), Belton (1984), Blake (1977), Brodkorb (1943), Contreras *et al.* (1990), Ferrari (1990), Foster (1971), Haverschmidt (1962), Herklots (1961), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Monroe (1968), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Sick (1985a, 1993), Slud (1964), Stiles & Skutch (1989), Thiollay (1985c, 1989a, 1989b, 1991a), Voous (1969), Wetmore (1965).

7. White-collared Kite

Leptodon forbesi

French: Milan de Forbes **German:** Kragenweih **Spanish:** Milano Acolarado

Taxonomy. *Odontriorchis forbesi* Swann, 1922, Pernambuco, Brazil.

Until recently considered a variant immature plumage of *L. cayanensis*, but specimens of both adult and immature birds collected in Alagoas (NE Brazil) fit type description and confirm validity of the species. Monotypic.

Distribution. NE Brazil: until recently, only known from Pernambuco; recently rediscovered in Alagoas (c. 9° 30' S, 36° W).

Descriptive notes. Male 50 cm, 580 g; female 49 cm, 550 g. A large kite, blackish above, white below; head grey, whiter on hindneck; tail black with broad median band and tips ashy white; mantle spotted and secondaries broadly tipped white; white underwing-coverts. Differs from *L. cayanensis* in whitish collar, different tail pattern, spotted mantle and white underwing-coverts.

Habitat. Atlantic coastal rain forest of NE Brazil.

Food and Feeding. No information available.

Breeding. No information available.

Movements. Presumably sedentary.

Status and Conservation. INSUFFICIENTLY KNOWN CITES II. Not rare locally, but has very limited range, continuing destruction of its forest habitat, which has now been reduced to 1% of its former extent. Combination of these two factors must place this amongst the most endangered raptors in the world.

Bibliography. Brown & Amadon (1968), Collar *et al.* (1992), Forrester (1993), Pinto (1964), Rusch (1979), Sick (1985a, 1993), Teixeira *et al.* (1987a, 1987b).

Genus *CHONDROHIERAX* Lesson, 1843

8. Hook-billed Kite

Chondrohierax uncinatus

French: Milan bec-en-croc German: Langschnabelweih Spanish: Milano Picogarrio

Taxonomy. *Falco uncinatus* Temminck, 1822, Bahia, Brazil.

Large-billed forms have been suggested to form a separate species (*C. megarhynchus*), but this view now discredited; race *wilsonii* of Cuba also recognized by some as full species. Mexican birds traditionally awarded separate race, *aquilonis*, but considerable individual variation (both in Mexico and elsewhere) indicates that subspecific status is not merited. Three subspecies recognized.

Subspecies and Distribution.

C. u. uncinatus (Temminck, 1822) - W Mexico (Sinaloa) and extreme S USA (S Texas) S through Central America, Trinidad, the Guianas and Brazil to E Peru and E Bolivia, Paraguay and N Argentina.

C. u. mirus Friedmann, 1934 - Grenada (Lesser Antilles).

C. u. wilsonii (Cassin, 1847) - E Cuba.

Descriptive notes. 38-42 cm; male 253 g, female 255-360 g. Very large, heavy, hooked bill. Extreme variation in bill size and plumage. Sexual, age-related and individual differences in plumage remarkable, including melanistic morph. Male usually bluish slate above, with grey breast finely barred white or buff, and 2-3 bands in tail; female brown above, with sides of head grey, rusty nuchal collar and rusty to brown breast finely barred white. Variation in bill size is not geographical, but bimodally distributed in many parts of range: large-billed individuals (with bill more than twice size of small-billed ones) found in all age and sex classes. Eye varies from white to pale green to bluish grey; cere greenish yellow, legs orange yellow. Immature dark brown above, creamy white below, with white nuchal collar and 4-5 bands in tail; melanistic juvenile all black with whitish bars in tail. Island forms somewhat smaller: race *mirus* shows some plumage differences; *wilsonii* has all yellowish bill.

Habitat. Rain forest, in lower canopy and dense understorey, forest edge, clearings and disturbed forest; low (5 m) xeric forest on Grenada; acacia thorn-scrub woodland in Mexico; both upland tall forest and seasonally flooded low-lying forests in Petén, Guatemala. Regularly soars over the forest.

Food and Feeding. Mostly tree snails, but also some reptiles, frogs, salamanders, freshwater crabs, and insects ("many caterpillars"). Lizards represented 8% of prey items in Petén. Snails extracted

from their shells in stereotyped manner: bird breaks inner whorls by forcing upper mandible towards apex of shell's spire, a method very different from that used by *Rostrihamus*. Island forms, with only one size of snail available, do not exhibit dimorphism in bill size; continental forms, with pronounced dimorphism in bill size, prey on different species and size classes of snails. Regularly catches food by perch-hunting, or by hopping about between branches.

Breeding. Birds in breeding condition Mar-Apr. in NE Colombia; in Surinam, nest building in Oct, laying late Nov, nest with young

in Apr; in Petén (Guatemala), laying late in dry season (Jun-Jul), after most other raptors in the area have already fledged young. Probable courtship display on Grenada included birds circling together, diving at each other and calling frequently. Stick nest lined with twigs, built by both sexes 5-7 m up in tree (Mexico), or average 25 m up (Petén), c. 5 m from top of nest tree; often placed precariously on thin branches far from main trunk; nest shallow and very small, so that both head and tail of incubating adult extend well beyond edge. 1-2 eggs; incubation c. 35 days, shared by male; male brings most food to nest, and occasionally feeds young; fledging in early to middle rainy season, presumably to take advantage of more plentiful tree snails when the other two sympatric breeding kites, *Elanoides* and *Ictinia plumbea*, are beginning to migrate S.

Movements. Presumably sedentary; no movements recorded.

Status and Conservation. Not globally threatened. CITES II: race *wilsonii* on CITES I. Widespread but unobtrusive, and generally appears to be uncommon. Has colonized S Texas in fairly recent times, with 10-20 pairs by mid-1980's. Race *mirus* of Grenada seriously endangered, currently numbering only 15-30 individuals, although this represents an increase over a 1982 survey; decline due to habitat loss and introduced snails, which are probably too large for present species to deal with, but which feed on the native snails upon which it depends. Total population of race *wilsonii* of Cuba greatly reduced, and probably now restricted to E part of the island.

Genus *HENICOPERNIS* G. R. Gray, 1859

9. Long-tailed Buzzard

Henicopernis longicauda

French: Bondrée à longue queue **German:** Langschwanzweih
Other common names: Long-tailed Honey-Buzzard

Spanish: Abejero Colilargo

Taxonomy. *Falco longicauda* Garnot, 1828, New Guinea.

Genus traditionally considered close to *Pernis*, but now considered part of endemic Australasian clade, related to old endemic Australian genera such as *Lophoictinia* (see page 55). Has been considered a race of *H. infuscatus*, with which it forms superspecies; separated by plumage. Two races formerly recognized: barely distinct *fraterculus* of Japan I; and smaller *minus* of Aru and W Papuan Is; but now considered invalid, because size varies clinally with altitude in mainland New Guinea, with birds smaller in coastal lowlands, larger in highlands. Monotypic.

Distribution. New Guinea, W Papuan islands, Aru Is.

Descriptive notes. 50-60 cm; male 447-630 g, larger female 570-730 g. Superficially similar to *Pernis*, but bill, face and feet more like *Lophoictinia*. Similar to *H. infuscatus*, but more mottled, barred and streaked; ventrally paler. Juvenile has extra (narrow) pale band through primaries and tail tip.

Habitat. Tropical rain forest, forest edge, and adjacent clearings, from sea-level to 3000 m. Nests in forest.

Food and Feeding. Mostly insects, including wasps and their larvae; also arboreal lizards, small birds and the contents of their nests, and small mammals. Forages by low, slow harrier.

like quartering close to forest canopy, or between tree trunks, and along the face of steep hillsides in open areas; also flies slowly between perches within forest, peering about. Hawks flying insects low over forest; one bird seen to seize terrestrial prey in adjacent grassland and return to forest.

Breeding. Breeding behaviour occurs from late wet season through dry season (austral autumn to spring); laying recorded May and Aug, active nest Apr-May, nestling May. Solitary. Nest of sticks usually built in tall tree (*Araucaria*, *Planchonella*, *Pandanus*), sometimes as low as 7 m; occasionally on cliff ledge. Clutch size unknown; one record of single nestling. No further information available.

Movements. Adults presumably sedentary, as inferred from geographical variation; no records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Fairly common and widespread throughout New Guinea, but subject to hunting and deforestation and becoming scarce in some areas; population trend and biology poorly known.

Bibliography. Andrew (1992), Beehler (1978), Beehler *et al.* (1986), Bell (1971), Coates (1985), Diamond (1972), Gilliard & LeCroy (1967a), Majne & Bulmer (1977), Mayr & Gilliard (1954), Rand & Gilliard (1967), Rupley (1964), Schodde (1993).

10. New Britain Buzzard

Henicopernis infuscatus

French: Bondrée noire **German:** Bismarckweih
Other common names: Black/New Britain Honey-Buzzard

Spanish: Abejero Negro

Taxonomy. *Henicopernis infuscatus* Gurney, 1882, Blanche Bay, New Britain.

Forms superspecies with *H. longicauda*, of which it has been considered a race; now assigned full species rank in recognition of its distinct plumage. Like *H. longicauda*, now considered to form part of old Australian clade (see page 55). Monotypic.

Distribution. New Britain.

Descriptive notes. 50 cm. Slightly smaller and much darker, less barred or streaked than *H. longicauda*, particularly on underparts. Juvenile unknown.

Habitat. Primary and partly disturbed lowland and hill tropical rain forest.

Food and Feeding. Lizards and spiders in stomachs of specimens; no field observations of feeding. Seen soaring over forest and gliding just above tree canopy; also a bird near ground within forest clambered up leaning trunk to subcanopy. One bird made long, powerful glide over forest canopy.

Breeding. Specimens in breeding condition in

May; no further information.

Movements. No information available. Presumably sedentary, as inferred from isolation, morphology, and lack of records outside normal range.

Status and Conservation. INDETERMINATE. CITES II. Seldom seen by ornithologists, biology unknown. Range, and therefore total population, small and subject to deforestation in lowlands.

Bibliography. Amadon & Bull (1988), Bishop (1983), Brown & Amadon (1968), Coates (1985), Collar & Andrew (1988), Schodde (1978).

Genus *PERNIS* Cuvier, 1817

11. Western Honey-buzzard

Pernis apivorus

French: Bondrée apivore **German:** Wespenbussard
Other common names: European/Eurasian Honey-buzzard

Spanish: Abejero Europeo

Taxonomy. *Falco apivorus* Linnaeus, 1758, Sweden.

Forms superspecies with *P. ptilorhynchus*, with which sometimes considered conspecific. Monotypic.

Distribution. Europe and W Asia, from Spain, France, SE England and E Scandinavia through W Russia and Caucasus to R Ob in SW Siberia. Winters mostly in Africa S of Sahara.

Descriptive notes. 52-60 cm; 440-1050 g; wingspan 130-150 cm. Polymorphic, with extremely variable coloration. Differs from true buzzards of genus *Buteo* in small head (resembling dove or cuckoo), slender bill, thin neck, longer tail and yellow iris. In flight, often shows black carpal patches on underwing; two dark bands at base of tail. Male normally has grey head; female generally darker, with brown head. Juvenile lacks well defined dark edging to wings; secondaries normally dark, breast often streaked dark; eyes brown; narrow, inconspicuous bars (normally 4) on tail.

Habitat. Forests and woods, preferably deciduous, in temperate and boreal zones; also varied habitats with both wooded and open areas. Normally at low or medium altitudes, but reaching almost 2000 m in mountainous areas (Caucasus, Pyrenees). Winters in Africa, in forests and other densely wooded areas.

Food and Feeding. Mainly wasps and hornets (Hymenoptera), feeding on larvae, pupae and adults; some other insects, including bumble-bees, beetles, Orthoptera, etc. Also takes small vertebrates, e.g. frogs, reptiles (lizards, slow-worms) and chicks and eggs of small and medium-sized birds. Follows wasps in flight to locate their nests; watches them from perch, sometimes catching them in the air. Will remove wasps' nests from trees and dig out ground nests with claws; chunks of "chewed" wasp comb frequently found near nests. Diet in Africa poorly known, but includes Hymenoptera, flying termites and Orthoptera.

Breeding. Laying Jun-Jul. Solitary. Nest is platform of twigs lined with fresh leaves, which are renewed throughout nesting period; nests in woods, preferring deciduous trees. Average 2 eggs (1-3), with laying interval of 3-5 days; incubation 30-35 days per egg, shared by both parents; chicks have long, buffy grey first down, shorter white second down; brooded continuously, mainly by female, at least during first week; both adults bring food to nest and feed chicks; fledging 40-44 days; young receive food from adults for at least 1 month more. Success in Germany, 0.1-1.1 chicks per attempt; heavily affected by fluctuations in food supply and weather. Oldest recorded bird 29 years old.

Movements. Migratory, wintering mainly in equatorial Africa. Leaves breeding zones in Aug-Sept, returning from Apr to early Jun. Gathers in large numbers at favoured crossing points; most birds from W & C Europe cross Straits of Gibraltar; E European birds cross Bosphorus, or follow route to E of Black Sea, passing from Asia to Africa across Gulf of Suez; much smaller numbers fly over Sicilian Channel.

Status and Conservation. Not globally threatened. CITES II. Population apparently stable, although some regional fluctuations. World population very high, presumably at least in hundreds of thousands of pairs, given spectacular numbers counted during migration: 851,598 birds in spring 1985 at Elat (Israel); and 117,175 at Gibraltar in autumn 1972. Precise counts in breeding zones difficult to carry out, but estimates in early 1990's include: 100,000 pairs in European Russia; 900-1700 pairs in Byelorussia; c. 200 pairs in Bulgaria; and 1500 pairs in Austria. In 1980's: 8000-12,000 pairs in France; 400-500 pairs in Netherlands; 800-1000 pairs in Denmark; c. 8000 pairs in Sweden; c. 5000 pairs in Finland; c.600 pairs in Czechoslovakia; and c. 1500-2000 pairs in Poland. This healthy status is possible because the insects on which present species feeds have not been heavily affected by insecticides. Large numbers of birds still shot during migration in some areas, most notoriously in Italy and on Malta.

Bibliography. Agostini (1992), Brown *et al.* (1982), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Divyabhusin (1990), Flint *et al.* (1984), Gómsbol (1986), Ginn *et al.* (1989), Glutz von Blotzheim *et al.* (1971), Goodman *et al.* (1989), Grimes (1987), Handrinos & Demetropoulos (1983), Holstein (1944), Kjellen (1992), Kosirzowa (1985, 1986, 1987, 1989, 1991), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Martin, B.P. (1992), Moreau (1972), Olech (1991), Paz (1987), Pickford *et al.* (1989), Pinto (1983), Rasmussen & Storgard (1989), Schubert (1977), Shirahai & Christie (1992), Simeonov *et al.* (1990), Stresemann (1940b), Thiollay (1989c), Tree (1973).

12. Crested Honey-buzzard

Pernis ptilorhynchus

French: Bondrée orientale **German:** Schopfweidenbussard
Other common names: Oriental/Eastern Honey-buzzard

Spanish: Abejero Oriental

Taxonomy. *Falco ptilorhynchus* Temminck, 1821, Java.

Forms superspecies with *P. apivorus*, in which sometimes included. All listed races may be close to species threshold. Other doubtful races not generally accepted include *japonicus*, *neglectus* and *gurneyi*, described respectively from Japan, Taiwan and Burma. Emendation of original spelling to *ptilorhynchus* is not justified. Six subspecies normally recognized.

Subspecies and Distribution.

P. p. orientalis Taczanowski, 1891 - S Siberia E to Amurland and Sakhalin, S to Manchuria, Japan and possibly Korea; winters S to SE Asia, Indonesia and Philippines.
P. p. ruficollis Lesson, 1830 - India and Sri Lanka E through Burma to SC China (Yunnan).
P. p. philippensis Mayr, 1939 - N & E Philippines.
P. p. palawanensis Stresemann, 1940 - Palawan and Calauit (W Philippines).
P. p. torquatus Lesson, 1831 - Malay Peninsula, Sumatra and Borneo.
P. p. ptilorhynchus (Temminck, 1821) - Java.

Descriptive notes. 52-68 cm; 750-1490 g; wingspan 135-150 cm. Polymorphic, with extremely variable coloration. Similar to *P. apivorus*, but larger; often has well developed nuchal crest and sometimes dark horseshoe-shaped spot on crop. Races separated mainly by coloration, size and development of crest.

Habitat. Wooded areas, preferring broad-leaved trees, in wide variety of biomes ranging from tropical forests to taiga. Dense forests, open wooded areas or mixed woodland and open areas. Lowlands, hills and lower and middle slopes of mountains, up to 1800 m in Himalayas and 1500 m in Japan.

Food and Feeding. Mainly bees and wasps, in particular their larvae, also eating bits of comb and honey; feeds on nests in tree holes and similarly on those hanging from branches. Also takes other

insects, e.g. crickets, flying termites and ants; occasionally vertebrates, including lizards, frogs, small mammals and birds. Can dig in ground to expose insect nests, subsequently eating larvae. Spends long periods scanning from perch.

Breeding. Laying starts Feb in S India; May and particularly Jun in N of range. Nests mainly in broad-leaved trees, but also in conifers and even coconut palms; sometimes at considerable height, up to 28 m above ground. Nest built in fork of tree; platform of twigs lined with leaves and other light material, c. 40 cm wide, 20 cm deep; built by both adults. Normally 2 eggs; incubation 28-35 days; by both adults; both also feed chicks; fledging 35-45 days.

Movements. Migratory in N populations, sedentary or with local movements in S. Arrives on breeding grounds in Siberia and Japan in May; leaves in Sept/Oct to winter from SE Asia S to Indonesia, where migrants may coincide with sedentary populations. Considerable movement recorded over Bali, with 2186 birds seen in 1 month, mainly from mid-Oct to early Nov. The late spring migration is related to availability of food in N breeding zones; arrival in some areas of the Punjab in Pakistan coincides with that of migratory rock bee (*Apis dorsata*). May travel long distances in search of feeding areas, e.g. on Indian Subcontinent. Recent records from Andaman Is may refer to migrants or perhaps to local breeding population.

Status and Conservation. Not globally threatened. CITES II. Status poorly known; retiring habits of species make its detection difficult. Rare or uncommon in most of N breeding zones, but more common in USSR/land; uncommon and local in Japan. In some areas of Pakistan, species has colonized irrigated forest plantations.

Bibliography. Ali & Ripley (1978), Ash (1993), Austin (1948), Bogorobskii (1988), Brazil (1991), Brazil & Hanawa (1991), Cheng Tso-hin (1987), Deignan (1945), Dementiev & Gladkov (1951), Dickinson *et al.* (1991), Divyabhanushin (1990), Eichécor & Húe (1978), Flint *et al.* (1984), González (1983), Hou *et al.* (1990), Inskipp & Inskipp (1985), Knystautas (1993), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Philipps (1993), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Parkes (1971), Prakash *et al.* (1993), Roberts (1991), de Roder (1989), Rogacheva (1992), Smythies (1981, 1986), Wilkinson *et al.* (1991a, 1991b).

13. Barred Honey-buzzard

Pernis celebensis

French: Bondrée des Célèbes **German:** Celebeswespenbussard **Spanish:** Abejero de Célebes

Taxonomy. *Pernis cristatus* var. *celebensis* Wallace, 1868, Sulawesi.
Two subspecies recognized.

Subspecies and Distribution.

P. c. celebensis Wallace, 1868 - Sulawesi, Muna I and Banggai Is.

P. c. steerei W. L. Slater, 1919 - Philippines (except Palawan).

Descriptive notes. 51-56 cm. Typical honey-buzzard, with flat talons and lacking supraorbital ridge. Bold barring on underparts; crest short (*steerei*) or lacking (*celebensis*). Plumage very similar to that of sympatric *Spizaetus lanceolatus* on Sulawesi; in contrast, in Philippines, sympatric *Spizaetus philippensis* is less similar. Juvenile paler and less heavily marked. Race *steerei* separated by short crest and less boldly barred belly.

Habitat. Primary forest and forest edge from sea-level up to 1800 m; perhaps at lower levels than sympatric *P. ptilorhynchus* in Philippines.

Food and Feeding. Little studied. Typical

honey-buzzard, feeding on Hymenoptera and honey combs; also birds. Flies through and below canopy from one open perch to another, searching for flying insects which may lead it to their nests.

Breeding. Poorly known. One record of nesting in Feb in Philippines; in Sulawesi, one clutch in May, one female ready to lay in Sept. Display flight involves claw-grasping. Single clutch known of 2 eggs. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Status poorly known; reported to be widespread but generally uncommon in Sulawesi, and uncommon in Philippines; apparently not uncommon in some parts of Sulawesi. Long-term threat is loss of forest habitat, especially in Philippines. Extensive research required; surveys also desirable.

Bibliography. Andrew (1992), van Bommel & Voous (1951), Bishop *et al.* (1994), Brown & Amadon (1968), Dickinson, Kennedy & Parkes (1991), Dickinson, Kennedy *et al.* (1989), Rand & Rabor (1960), Stresemann (1940a), White & Bruce (1986).

Genus LOPHOICTINIA Kaup, 1847

14. Square-tailed Kite

Lophoictinia isura

French: Milan à queue carrée **German:** Schopfmilan **Spanish:** Milano Colicudrado
Other common names: Long-winged Kite

Taxonomy. *Milvus isurus* Gould, 1838, New South Wales.

Has been regarded as related to *Milvus*, but resemblance superficial and convergent; now considered part of old endemic Australasian clade (see page 55). Monotypic.

Distribution. Australia breeding mainly in W, S & E, but also occupying N in non-breeding season.

Descriptive notes. 50-56 cm; 501-680 g; wingspan 131-145 cm. Slender, long-winged hawk superficially resembling *Milvus milvus*, but with square or slightly notched tail tip. Distinguished from related *Hamirostra* by slighter build, narrower wings and long tail. Female larger and heavier. Juvenile has rufous head; lacks white face and heavy streaking.

Habitat. Open forest, woodland and edge, less often scrub, heath, grassland, farmland and urban fringe; from sea-level to 1000 m. Avoids treeless, arid and alpine areas. Nests in forest and woodland, often in riparian situations.

Food and Feeding. Mostly small birds, and particularly their eggs and nestlings, often honeyeaters (Meliphagidae) and other passerines that build nests in foliage. Also insects, reptiles, tree-frogs and rarely small mammals; not carrion. Foraging is

solitary and entirely aerial by low, slow quartering of tree and shrub canopy; also hawks flying insects. Drops suddenly to snatch prey from foliage or seize prey startled into flight; reaches into, tears apart, or removes, nests; rarely alights on ground.

Breeding. Jul-Dec. Solitary, but sometimes near raptors of other species. Nest is platform of sticks 50-85 cm wide, 25-60 cm deep, lined with green leaves; placed 8-34 m above ground in forks of living trees. Usually 3 eggs (2-3); incubation c. 37-42 days; chicks have white down; fledging c. 59-65 days; post-fledging dependence over 1 month. Sexual maturity apparently at 2 years old, but rarely breeds in immature (2nd year) plumage. Broods of 1 or 2 young fledge; some brood reduction in nest through starvation, and storms blow nests down. Success of 1-3 young per year for one pair over 7 years; another pair consistently failed over 15 years, because eggs regularly collected.

Movements. Spring breeding migrant in S, non-breeding migrant to N Australia in dry season (austral winter); some breeding birds resident in SW and coastal E Australia, but these expand home ranges or make local movements in winter. Movement diffuse, without flocking or major concentration points, but individuals may follow ridge systems or rivers.

Status and Conservation. Not globally threatened. CITES II. This highly specialized raptor is uncommon and declining, subject to habitat clearance and illegal egg-collecting in its S and E breeding range; may be threatened. Has low breeding density and recruitment rate. Population estimated at 20-50 pairs in Victoria; under 10 birds in South Australia, where few recent successful breeding records. Recently adapting to well vegetated outer fringes of cities in subtropical E Australia, where it feeds on abundant exotic and native passerines. Eggshell thickness not significantly reduced by DDT.

Bibliography. Binns *et al.* (1991), Cameron (1976, 1992), Cupper & Cupper (1981), Debus (1991a, 1993a), Debus & Czechura (1989, 1992a), Debus & Silveira (1989), Debus, Earle *et al.* (1992), Debus, McAllan & Morris (1993), Fraser (1993), Garnett (1992), Hollands (1984), Johnston (1983), Marchant & Higgins (1993), Olsen (1991), Olsen & Marples (1993), Olsen, Crome & Olsen (1993), Schodde (1993), Schodde & Tidemann (1988), Schulz (1983).

Genus HAMIROSTRA T. Brown, 1846

15. Black-breasted Buzzard

Hamirostra melanosternon

French: Milan à plastron **German:** Schwarzbrustmilan **Spanish:** Milano Pechinegro
Other common names: Black-breasted Kite/Buzzard-kite

Taxonomy. *Buteo melanosternon* Gould, 1841, interior of New South Wales.

Traditionally regarded as a primitive kite of *Milvus* affinity, to which unrelated; now considered part of old endemic Australasian clade (see page 55). Monotypic.

Distribution. Australia, except S and E.

Descriptive notes. 51-61 cm; 1150-1450 g; wingspan 147-156 cm. Adult, with mostly black body, short tail and white patches in wings, unmistakable. Distinguished from related *Lophoictinia* by heavy build, larger bill and feet, and shorter tail. Alleged "pale morph" has recently been shown to be second immature plumage, adopted in the bird's third or fourth year. Female larger and heavier than male. Juvenile rufous, streaked black.

Habitat. Woodland, savanna, plains and deserts of tropical N and arid C Australia; from sea-level to at least 500 m; avoids forest. Nests in woodland.

Food and Feeding. Mammals, birds, reptiles, carrion, and occasionally large insects; prefers young rabbits, bird nestlings (including those of other raptors) and eggs, and large lizards. Forages by fast gliding transects at moderate height, and also by low, slow quartering and high soaring; sometimes walks on ground, searching. Swoops to snatch prey from trees or seize it on ground. Breaks eggs of large ground-nesting birds with blows of bill, or uses bill to hurl stones at them from standing position on ground.

Breeding. Jun-Nov, usually Aug-Oct. Solitary, but sometimes nests near raptors of other species; usually monogamous but one record of polyandrous trio persisting over 4 years. Nest is platform of sticks 70-120 cm wide, 40-55 cm deep, lined with green leaves; placed 6-22 m above ground in forks of living or dead tree. Usually 2 eggs (1-2, rarely 3); incubation c. 36-40 days; chicks have white down; fledging c. 60 days; post-fledging dependence at least 2 months. Sexual maturity at 2 years or older; occasionally breeds in immature (2nd or 3rd year) plumage. Usually 1 young fledges (1-2); nest success 62%, or 1-3 young per successful nest, and 1-1 per nest started; 0.76 young per pair per year.

Movements. Poorly understood; apparently some resident and some migratory populations. Breeding birds sedentary in C Australia unless forced to move by drought; dry season (austral winter and spring) breeding migrant to N Australia, withdrawing from tropical coasts in wet season; avoids CW Australia in summer. Occasional minor irruptions to S and E parts of range during inland drought.

Status and Conservation. Not globally threatened. CITES II. Has conservation status of concern. Generally uncommon and has declined in SE of range through habitat clearance and poisoning of carcasses on which it scavenges; habitat degraded and some prey mammals extinct in SE and SC Australia, but may have benefited from introduced rabbit and abundance of stock carrion. Low breeding density and recruitment rate; sensitive to human activity near nest. Sometimes killed when scavenging on roads; subject to illegal egg-collecting.

Bibliography. Angus (1992), Aumann (1990a), Baker-Gabb (1990), Cupper (1977), Cupper & Cupper (1981), Debus (1991b), Debus & Czechura (1992b), Garnett (1992), Hollands (1984), Marchant & Higgins (1993), Olsen (1991), Olsen & Marples (1993), Olsen, Crome & Olsen (1993), Pepper-Edwards & Norley (1991a, 1991b), Schodde (1993), Schodde & Tidemann (1988).

Genus ELANOIDES Vieillot, 1818

16. American Swallow-tailed Kite

Elanoides forficatus

French: Milan à queue fourchue **German:** Schwalbenweih **Spanish:** Elanio Tijereta
Other common names: Swallow-tailed Kite

Taxonomy. *Falco forficatus* Linnaeus, 1758, America = Carolina.

Not clearly or closely related to any other genus, but some similarities with *Elanus* and the *Pernis* group. Two subspecies recognized.

Subspecies and Distribution.

E. f. forficatus (Linnaeus, 1758) - coastal SE USA to N Mexico.

E. f. yelapa (Vieillot, 1818) - S Mexico (except Yucatán) S through Central America (excluding El Salvador) to E Bolivia, Paraguay and NE Argentina (Misiones).

Descriptive notes. 56-66 cm; 375 g; wingspan 130 cm. Unmistakable, with long, pointed wings and long, deeply forked tail. Above black, with bluish purple sheen; head, neck and underside, including underwing-coverts, pure white; flight-feathers and tail black. Iris dark brown to reddish. Immature generally similar to adult, but tail less deeply forked. Race *yelapa* has greenish sheen on upperparts.

Habitat. Primarily over forests in tropical and subtropical zones, perhaps higher; sometimes shows certain preference for swampy areas and marshes.

Food and Feeding. Insects, often feeding on insect swarms or hatches, e.g. of *Atta sexdens*; paperwasp nest delivered to young in nest. Also takes small vertebrates, including a bat and a small snake; frogs can be important; in Florida (USA) c. 99% of prey delivered to nest made up of anole lizards. Some fruit (Moraceae, Sapindaceae); in the Petén, Guatemala, fruit rarely delivered to nest, but at least one instance at most nests. Takes young birds from nests, carrying off entire nests of smaller species; nestling birds 18% of prey delivered to nests in Petén. Insects taken and consumed on the wing, often high up, but can be gleaned off canopy in low glides; sometimes takes fruit in like manner; also catches hummingbirds, which may be "gleaned" off canopy perches or perhaps as they are hovering at a canopy flower feeding on nectar. Often highly gregarious.

Breeding. Laying in mid-Mar in Florida; season Jan-May/Jun in Costa Rica; Mar in Panama and Colombia. Often several pairs nesting within a few hundred metres. Twig nest, frequently lined with moss, precariously placed in very top of tall trees (under 1 m from top); situated on very small branches, which probably reduces chance of predation by mammals, but avian predation can occur, and nests are not infrequently lost in strong winds; nests not normally reused, but pair recorded using old nest of *Ictinia mississippiensis*, under 100 m from previous year's nest. Copulation often preceded by courtship feeding; unmated male recorded interfering with copulation and courtship of mated pair. Both parents share all aspects of rearing brood, from incubation to feeding, although females do more at nest, males spend more time providing food. Usually 1-2 eggs (average 1.83 in Petén, higher in USA), but up to 3 in USA; incubation from c. 28 days (USA) to 31 days (Petén), beginning with first egg, which is significantly larger than the second; fledging c. 40 days in USA, average 52.3 days in Petén. Renesting recorded (Petén). Siblicide in first week reported in all Petén nests where 2 eggs hatched. As many as 6 additional adults seen soaring near an active nest and perched in nest tree, but no evidence of helping to feed young.

Movements. Migratory in N and S of range. In late Jul/early Aug, large concentrations at communal night roosts (over 1300 birds leaving one morning) at Lake Okeechobee, Florida, apparently a staging post prior to southward migration; departs from Petén by end Aug. Arrives in Costa Rica in Jan, all birds disappearing by Jul or early Aug. Arrives in Florida in Mar, in Petén in early Feb. Birds ringed in USA have been shot while wintering in S and SE Brazil. Over most of South American range, unclear where species is resident and where only migrant, as very few breeding records; birds in breeding condition in SE Colombia (Vaupés), but otherwise most of Colombian birds may be migrants. In Amazonia, only one nest reported on upper R Negro, Brazil, although species doubtless breeds in the region. Nomadic at least in parts of South America over rain forest. Wanders to 2600 m in Andes of Colombia, and recorded at 5000 m near Lima, Peru. Accidental in Bahamas.

Status and Conservation. Not globally threatened. CITES II. Relatively common over much of its extensive distribution. Estimated average density of at least 10 individuals/10,000 ha at one forest site in French Guiana. Formerly occurred further inland in USA, to Oklahoma, Minnesota and North Carolina; probable causes of decline include direct persecution, and possibly habitat transformation, mainly for agriculture; slight recovery since 1950's.

Genus MACHEIRAMPHUS

Bonaparte, 1850

17. Bat Hawk

Macheiramphus alcinus

French: Milan des chauves-souris **German:** Fledermausaar **Spanish:** Milano Murciélaguero
Other common names: Bat Falcon/Pern/Kite, Bat-eating Buzzard/Hawk

Taxonomy. *Macheiramphus alcinus* Bonaparte, 1850, Malacca.

Monotypic genus with affinities uncertain; formerly classified in Falconidae. Genus name often spelt *Macheiramphus*, but *Macheiramphus* has priority. Little known population of Sulawesi might refer to distinct, undescribed race. Three subspecies recognized.

Subspecies and Distribution.

M. a. alcinus Bonaparte, 1850 - S Burma, W Thailand, Malay Peninsula, Sumatra, Borneo and NC Sulawesi.

M. a. papuanus Mayr, 1940 - E New Guinea.

M. a. anderssoni (Gurney, 1866) - Senegambia E to Ethiopia and S to South Africa, Madagascar.

Descriptive notes. 45 cm; 600-650 g. Wide gape and small delicate bill. Yellow eyes, together with white eyelids, throat and occipital spots, all contrast with dark plumage. White on underparts may be completely covered but always present and more extensive in juvenile. Long, pointed wings and tail, barred flight-feathers and protruding carpal joint notable in flight. Races distinguished by darkness of plumage, extent of white on underparts and crest, size and crest length.

Habitat. Most widespread in evergreen forest and dense deciduous woodland, often associated with limestone; extends to drier savanna, where bats and exotic plantations exist, often entering towns. Roosts by day in densely foliated tree.

Food and Feeding. Primarily 20-75 g insectivorous bats; small birds up to size of doves also important, and some large flying insects taken. Captures all prey by fast aerial pursuit from the rear; mainly crepuscular, but hunts throughout night when moonlit. Less commonly soars and hunts during the day. Favours open hunting areas, especially over water and around floodlights. Takes prey in the feet and usually swallows it whole in flight via large gape; even birds dealt with thus, but larger bats and birds may be taken to a perch. Can capture and ingest a single bat in 6 sec, 5 in 5 min, or up to 17 (total

daily requirements) in an evening.

Breeding. Laying probably Apr in Gabon; Mar, Oct-Nov in Sierra Leone; Apr-Jun, Oct in E Africa; Aug-May (peak Sept-Nov) in S Africa; Apr-Jul in Malaysia and Sumatra. Builds substantial platform of sticks, broken off with the feet in flight; favours outer lateral forks on uncluttered branches to facilitate landing. Usually in large light-barked emergent tree, e.g. eucalypts or baobabs, as these are easily visible at night. 1 large egg (rarely 2); incubation 48 days, fledging 67 days, both unusually prolonged; chicks have white down. No obvious sexual size dimorphism or provisioning of female by male; both sexes share incubation, brooding and feeding of chick.

Movements. Generally considered resident in tropics, but renowned in subtropical S Africa for appearing far from normal habitat; described as visitor to parts of NE Africa.

Status and Conservation. Not globally threatened. CITES II. Status difficult to assess due to nocturnal habits and custom of roosting in densely foliated trees; often considered uncommon to rare. Probably at low densities, with home range of c. 450 km² in South Africa. May be declining in Borneo. Apparently more widespread and common in tropical areas, and even in cities. Nests vulnerable to destruction by high winds. Not known to be affected by pesticides although bat prey probably susceptible.

Bibliography. Auburn (1987), Ballance (1981), Bartels (1952), Beehler *et al.* (1986), Benson & Benson (1975), Black *et al.* (1979), Brooke & Clancey (1981), Brown *et al.* (1982), Chapin (1932), Coates (1985), Deignan (1960), Fenton *et al.* (1978), Ginn *et al.* (1989), Grimes (1987), Harris *et al.* (1990), Hartley (1988), Hartley & Husler (1993), Husler (1983b), Kemp & Kemp (1975b), Langrand (1990), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Madoc (1976), van Marle & Voous (1988), Medway & Wells (1976), Milon *et al.* (1973), Milstein *et al.* (1975), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Smythies (1981), Steyn (1982), Tarboton & Allan (1984), Thiollay (1978c), Thomson (1975), Vernon (1979).

Genus GAMPSONYX Vigors, 1825

18. Pearl Kite

Gampsonyx swainsonii

French: Élanion perle

German: Perlhaar

Spanish: Elanio Enano

Taxonomy. *Gampsonyx swainsonii* Vigors, 1825, tableland of Bahia, Brazil.

Formerly thought to be a falconid related to *Polihiherax* and *Spizapteryx*, but osteological evidence, scutellation and moult pattern convincingly place it near *Elanus*. Disjunct Nicaraguan population reportedly indistinguishable from South American populations. Three subspecies recognized.

Subspecies and Distribution.

G. s. leonae Chubb, 1918 - Nicaragua; N Colombia through Venezuela and Trinidad to Guyana and Surinam, and S to R Amazon.

G. s. swainsonii Vigors, 1825 - Brazil S of R Amazon to E Peru, E Bolivia, Paraguay and N Argentina.

G. s. magnus Chubb, 1918 - coastal W Colombia, Ecuador and N Peru.

Descriptive notes. 20-28 cm; male 94 g; wing-span 54 cm. Very small and falcon-like. Blackish above, mostly white below with black patch on side of breast and rusty brown thighs; forehead and cheek patches yellowish or orange buff, with inconspicuous white nuchal collar followed by dark rufous band. Trailing edge of wings white. Iris brown, cere black, legs bright yellow. Female slightly larger than male. Immature like adult, but nuchal collar yellowish and back and secondary feathers edged rufous. Races *leonae* and *magnus* both have rufous flanks; *magnus* somewhat larger.

Habitat. Dry to and regions, shrubby pasture, savanna, *cerrado* and open tropical woodland; occurs up to 1000 m in Colombia. Usually nests in sparse woods.

Food and Feeding. Predominantly lizards, which constituted 90% of identified prey items in Trinidad; also large insects, and sometimes small birds. Prey usually taken after a short dive to the ground from a perch.

Breeding. Season variable, perhaps related to rains. Flimsy twig nest built 5 m up at tip of horizontal branch; on Trinidad, nests c. 20 m high in 25 m trees, often supported by vine tangles; nest c. 20 cm wide, 10 cm deep. Male has flutter-glide courtship display flight, sometimes used by female too. Courtship feeding often precedes copulation. 2-3 eggs; incubation mainly by female, period unrecorded; fledging c. 35 days. On Trinidad, a pair successfully reared 2 broods/year in 3 consecutive years, fledging 1-4 young per nesting attempt; nesting timed so that young reach independence at beginning (May) and end of rainy season; courtship sometimes begins only 2 weeks after last young dispersed from previous nesting attempt. Records of incubation in Nov in Colombia and chicks in Apr in Venezuela suggest continental birds too may rear more than 1 brood per pair per year.

Movements. Apparently sedentary. Young birds disperse from natal territory within 12-14 weeks of the initiation of a nesting attempt. First record in Panama in 1977 more likely a bird coming N from South America, rather than a vagrant from Nicaraguan population.

Status and Conservation. Not globally threatened. CITES II. Locally distributed and not generally common, but probably benefits from forest destruction, e.g. numerous in partly deforested areas of S Córdoba (NW Colombia), which may only have been colonized quite recently; the only carefully studied nest was in an extensive suburban housing development. In general, fairly common in suitable habitats in Colombia.

Bibliography. ssp caeruleus

ssp hypoleucus

ssp migrans

ssp aegyptius

ssp girrenera

ssp indus

ssp lineatus

PLATE 5

inches 10
cm 25

Genus *ELANUS* Savigny, 1809

19. Common Black-shouldered Kite

Elanus caeruleus

French: Élanion blanc

German: Gleitaar

Spanish: Elanio Común

Other common names: Black-shouldered/Black-winged Kite

Taxonomy. *Falco caeruleus* Desfontaines, 1789, Algiers.

Forms closely related to *Chelictinia*. Forms superspecies with *E. leucurus* and *E. axillaris*, and all three sometimes considered conspecific. Race *hypoleucus* has been considered separate species. Birds of Sumatra have been awarded separate race, *sumatranus*, but validity doubtful. Four subspecies normally recognized.

Subspecies and Distribution.

E. c. caeruleus (Desfontaines, 1789) - SW Iberian Peninsula, most of Africa and SW Arabia.

E. c. vociferus (Latham, 1790) - Pakistan E to S & E China, Indochina and Malay Peninsula.

E. c. hypoleucus Gould, 1859 - Sumatra, Java, Borneo, Philippines, Sulawesi, Kalao and Lesser Sundas.

E. c. wahgiensis Mayr & Gilliard, 1954 - New Guinea.

Descriptive notes. 30 cm; male 197-277 g, female 219-343 g; wingspan 84 cm. Distinctive black shoulder patches evident at all ages, when perched or in buoyant, gull-like flight; often hovers, and when perched pumps tail up and down. Pale primary coverts on underwing separate from congeners. Juvenile browner, eye pale yellow not red. Races separated on size and intensity of plumage colour.

Habitat. Open savanna grasslands with scattered bushes and small trees; extends into arid steppe, desert or clearings in dense woodland, wherever prey is abundant. Outside breeding season, up to 500 birds may roost communally

in trees or reedbeds, spreading out by day to individual hunting territories.

Food and Feeding. Primarily rodents of 40-90 g; shrews, bats, small birds, reptiles and insects also predominate at times. Hunts from perch or hovers, usually making a slow descent in stages, with wings held in high dihedral above the back and feet extended below, and ending with a fast plunge into ground cover. Hovers in still or windy conditions. Often crepuscular in hunting.

Breeding. Peak laying at beginning or end of summer or wet season in sub-Saharan Africa and India, but recorded in all months in opportunistic reaction to rodent availability, especially that of larger species; more seasonal in N Africa and S Europe, Feb-Apr; Jan-Jun in Malaysia; Apr and Aug in Sumatra. Rapidly builds small platform of sticks and weeds, lined with grass, in fork of tree, bush or pylon, 2-20 m above ground. Usually 3-4 eggs (2-6); incubation 30-33 days; chicks have pale grey-brown down; fledging 30-35 days; may rear multiple broods in succession (e.g. 7 attempts in 19 months), with male taking over all feeding of fledglings, and female starting new clutch with a different mate.

Movements. Nomadic, ranging widely throughout its extensive range, in search of conditions supporting abundant prey; often travels long distances, and even crosses equator, e.g. from Transvaal (South Africa) to Uganda. Considerable monthly turnover, even in local populations which appear to be stable and sedentary, usually with males arriving first and remaining longest on territories, and females wandering about in search of mates and nesting opportunities.

Status and Conservation. Not globally threatened, CITES II. One of the commonest birds of prey throughout its wide range, e.g. estimated 44,000 pairs in Transvaal alone. In Borneo, rare in N, but widespread and locally common in Kalimantan; locally fairly common in Thailand and Sumatra; common in reserve of Nam Cat Tien (S Vietnam) in mid-1980's. Patchily distributed in some areas, notably India and Iberia; in mid-1980's, 150-200 pairs in Portugal, 100+ pairs in Spain. One of few species to prosper in areas of agriculture, bush clearing and heavy grazing, e.g. along R Nile; currently in expansion in several parts of range. Mobility and reproductive biology ensure optimum use of resources, repeated colonization of ephemeral or marginal habitats, high fecundity and maintenance of large megapopulations. Affected locally by rodenticides.

Bibliography. Ali & Ripley (1978), Allan (1983b), Barnard (1986), Beeher *et al.* (1986), Benson & Benson (1975), Bergier (1987), Brown *et al.* (1982), Clark & Banks (1992), Coates (1985), Collar (1978), Cramp & Simmons (1980), Etchécopar & Hue (1978), Ginn *et al.* (1989), Goodman *et al.* (1989), Grimes (1987), Lewis & Pomeroy (1989), Maclean (1993), Mackworth-Præd & Grant (1962), van Marle & Voous (1988), Medway & Wells (1976), Mees (1982), Meininger (1991), Mendelsohn (1982, 1983, 1984, 1988a, 1989), Mendelsohn & Jaksic (1989), Mian & Wajid (1990), Morel & Poulet (1976), Pakenham (1979), Paz (1987), Roberts (1991), Simeonov *et al.* (1990), Slotow *et al.* (1987), Slotow & Perrin (1992), Smythies (1986), van Someren (1956), Steyn (1971, 1982), Suetens & van Groenendael (1977), Tarboton (1977a, 1978a), Tarboton & Allan (1984), Thiollay (1978c).

20. Australian Black-shouldered Kite

Elanus axillaris

French: Élanion d'Australie

German: Australischer Gleitaar

Spanish: Elanio Australiano

Taxonomy. *Falco axillaris* Latham, 1801, Sydney, New South Wales.

Sometimes regarded as race of *E. caeruleus*, with which it forms superspecies, along with *E. leucurus*; separated by plumage. Has been called *E. notatus* on the grounds that Latham's *axillaris* was supposedly unidentifiable and could have applied to *E. scriptus*, but the illustration examined by Latham clearly does not depict *scriptus*. Monotypic.

Distribution. Australia.

Descriptive notes. 33-37 cm; 181-365 g; wingspan 82-94 cm. Distinguished from sympatric *E. scriptus* by facial features, and by underwing: white inner half, black carpal spot, dark primaries. Differences from other congeners slight: size and body proportions, shade of upperparts, underwing carpal spot, and juvenile plumage. Female larger than male. Juvenile washed rusty on head and body, with feathers of back and upperwings tipped white.

Habitat. Grassland and other sparsely wooded habitats with ground cover, including savanna, farmland, heath, vacant urban grassy land. Nests in trees.

Food and Feeding. Mostly small rodents; occasionally small birds, lizards and insects. Diurnal, crepuscular and occasionally nocturnal, using moonlight. Forages by quartering and hovering, then dropping onto prey on ground.

Breeding. Season variable, throughout most of year with peaks in autumn and spring; continuous when food abundant, when pairs have 2 broods per year. Solitary, or in loose colonies when prey abundant. Platform of sticks 27-45 cm wide, 13-15 cm deep, lined with green leaves; placed 4-35 m above ground in canopy of live tree, rarely on artificial structure.

Usually 3-4 eggs (2-5); incubation 29-34 days; chicks have fawn first down, then pale grey second down; fledging 33-38 days; post-fledging dependence c. 1 month. Age at first breeding probably 1 year. Oldest ringed bird 3.5 years. Of all eggs laid 73% hatch, and 54% result in fledglings.

Movements. Resident populations in temperate coastal lowlands; others dispersive, partly migratory and irruptive in response to plagues of prey. Irregular in semi-arid zone; regular wintering on coast.

Status and Conservation. Not globally threatened, CITES II. Common and widespread; has increased in range and numbers in cleared and farmed areas of S Australia in response to creation of habitat and introduction of suitable prey.

Bibliography. Baker-Gabb (1984a), Condon (1937), Cupper & Cupper (1981), Hollands (1984), McLaughlin (1989), Marchant & Higgins (1993), Olsen & Marples (1993), Olsen & Olsen (1987a), Olsen, Crome & Olsen (1993), Pedler (1976), Ragless (1958), Schodde & Tidemann (1988).

21. White-tailed Kite

Elanus leucurus

French: Élanion à queue blanche

German: Weißschwanzaar

Spanish: Elanio Maromero

Taxonomy. *Milvus leucurus* Vieillot, 1818, Paraguay.

Forms superspecies with *E. caeruleus* and *E. axillaris*; these three sometimes considered a single species, but morphology and behavioural differences support specific status for *E. leucurus*. Two subspecies recognized.

Subspecies and Distribution.

E. l. majusculus Bangs & Penard, 1920 - W & S USA (from Oregon to C Florida, occasionally to South Carolina) and N Mexico; also most of Central America (race uncertain).

E. l. leucurus (Vieillot, 1818) - Panama, S through Amazonia to C Argentina (Mendoza and Buenos Aires) and C Chile (Valdivia).

Descriptive notes. 38-43 cm; c. 300 g; wingspan 100 cm. Above pale bluish grey with black shoulder, below white. Differs from *E. caeruleus* in underwing pattern; largest *Elanus*. Iris rufous orange, cere and legs yellow. Head grey, but for white forehead, supraorbital area and cheeks, and dark patch immediately above and in front of eye; white outer tail feathers contrast with grey central retrices. No sexual size dimorphism, but female somewhat darker grey above. Immature streaked brown and white on nape and back of crown, back brownish with white edging, throat and breast streaked cinnamon. Race *majusculus* larger.

Habitat. Open or cleared agricultural or range lands, lightly wooded savanna or marshes. Prospers in disturbed areas, e.g. farmland or dumps, and also in natural shrubland; both open and dense chaparral in Chile. In California (USA) always near riparian habitat. Usually below 1000 m in Colombia and Venezuela, but occurs up to 2600 m, and recorded at 4200 m in Peru.

Food and Feeding. Primarily mice and voles, but also other small mammals, occasionally birds, lizards and amphibians; 98% rodents, including large *Rattus norvegicus*, at one site in Chile. Often specializes on one prey species e.g. *Mus musculus* or *Mus californicus* in California, and *Akodon olivaceus* in Chile. Hunts by intermittent soaring, hovering and flapping flight, usually less than 30 m above the ground, rarely from a perch; most attempts to capture prey are initiated from hovering position. Males observed catching small birds in flight. May congregate to take advantage of locally abundant diurnal mammals, which tend to have pronounced, cyclical population fluctuations; up to 40 birds roost together at night in non-breeding season. Hunts all day, but peak of activity crepuscular in Chile; uses first 4 and last 4 hours of daylight in North America. Catches prey.

Breeding. Pairing starts in Jan. in California (USA); in Panama, eggs in Dec, fledged young in Jun; nesting Feb-May, in N South America; Sept-Nov in Chile and Argentina. In California, populations spread out and territories defended; elsewhere nests only c. 200 m apart. Stick nest lined with grass, high up in tall trees; sometimes uses old nests of other species, normally rebuilding. Normally 3-5 eggs, very rarely 6; incubation 30-32 days; second clutch possible in good years; chicks have greyish or buff first down, dark bluish grey second down; fledging c. 35-40 days. Both sexes build nest, but once copulation starts, male provides food until young near fledging.

Movements. Migratory or nomadic, when prey abundance declines; in California, one population stays in a reserve, despite sharp drop in prey (vole) abundance, even continuing to catch same proportion of voles, but presumably requiring more time per capture. Transition between migratory and resident populations unknown, especially in S South America: birds from extreme S of range (close N to C Chile in May-Jun, in Sumatra, most birds are austral migrants, although a few breed). Congregates in large flocks in winter. Often roosts in flocks, usually in trees; one flock of over 100 birds roosted overnight in tall sugarcane, after staging on ground in nearby ploughed field.

Status and Conservation. Not globally threatened, CITES II. Seems to be increasing over much of range, especially from S Mexico to Panama, with Nicaraguan birds apparently of Californian origin. Boom apparently due to intensified agriculture, especially year-round irrigation in California; also due to road building in Central America, which opened way for agriculture. Very rare E of Mississippi R, but appears to be spreading, with recent breeding records in S USA and sightings in much of USA; in mid-1970's, dramatic rise in winter in Oregon, where first nesting in late 1970's; nearly extirpated from California in early 20th century, but increased exponentially in period 1949-1978, although with strong fluctuations, population of Texas growing since 1968. In Costa Rica, numbers

up at any rate between late 1950's and 1960's. Increasing in Brazil and has recently spread into Bolivia from N Argentina, where is quite common.

Bibliography. Blake (1977), Bolander & Arnold (1965), Bond, J. (1964), Bond, R.M. (1940), Clark & Banks (1992), Clark & Wheeler (1989), Contreras *et al.* (1990), Cunningham (1955), Dixon *et al.* (1957), Eisenmann (1971), ffrinch (1985), Fjeldså & Krabbe (1990), Fraga (1984), Gallardo (1986), Greer & Bullock (1966), Haverschmidt (1959a, 1962, 1968), Hawbecker (1940, 1942), Henny & Anneer (1978), Hilty & Brown (1986), Housse (1935), Husain (1959), Jakšić & Delibes (1987), Jakšić & Jiménez (1986), Jakšić, Greene & Yáñez (1981), Jakšić, Rozzi *et al.* (1987), Johnson (1965), Koplin *et al.* (1980), Larson (1980), Mendelsohn & Jakšić (1989), Meserve (1977), Meyer de Schauensee & Phelps (1978), Miles (1964), Moore & Barr (1941), Morgan (1948), Orians & Paulson (1969), Palmer (1988), Parkes (1958), de la Peña (1992), Peyton (1915), Pickwell (1930, 1932), Pinto (1964), Pruett-Jones *et al.* (1980), Remsen & Ridgely (1980), Ridgely & Gwynne (1989), Russell (1964), Schlatter, Toro *et al.* (1980), Sick (1985a, 1993), Slud (1964), Stendell (1972), Stendell & Myers (1973), Stiles & Skutch (1989), Thiollay (1980b), Thurber & Serrana (1972), Voous (1969), Waian (1973), Waian & Stendall (1970), Warner & Rudd (1975), Watson (1940).

22. Letter-winged Kite

Elanus scriptus

French: Élanion lettré

German: Schwarzschildläufer

Spanish: Elanio Escrito

Taxonomy. *Elanus scriptus* Gould, 1842, Cooper Creek, South Australia.

Monotypic.

Distribution. Australia, mainly in interior.

Descriptive notes. 34-37 cm; 160-427 g; wing-span 84-89 cm. Distinguished from sympatric *E. axillaris* and other congeners by black rings encircling eyes, enhancing more owl-like face; underwings with black line along inner half and pale primaries. Female larger than male. Juvenile washed rusty on head and body.

Habitat. Sparsely treed grasslands and plains of arid and semi-arid zones; occasionally irrupts to similarly open areas on coast. Nests in riparian woodland in arid zone.

Food and Feeding. Mostly rodents, especially *Rattus villosissimus*; occasionally other small mammals and insects. Normally nocturnal, like

major prey; this habit almost unique in family. Forages by quartering and hovering, dropping onto prey on ground.

Breeding. Season irregular; continuous (mostly autumn to spring) during times of abundant prey following rains, but little or no breeding in years between rat plagues. Loosely colonial; occasionally solitary. Platform of twigs and herbage 28-51 cm wide, 20-34 cm deep, lined with green leaves or cattle dung; placed 2-11 m above ground in canopy of live tree. Usually 4-5 eggs (3-6); incubation c. 36 days; chicks have cream first down, then fawn second down; fledging 30-35 days. Can breed within first year. Success varies according to rat abundance: 17 pairs laid 19 eggs and fledged 2 young in non-plague year; 9 nests produced 31 eggs and 19 fledglings during plague year.

Movements. Dispersive and irruptive. Breeding birds concentrate around rat plagues, slowly moving with advancing plague front. When plague collapses, many birds (mostly immatures) disperse randomly towards coast where they die of starvation. Subsequent repopulation of arid zone by nucleus of surviving adults that stay put.

Status and Conservation. Not globally threatened. CITES II. Conservation status is of some concern. Generally uncommon; core breeding range and population small and subject to habitat degradation by overgrazing, which exacerbates effects of regular droughts. Breeding colonies also threatened by increase of feral cats, which occupy nests and eat young. Irruptions give false impression of abundance; these birds are the doomed surplus.

Bibliography. Baker-Gabb & Pettigrew (1982), Cameron (1974), Cupper & Cupper (1981), Ey (1984), Garnett (1992), Hollands (1977, 1979, 1984), Marchant & Higgins (1993), Olsen & Marples (1993), Olsen, Crome & Olsen (1993), Pettigrew (1982), Schodde & Mason (1980), Schodde & Tidemann (1988).

Genus CHELICTINIA Lesson, 1843

23. African Swallow-tailed Kite

Chelictinia riocourii

French: Élanion nacler

German: Schwalbenschwanzar

Spanish: Elanio Golondrina

Other common names: Swallow-tailed/Scissor-tailed/Fork-tailed Kite

Taxonomy. *Elanoides riocourii* Vieillot, 1822, Senegal.

Sometimes included within genus *Elanus*, to which closely related, but usually awarded monotypic genus on grounds of morphology, insect food and gregarious habits. Monotypic.

Distribution. Senegambia E to Ethiopia and Somalia, and S to NE Uganda and NE Kenya, in Kedong Valley.

Descriptive notes. 35 cm; one fat individual 110 g. Tern-like in flight, and in coloration and elongate outer tail feathers, with black bar across underwing-coverts. Pumps tail up and down when agitated like *Elanus caeruleus*. Juvenile has rufous edges to dorsal feathers and less forked tail.

Habitat. Arid sub-Saharan steppe and scrub savanna. Roosts colonially at night.

Food and Feeding. Mainly insects and arachnids; takes more lizards and rodents when it is breeding. Hunts mainly on the wing, soaring and hovering buoyantly, before descending to hawk prey or pick it up from ground; some-

times quarters low over ground. Often eats on the wing. Usually gregarious, hunting in loose flocks, sometimes over cattle. Attracted to grass fires to catch fleeing insects, and hundreds may gather at grasshopper emergences.

Breeding. Laying May-Jun in W Africa; Mar-Jun, Aug in N Kenya. Builds small stick nest in dense thorny bush, often in association with other nesting raptor species; once just below active nest of Secretarybird (*Secretarius secretarius*). Nests become coated in white droppings and conspicuous. Usually 4 eggs; incubation and fledging periods unrecorded. Often nests in loose colonies.

Movements. Performs regular movements, but extent varies annually. In W Africa, moves S in Nov at start of dry season, and N to breed in Sahel zone when rains start in Feb. In E Africa moves S in Mar to breed, also during rainy season; small population resident in some areas of N Kenya, e.g. Kedong Valley; other birds may occur further S, but generally only as irregular non-breeding vagrants.

Status and Conservation. Not globally threatened. CITES II. Little studied; status difficult to assess due to nomadic habits. May be locally common at times, but vulnerable to degradation of Sahel zone. Appears to have declined over much of W Africa since 1970, especially during locust control operations of 1986-1989, despite its potential as an important locust predator. Vulnerable to pesticides.

Bibliography. Ash & Miskell (1983), Blankenship *et al.* (1971), Brown *et al.* (1982), Davey & Davey (1980), Dewhurst & Fishpool (1984), Gatter (1988), Gore (1990), Grimes (1987), Hollom *et al.* (1988), Jensen & Kirkeby (1980), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957-1973), Morel & Morel (1990), Mullie *et al.* (1992), Nikolaus (1987), Serle *et al.* (1977), Short *et al.* (1990), Snow (1978), Sutton *et al.* (1984), Thiollay (1978c).

Genus ROSTRHAMUS Lesson, 1830

24. Snail Kite

Rostrhamus sociabilis

French: Milan des marais

German: Schneckenweih

Spanish: Caracolero Común

Other common names: Everglade Kite (*plumbeus*)

Taxonomy. *Herpetotheres sociabilis* Vieillot, 1817, Corrientes, near Río de la Plata, Argentina. Highly specialized genus, with no clear taxonomic affinities to other genera. Cuban population sometimes awarded separate race, *levis*. Three subspecies currently recognized.

Subspecies and Distribution.

R. s. plumbeus Ridgway, 1874 - Florida Everglades (SE USA), Cuba and I of Pines.

R. s. major Nelson & Goldman 1933 - E Mexico and Petén (Guatemala).

R. s. sociabilis (Vieillot, 1817) - Honduras and Nicaragua through Panama to South America, occurring W of Andes in Colombia and Ecuador, and E of Andes throughout to NE Argentina, except Guyana Massif and Brazilian Plateau.

Descriptive notes. 40-45 cm; 360-393 g; wing-span 115 cm. Very slender, strongly curved bill; both sexes differ from *R. hamatus* in red iris. Adult male slate grey, with black wing tips; black tail with large white patch at base and narrow white terminal band; bare parts orange-red, duller outside breeding season. Female buffy brown above, white to buffy with heavy brown streaking below; bare parts yellow to orange; slightly larger than male. Immature similar to female, but iris brown; takes 4 years to attain full adult plumage. Races distinguished by size.

Habitat. Lowlands of subtropics to tropics; needs marshes continuously flooded for at least

2 years to accumulate sufficient prey (snails). In Surinam, large flocks, mostly of immatures, congregate throughout year around rice plantations. In Florida (USA), 97% of foraging over sparsely vegetated marshes, as can not feed where dense, sometimes exotic (e.g. water hyacinth), vegetation hides prey. Congregates at end of day in large communal roosts, of over 1000 birds, often associated with herons, in marshes; same sites can be nesting colonies. Most roosts not used for more than 3 years, reflecting changing conditions of marshes, and nomadic habits of birds, which must keep near prime snail areas.

Food and Feeding. Highly specialized morphologically to feed on apple snails (*Pomacea*), but will take other snails and very different prey during droughts, including turtles, crabs, rodents. In Venezuela, diet shifts to 10% freshwater crabs, as snail availability decreases. Takes medium-sized snails disproportionately; adults take larger prey than juveniles, although largest items usually taken to nest. Modified bill used to sever snail's columellar muscle, freeing it quickly and easily from shell. Snatches snails from shallow water (down to 16 cm deep) with feet, then perches to extract snail from shell. Hunting occurs from perch, with bird sallying short distances to a snail seen from perch; also from coursing flight (less than 10 m up) over appropriate habitat; females more successful at coursing hunting than males. Occasionally steals snails from foraging Limpkins (*Aramus guarauna*), approaching and striking from behind. Forages throughout most of day. In Florida, birds seen defending feeding territories where snails superabundant in 30 m x 75 m stretch of canal. Up to 26% of birds arriving at roost carry snails in bill.

Breeding. Duration variable, 5-10 months. Nests Feb-Jul in USA; rainy season in tropics, e.g. Jan-Jul in Surinam; Oct-Feb in Argentina. Nests in loose colonies, nests sometimes only a few metres apart; 90 nests in one colony in Surinam. Stick nests often on small branches of live or dead trees. Both sexes take part in all stages of nesting. Usually 2-3 eggs; second and third clutches possible; incubation 26-28 days; chicks have buff first down, dark greyish brown second down; fledging c. 40-49 days, although birds can leave nest considerably earlier. First breeding at only 10 months old. Practises both serial polygyny and polyandry in Florida and N South America; when food abundant, either member of pair may desert to renege with different mate (see page 75). Nests with smaller clutches and those near good food supplies have higher chance of desertion. Very low mortality of single-parent chicks, e.g. only 1 from 28 nests. Very high overall failure rate, e.g. 86-64% of nests in a study in Florida; mostly due to nest predation and unstable nest structures; nonetheless, this population has increased in years of prey abundance, because of renegeing, long breeding season and high survivorship of fledged young. Species seems to have low fecundity, moderate first year survival rate and very high adult survival rate.

Movements. Southernmost populations migratory, although transition between migratory and resident populations not documented; otherwise nomadic in response to droughts or drainage of feeding areas. Leaves S Brazil in Apr, returning in Sept, some birds moving to Pantanal, where groups of up to 600 congregate in feeding areas; most common along R Paraguay in Oct, when large numbers move S in loose flocks. Occasionally wanders to lower temperate zone in Andes. Will commute over large distances between feeding and nesting areas.

Status and Conservation. Not globally threatened. CITES II. Often abundant in suitable habitat throughout most of range. "Boom or bust" cycles closely tied to droughts in Florida, where population c. 500 individuals, surveyed annually. Rare through much of Central America; on increase in Cuba, where now widespread. Locally fairly common in Colombia; large numbers congregate in Chaco-Pantanal zone outside breeding season. Nomadic habits make it difficult to protect species with "key" areas, as flocks will move off when droughts hit. Florida population was down perhaps to under 50 individuals in mid-1960's, but now seems to have recovered significantly with eightfold increase from lowest levels by 1980, when most of population confined to areas around three freshwater containment areas; breeding success entirely dependent upon water levels in swamps, now largely controlled by man; during drought periods, some areas can be maintained flooded to support the population. In Brazil, adversely affected by introduced *Tilapia* fish, which remove vegetation on which snails live. Also affected in many areas by drainage or deterioration of wetlands. Pesticides

may be major threat, and very high concentrations have been found in nestlings and eggs in Florida; in Surinam, 50 birds found dead after spraying of rice fields.

Bibliography. Albuquerque *et al.* (1986), Amadon (1983), Beissinger (1983, 1984, 1986, 1987a, 1987b, 1990a, 1990b), Beissinger & Snyder (1987), Beissinger & Takekawa (1983), Beissinger, Sprunt & Chandler (1983), Beissinger, Thomas & Strahl (1988), Blake (1977), Bourne (1985a, 1985b), Carey (1985), Chandler & Anderson (1974), Cintra & Yamashita (1990), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Garrido (1985), Haverschmidt (1954, 1959b, 1962, 1970), Hayes (1991), Hilty & Brown (1986), Kushlan & Bass (1983b), Mader (1981), Meyer de Schauensee & Phelps (1978), Miller & Tilton (1985), Murphy (1955), Nichols *et al.* (1980), Nicholson (1926), Palmer (1988), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Rodgers *et al.* (1988), Sick (1985a, 1993), Slud (1964), Snyder & Kale (1983), Snyder & Snyder (1969, 1970), Snyder *et al.* (1989), Sprunt (1945), Stieglitz & Thompson (1967), Stiles & Skutch (1989), Sykes (1979, 1983a, 1983b, 1984, 1985a, 1985b, 1987), Sykes & Kale (1974), Takekawa & Beissinger (1983, 1989), Vermeer *et al.* (1974), Voous (1969), Voous & Van Dijk (1973), Wetmore (1965), Wiley (1985, 1986), Wotzkow (1985).

25. Slender-billed Kite

Rostrhamus hamatus

French: Milan à long bec

German: HakenweiB

Spanish: Caracolero Plomizo

Taxonomy. *Falco hamatus* Temminck, 1821, Brazil.

Traditionally, and perhaps more appropriately placed in its own genus, *Helicolestes*, due to marked differences with *R. sociabilis* in proportions and shape (especially in flight), style of flight, calls, display and habitat. Monotypic.

Distribution. E Panama, through N & E Colombia, to W, N & SE Venezuela and Surinam; also S through Amazonian Brazil to E Peru and N Bolivia (Beni); limits of range poorly documented, in part due to confusion with *R. sociabilis*.

Descriptive notes. 37-41 cm; male 377-448 g, female 367-485 g. Slate grey, primaries and tail black; iris to yellow white, legs, cere and facial skin orange-red. Separated from male *R. sociabilis* by eye colour, dark rump, broader wings and much shorter tail. Sexes alike. Immature similar, but tail has 2-3 white bars and white tip; buff or white edging to wing-coverts, secondaries and rump.

Habitat. Flooded forest margins. Rain forest, edges of swampy forest, especially *várzea*; also stagnant lagoons, and wooded plantations, up to 700 m. Regularly soars in groups, although not very high up.

Food and Feeding. Specializes on snails of genus *Pomacea*. Extracts snail from shell by piercing and severing its columellar muscle at point of attachment to shell. Usually hunts from a low perch. In one study, 8% of diet was freshwater crabs (*Dilocarcinus dentatus*).

Breeding. Poorly known. In Venezuela and the Guianas, nests Jul-Oct, during wet season. Nests about 1 km apart. Flimsy stick nest, on average 14 m high on slanting limbs or in crotch of tree, in flooded gallery forest; trimmed with fresh boughs by both adults. 2 eggs (possibly more); incubation c. 30 days; chicks have brown down with some whitish markings; fledging 35 days, with birds flying at 40 days. Both sexes incubate, brood and feed young. No evidence of sequential polyandry or polygyny, as in *R. sociabilis*.

Movements. No movements reported.

Status and Conservation. Not globally threatened. CITES II. Poorly known, and requires further study. Restriction to gallery forest and flooded forest may make species very susceptible to effects of deforestation; highly specialized diet.

Bibliography. Amadon (1964), Beissinger *et al.* (1988), Blake (1977), Cabot & Serrano (1986), Haverschmidt (1959b), Hilty & Brown (1986), Mader (1981), Meyer de Schauensee & Phelps (1978), Pearson (1975), Pinto (1964), Ridgely & Gwynne (1989), Sick (1985a, 1993), Thiollay (1989b), Voous (1969), Voous & Van Dijk (1973), Wetmore (1965).

Genus HARPAGUS Vigors, 1824

26. Double-toothed Kite

Harpagus bidentatus

French: Milan bidenté

German: DoppelzahnweiB

Spanish: Milano Bidentado

Taxonomy. *Falco bidentatus* Latham, 1790, Cayenne.

Genus distinctive, with no very close allies, but belongs in same subgroup as *Elanus*; relationship with *Accipiter* claimed, due to similarity in plumage, but now discredited; some similarities with *Aviceda*. Two subspecies recognized.

Subspecies and Distribution.

H. b. fasciatus Lawrence, 1869 - E Mexico (Oaxaca and Veracruz) to W Colombia and W Ecuador.
H. b. bidentatus (Latham, 1790) - E Colombia and E Ecuador through Amazonia to E Bolivia (Beni) and SE Brazil; Trinidad.

Descriptive notes. 33-38 cm; 168-229 g. Double "tooth" in upper mandible. More similar to an *Accipiter* than to other kites; prominent white undertail-coverts. Head dark grey, throat white with dark central stripe; dorsally paler grey, blackish tail tipped grey with three greyish bands; breast and belly predominantly rufous, with grey and whitish barring on belly, and sometimes on lower breast. Eyes red, cere greenish yellow, legs and feet yellow. Female slightly larger with browner wings and rump, barred breast and much more rufous ventrally. Immature deep brown above; ventrally whitish to buff with vertical brown streaking. Race *fasciatus* more heavily barred on breast and upper belly; somewhat less rufous below.

Habitat. Tropical and occasionally subtropical zones, to c. 1200 m in Colombia, 2100 m in Ecuador; rain forest, forest edge, clearings, second growth and disturbed forest. One nest in highlands of Costa Rica, at 1233 m. Soars over the forest, but hunts under the canopy.

Food and Feeding. Mostly arthropods and small vertebrates, especially lizards and sometimes frogs. Prey usually taken in upper storeys of forest. Regularly follows primates quite closely, catching

lizards, cicadas, other arthropods and tent-making bats (once) flushed by the monkeys. Sometimes two adults follow, occasionally with juvenile, perching from 30 m away to within periphery of foraging troop. Reported following: tamarins *Saguinus mystax*, *S. fuscicollis* and *S. bicolor* in Brazil; often squirrel monkey *Saimiri oerstedii*, and sometimes capuchin *Cebus capucinus* in Costa Rica and Panama; also tamarin *Saguinus geoffroyi*, and less frequently red howler (*Alouatta*) and spider monkeys (*Ateles*) in Panama. 19% of *Harpagus* observations had kites in association. In some areas, spends twice as much time with monkeys in rainy season as in dry season; elsewhere, no significant diurnal or seasonal variation in attendance of monkey troops. Will hover over resting tamarin, touching it with talons, perhaps to get it moving. Capuchins (*Cebus*) sometimes try to catch perching kites; *Saguinus mystax* and *S. fuscicollis* will try to drive away perched kites, and give alarm calls when kites are flying. Relationship seems to be parasitic rather than commensal, with no apparent protection through similarity to more aggressive hawks.

Breeding. Nest building in early Apr in Mexico; incubation in early Jul in Panama. Nest is shallow saucer of twigs in small limbed fork of tree; placed 7-33 m off ground, often at forest edge; in Panama, nest in thick foliage of spiny cedar (*Bombacopsis fendleri*). Courtship feeding recorded. One nest in Costa Rica had 2 nestlings. After fledging 1 parent roosts on nest while young still in vicinity. One nest in Panama unsuccessful due to predation by toucan.

Movements. No movements known.

Status and Conservation. Not globally threatened. CITES II. No immediate cause for concern, but species will not persist in areas of extensive deforestation. Relatively common in appropriate habitat. Estimated average density of at least 15 individuals/10,000 ha at one forest site in French Guiana.

Bibliography. Amadon (1961b, 1964), Blake (1977), Boinski & Scott (1988), Boinski & Timm (1985), Cabot & Serrano (1986), Egler (1991), French (1992), Fontaine (1980), Greenlaw (1967), Heymann (1992), Hilty & Brown (1986), Laughlin (1952), Meyer de Schauensee & Phelps (1978), Monroe (1968), Olson (1987), Pinto (1964), Ridgely & Gwynne (1989), Schubart *et al.* (1965), Sick (1985a, 1993), Skutch (1965), Slud (1964), Stiles & Skutch (1989), Terborgh (1983), Thiollay (1985b, 1989b, 1991a), Voous (1969), Wetmore (1965).

27. Rufous-thighed Kite

Harpagus diodon

French: Milan diodon

German: BraunschenkelweiB

Spanish: Milano Muslirrufo

Taxonomy. *Falco diodon* Temminck, 1823, Villa Viçosa, Rio Peruípe, Bahia, Brazil.

Plumage shows very close resemblance to *Accipiter bicolor*, perhaps suggesting protective mimicry. Monotypic.

Distribution. Locally in the Guianas, through E Brazil (Amazonia W to R Branco and R Purús) S to E Bolivia (Santa Cruz), Paraguay and N Argentina (Misiones, Jujuy and Salta).

Descriptive notes. 30-35 cm. As in *H. bidentatus*, upper mandible has two notches, resembling teeth. Both adult and immature plumages strikingly similar to corresponding plumages of *Accipiter bicolor*. Above slate grey, tail feathers with three pale bars and white tips; throat whitish with dark central streak; below grey fading to white undertail-coverts, with chestnut thighs. Eye red or orange, cere lemon yellow, legs yellow to orange. Female similar, but slightly larger. Immature dark brown above; side of head streaked; below whitish with fuscous streaking on breast and belly, barring on flanks; chestnut thighs.

Habitat. Primary lowland rain forest. Reported by some authors to be present in dense forest, but by others to be found in more open forests than *H. bidentatus*; in French Guiana, found only in primary forest, while *H. bidentatus* is more tolerant of disturbed forest and second growth. Regularly soars over the forest, but hunts in middle to lower strata. More mesic and open forests in E Brazil, but dense forest in Argentina.

Food and Feeding. Very few data available; insects, including cicadas; presumably also lizards. Close similarity to bird-eating *Accipiter bicolor* may frighten small birds, which might otherwise mob present species and diminish its foraging success on lizards and large insects. Sometimes follows *Eciton* army ant swarms, feeding on flushed insects.

Breeding. Very little known. One nest in Minas Gerais, Brazil, built of twigs, lined with leaves in a small tree; contained 2 eggs on 21 Oct (austral spring).

Movements. No information available; presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Status very poorly known; generally rare, but perhaps overlooked. Estimated average density of at least 4 individuals/10,000 ha at one site in French Guiana.

Bibliography. Amadon (1961b), Belton (1984), Blake (1977), Navas & Bó (1991), Olrog (1985), de la Peña (1992), Pinto (1964), Remsen & T aylor (1989), Ruschi (1979), Sick (1985a, 1993), Snyder (1966), Thiollay (1985b, 1989a, 1989b), Willis (1976).

Genus ICTINIA Vieillot, 1816

28. Mississippi Kite

Ictinia mississippiensis

French: Milan du Mississippi

German: MississippweiB

Spanish: Elanio del Mississippi

Taxonomy. *Falco mississippiensis* [sic] Wilson, 1811, below Natchez, Mississippi.

No clear affinities to other genera. Forms superspecies with *I. plumbea*. Monotypic.

Distribution. Southern tier of USA, from Arizona to Florida. Winters in South America, S to N Argentina and Paraguay.

Descriptive notes. 35-38 cm; 220-390 g, female slightly larger; wingspan 96 cm. More like falcon than hawk; adult solid medium grey body with blackish wings and tail. Paler than *I. plumbea*, with orangish to blackish legs; lacks rufous in wing and whitish bars on undertail. Juvenile brown with streaked underparts, and conspicuous pale bars on tail.

Habitat. Woodlands, shelterbelts (windbreaks), and clumps of trees (farm lots) for nesting; woodland edge, grassland and savanna preferred for feeding. Common in man-altered habitats, e.g. agricultural land and some towns. Riparian habitats with trees. In Neotropical non-breeding grounds also occupies open and edge habitats, and savanna; forages over woodland.

Food and Feeding. Insects constitute c. 90% of food, e.g. cicadas, katydids, grasshoppers, dragonflies and beetles. Vertebrates taken are mainly amphibians, reptiles, small rodents or bats. Feeds mainly

on the wing in apparently effortless manner; feeds on insects flushed by herding ungulates or by fires.

Breeding. May-Jul. Nests in loose semi-colonial aggregations; as little as 0.3 ha per territory, or nests 125 m apart, in linear, riparian habitat. Nest built 2-45 m above ground, in trees of many species, but conifers little used; stick nest frequently appears flimsy, and usually placed in branch crotches with 3-4 supporting limbs; shallow nest bowl lined with mat of green leaves, and greenery added frequently. Usually 2 eggs; incubation 29-31 days; chicks have white down, with greyish black eye-rings

and lores; fledging c. 34 days, but chicks may climb from nest by day 25. Found paired as yearlings, but yearlings are also helpers at nests with adult pairs. May live to 8-9 years, but high 2nd year mortality of 50-60%. Nest success c. 55% of attempts; c. 0.6 young fledged per attempt.

Movements. Long distance Neotropical migrant; pre-migratory flocks by early Aug. Loose aggregations of 200-300 birds moving S by early Sept. Birds move S as far as N Argentina and Paraguay, but extent of Neotropical range poorly known. May remain on austral grounds into Mar. In late Apr, as many as 2300 birds per day moving N through coastal Mexico.

Status and Conservation. Not globally threatened. CITES II. Declined early in century but currently (1993) on increase, perhaps because of habitat modifications involving tree planting in steppe regions and opening of forests elsewhere. Range expanding; has recently colonized towns in plains and moved into riparian regions in SW. Total population may be a minimum of 274,000 individuals (migration count). Not threatened by pesticides. Lack of reforesting, after clutch loss, and small clutch sizes reduces reproductive potential, which might be a threat if mortality increased.

Bibliography. Blake (1977), Bolen & Flores (1993), Boteho *et al.* (1993), Contreras *et al.* (1990), Davis (1989), Eisenmann (1963), Evans (1981), Fitch (1963), Friedmann (1950), Gennaro (1988), Glinski & Gennaro (1988), Glinski & Ohmart (1983), Hilty & Brown (1986), Johnsgard (1990), Kalla & Alsop (1983), Love *et al.* (1985), Meyer (1990), Monroe (1968), Palmer (1988), Parker (1974, 1976, 1977), Parker & Ogden (1979), Parker & Ports (1982), de la Peña (1992), Ridgely & Gwynne (1989), Shaw (1985), Shaw & Maxwell (1988), Sick (1985a, 1993), Slud (1964), Smith, J.W. (1986), Smith, N.G. (1985), Snyder & Snyder (1991), Snyder & Wiley (1976), Sweet (1986, 1991), Thiollay (1977d, 1980a).

29. Plumbeous Kite

Ictinia plumbea

French: Milan bleuâtre

German: Schwebeweih

Spanish: Elanio Plomizo

Taxonomy. *Falco plumbeus* Gmelin, 1788, Cayenne.

Sometimes treated as conspecific with *I. mississippiensis*, with which forms superspecies. Monotypic. **Distribution.** NE Mexico (Tamaulipas) S through Central America to South America, W of Andes S to W Ecuador, E of Andes S to Paraguay and N Argentina.

Descriptive notes. 34-37.5 cm; male 190-267 g, female 232-280 g. Inner webs of primaries chestnut rufous, very conspicuous in flight; wings longer in relation to tail than in paler *I. mississippiensis*, extending beyond tail when bird perched. Above blackish slate grey; below and on head pale grey; tail black with 2-3 pale bars on undersurface. Legs yellow to orange red, iris red (yellow in Ecuador). Female slightly larger. Immature heavily streaked dusky on head, neck and underside; back blackish, with contour feathers tipped white; tail with three distinct bars below; rufous wing patch of adult also present.

Habitat. Lowlands of tropical and subtropical zones, along forest edge and gallery forest; also over primary forest, often near rivers. Recorded at 2300 m and 2600 m in Colombia.

Food and Feeding. Insects are primary prey, representing over 95% of recorded prey items; a few snakes and snails also reported. Hunts from perch or on the wing, often in flocks; most prey captured in flight, but some snatched off canopy foliage. Seasonally feeds in association with marmosets in Minas Gerais, SE Brazil; follows singly or in pairs for 2-6 hours per day, in morning, catching fleeing cicadas in the air after short flights.

Breeding. Mar in Central America; Mar-May in Colombia; Aug near Puyo, EC Ecuador; starts in Sept in Argentina, while migrating flocks still arriving, with chicks in Dec and Feb. Stick nests shallow but bulky, placed high in trees on thick branches, sometimes over water in mangrove swamps. 1-2 eggs; incubation 32-33 days; chicks have white down; fledging c. 1 month. Both adults feed young in nest. Nesting pairs very aggressive to any passing bird near the nest; one adult will remain perched over nest for hours on end.

Movements. Migratory in N and S of range in respective autumns; N birds move S through Panama in Aug and Sept, returning to breed in Mar; Central American population certainly migratory, while even those in N Venezuela and Colombia may migrate S during dry season, when insects less abundant. Limits of permanently resident populations not known. Flocks appear sporadically over C Amazon; may be nomadic migrants.

Status and Conservation. Not globally threatened. CITES II. Relatively common, e.g. in parts of Brazil and Colombia. Estimated average density of at least c. 9 individuals/10,000 ha at one forest site in French Guiana.

Bibliography. Genus MILVUS Lacépède, 1799

30. Red Kite

Milvus milvus

French: Milan royal

German: Rotmilan

Spanish: Milano Real

Taxonomy. *Falco Milvus* Linnaeus, 1758, Sweden.

Race *fasciicauda* may be distinct species; hybridizes with *M. migrans*. Two subspecies recognized.

Subspecies and Distribution.

M. m. milvus (Linnaeus, 1758) - S Sweden E to Ukraine and S through C Europe to W & C Mediterranean Basin; Wales; Caucasus; formerly Canary Is.

M. m. fasciicauda Hartert, 1914 - Cape Verde Is.

Descriptive notes. 61-66 cm; 757-1221 g; wingspan 175-195 cm. Larger than *M. migrans* and redder brown; tail more clearly forked and reddish on top; head whiter; underwing shows larger, whiter patches on primaries. Juvenile has paler body, darker head and less rusty coloured tail. Race *fasciicauda* smaller and darker. **Habitat.** Open wooded land; varied country, including forests or woods mixed with farmland, pasture or heathland. Normally at low or medium altitudes, but occurs in woods up to 2500 m in Morocco. In winter, tends to occupy more open areas, e.g. farmland without trees, wasteland, scrub and wetlands; also in winter.

roosts in groups of up to 100+ in clumps of trees, which may be traditional sites, although sedentary adults seem to continue roosting on or near their nests. Historically occurred in cities, e.g. urban scavenger in London in 16th century; still quite closely associated with man, visiting rich feeding areas on edges of towns, e.g. rubbish dumps.

Food and Feeding. Wide range of food types, but essentially carrion and small or medium-sized mammals and birds; diet varies according to local availability, with proportionally more prey captured during breeding. Carrion includes sheep and other livestock, dogs, cats, chickens and their eggs, and all sorts of small animals, including animals knocked down on roads and those wounded by hunters. In Doñana (S Spain), Greylag Goose (*Anser anser*) and other Anatidae are important source of carrion, due to their abundance in winter. Mammals hunted include rodents (voles, rats, mice, hamsters, muskrats), insectivores (moles, shrews), lagomorphs (rabbits, hares); birds, especially juveniles, include Corvidae (magpies, jackdaws, crows), Black-headed Gulls (*Larus ridibundus*) in Wales, and thrushes, larks and starlings. Reptiles, amphibians and fish generally much less important, as (at least in terms of weight) are invertebrates, e.g. beetles, grasshoppers and earthworms, all taken on ground, and alate ants, taken on wing. Forages mainly in open areas, with low flapping or gliding flight, or by diving onto terrestrial prey from higher, soaring flight. Often visits rubbish dumps in search of offal and waste from abattoirs; from nest will travel up to 8 km to hunt, and from roost moves much further afield.

Breeding. Laying Mar-May. Nests in trees, coniferous or broad-leaved, in forests, woods or clumps of trees. Each pair normally has several nests, using same one each year or alternating. Nest built in fork of tree or on wide side branch; platform of sticks which often includes rags or plastic, and normally lined with wool. Normally 2 eggs, sometimes 3 (1-4), laid at interval of 3 days; replacement laying occurs; incubation 31-32 days per egg, essentially by female, starting with first egg; female also broods and feeds chicks, though male brings most food; chicks have buff-coloured first down, second down tinged reddish; fledging 50-60 days; chicks fed by adults for at least 2-3 weeks more. 1 or 2 chicks fledge, very occasionally 3. First breeding sometimes at 2 years, but normally later, up to 7 years. Adult survival rate possibly 95% in Wales. Can live to 26 years old (38 in captivity). **Movements.** Mainly migratory in N and C Europe, although increasing tendency to winter in these areas, including S Sweden. Populations in S of range and Wales sedentary, with varying degree of dispersal of juveniles. The vast majority of migrants winter in S France and especially Iberian Peninsula, passing over W Pyrenees, where 10,300 birds recorded on autumn migration in 1989. Some migration to N Africa, mainly via Gibraltar; recorded S even to S Africa.

Status and Conservation. INSUFFICIENTLY KNOWN. CITES II. Historical decline from 19th century or earlier, leading to current disjunct distribution; basic causes direct persecution and use of poisoned baits. Following protection measures, notable recovery in C and N Europe. World population estimated in early 1990's at 11,000-12,000 pairs, subject to considerable variation with new data about certain populations. Highest estimates are for France with c. 2300-2900 pairs. Germany c. 4000-4500 pairs, Spain perhaps 3000 pairs, Switzerland c. 230-300 pairs, Italy 180-230 pairs (in decline), Poland c. 300-500 pairs, and Sweden c. 200 pairs. Almost wiped out of SE Europe; very rare in former USSR; formerly common, though not numerous in W & C Ukraine, but, due to deforestation and direct persecution, has declined steeply, and now very rare; possibly extinct in Turkey. Only a few dozen pairs in Morocco; extinct as breeder in Canary Is at end of 1960's, probably due to massive use of insecticides against locusts; in Cape Verde Is (race *fasciicauda*) has hybridized with invading *M. migrans*; by late 1980's, possibly only 50-100 birds remained, and these hybridized to greater or lesser degrees. Status in Mediterranean islands of some concern, although population seems stable in Corsica, with 100-180 pairs in early 1990's. Almost extinct in Britain by end of 19th century; residual Welsh population has gradually grown, reaching 79 breeding pairs in 1992; reintroduced to Scotland and England in 1989, breeding successfully for first time in 1992. Main threats still include hunting, as species conspicuous with slow flight, making it an easy target for shooters; poisoning too continues; may also be greatly affected by decline in extensive livestock farming, and elimination of small rural rubbish dumps.

31. Black Kite

Milvus migrans

French: Milan noir

German: Schwarzmilan

Spanish: Milano Negro

Other common names: Black-eared/Eared/Large Indian Kite (*lineatus*); Pauran/Indian Kite (*goyindai*); Yellow-billed Kite (*aegyptius*, *parasitus*); Fork-tailed Kite (*affinis*)

Taxonomy. *Falco migrans* Boddaert, 1783, France.

Hybridizes with *M. milvus* on Cape Verde Is. Several of races frequently awarded separate species status, most notably *lineatus* and *aegyptius* (incorporating *parasitus*); intergradation indicates probably best regarded as single species, with several well marked races. Seven subspecies normally recognized.

Subspecies and Distribution.

M. m. migrans (Boddaert, 1783) - NW Africa and Europe E to C Asia (Tien Shan) and S to Pakistan; winters S to Africa S of Sahara.

M. m. lineatus (J. E. Gray, 1831) - Siberia E to Amurland and Japan S to N India, N Burma and N China and Ryukyu Is; winters S to S Iraq, S India and SE Asia.

M. m. formosanus Nagamichi Kuroda, 1920 - Taiwan and Hainan (S China).
M. m. govinda Sykes, 1832 - E Pakistan E through India and Sri Lanka to Indochina and Malay Peninsula.
M. m. affinis Gould, 1838 - Sulawesi and possibly Lesser Sunda Is; E New Guinea and New Britain; N Australia S (in E) to Victoria.
M. m. aegyptius (Gmelin, 1788) - Egypt, SW Arabia and coastal E Africa S to Kenya.
M. m. parasitus (Daudin, 1800) - Africa S of Sahara, Cape Verde Is, Comoro Is and Madagascar.

Descriptive notes. 55-60 cm; 567-941 g; wingspan 135-155 cm. Mostly reddish brown; tail brown and only slightly forked. Juvenile generally paler and more heavily marked, with more contrasted pattern. Races vary most notably in bill colour; also in plumage and size.

Habitat. Ubiquitous, occurring from semi-desert, grassland and savanna to woodland, but avoids dense forest: wooded areas particularly important for nesting and roosting. Commonly aquatic habitats, e.g. rivers, lakes, wetlands, seashores and nearby in meadows and along margins of wetlands. Often linked with man to greater or lesser degree, frequenting suburbs,

harbours, villages, nomads' camps; has colonized, extremely successfully, large urban areas of Africa and Asia, e.g. Karachi (Pakistan). Normally in lowlands, but sometimes forages, and may breed, above 2000 m; even recorded on occasion foraging at around 4000 m, in Himalayas. Gregarious, sometimes roosting communally, mainly in trees.

Food and Feeding. Very adaptable; has become extensively commensal with man. Feeds on wide variety of animal remains, e.g. offal from abattoirs or fisheries, garbage, scraps, any kind of carrion. Also catches live prey: mammals, e.g. voles and other small rodents, moles, young rabbits and hares, bats; small birds, both terrestrial and aquatic, often juveniles, including chicks of domestic poultry; also fish, lizards, amphibians and invertebrates, e.g. grasshoppers, locusts, crickets, beetles, termites, flying ants, earthworms, crustaceans and molluscs. Fish often important in diet, normally dead or disabled, and especially small fish; invertebrates can be important locally or seasonally. More unusually, vegetable matter, particularly oil palm fruits. Catches prey on ground or water: large insects caught in air, and then eaten on wing. Often forages around margins of water bodies, and by refuse dumps, slaughterhouses or roads, where looks for animals knocked down by traffic. Flies up to 30+ km from roosts; slow, fairly low surveying flight, very agile and manoeuvrable; skilful, shameless urban scavenger, taking food from markets or busy streets; also steals from other raptors and other birds.

Breeding. Laying dates very variable, due to vast size of range: in temperate zones of Eurasia, Mar/Apr-Jun; in tropical Africa, normally in dry season; in S Africa, normally Aug-Dec; in Australia, variable, but mainly Jul-Nov in S. Solitary or loosely colonial, up to tens of pairs together. Normally nests in trees (broad-leaved, coniferous, palms), building nest in fork or on branch; also on cliff ledges, locally along coast, on buildings (e.g. Egypt, India) or on pylons. Nest, or nest-site at least, reused annually; stick nest lined with materials such as rags, plastic, paper, dung or skin. Normally 2-3 eggs (1-4), laid at intervals of 1-2 days; incubation 26-38 days, normally by female almost exclusively; if male brings sufficient food, female may not hunt during entire breeding attempt; fledging 42-50 days; young independent c. 15-36 days later. Up to 4 young per nest fledge, but usually only 1; average 0.9-1.2 per breeding pair. First breeding sometimes in first year. Oldest recorded bird 23 years.

Movements. Mainly migratory; at least, shows certain nomadic or dispersive tendency after breeding. Nominate *migrans* markedly migratory, wintering mainly in sub-Saharan Africa (S to South Africa), and to lesser extent in Middle East; *lineatus* also migratory, although only partially, or even resident, in China and Japan, but some wintering from SE Asia and Indian Subcontinent, W to Middle East. Race *govinda* makes movements to avoid monsoon, and depending on food availability; *parasitus* shows complex pattern, influenced, like *govinda* and *affinis*, by seasonal rains, with South African populations migrating N after breeding; *aegyptius* mainly resident, although appears S to Kenya and Tanzania outside breeding season. Race *affinis* has resident, partly migratory and irruptive populations; status of birds in Lesser Sunda uncertain, perhaps only vagrants from Australia. Migrates in flocks and gathers to cross sea straits; 40,000-60,000 birds in post-breeding migration at Gibraltar each year; 36,690 recorded in spring 1980 at Elat (Israel).

Status and Conservation. Not globally threatened. CITES II. One of commonest of all diurnal raptors, and regionally the commonest, e.g. in Japan and probably in Africa. Favoured by adaptability and also tolerance of man, although has suffered due to shooting and especially poisons, pesticides and chemical pollution of water; in decline over wide area, notably in most of Europe, former USSR and N Africa. Still abundant in much of range, e.g. sub-Saharan Africa and Indian Subcontinent, where c. 2400 pairs in Delhi alone in late 1960's; however, estimates of population sizes mostly lacking. In 1980's perhaps c. 20,000-24,000 pairs in Europe (excluding former USSR), including c. 9000 in Spain and 5800-8000 in France; in early 1990's, perhaps c. 60,000 pairs in European Russia and 500-600 pairs in Byelorussia; still fairly common, but declining throughout Ukraine. In Israel, in early 1970's, recolonization as breeder, and particularly as winter visitor, following extirpation due to agricultural pesticide poisoning in 1950's.

Genus HALIASTUR Selby, 1840

32. Whistling Kite

Haliastur sphenurus

French: Milan siffleur **German:** Keilschwanzweih **Spanish:** Milano Silbador
Other common names: Whistling Eagle/Hawk

Taxonomy. *Milvus sphenurus* Vieillot, 1818, New South Wales.

Placed in genus *Milvus* by some authorities, but differs in plumage, voice and behaviour. Monotypic.
Distribution. Australia, New Caledonia, and New Guinea (except NW and central mountains).

Descriptive notes. 51-59 cm; 380-1050 g; wingspan 123-146 cm. Similar to juvenile *H. indus* but has longer primaries and tail. Female larger and heavier than male. Juvenile heavily streaked and spotted. Larger in S than in tropics.

Habitat. Lightly wooded and open habitats, typically near or over terrestrial and marine wetlands; from sea-level to 1400 m. Nests in woodland, often riparian.

Food and Feeding. Variety of small animals and carrion, including mammals, birds, reptiles, fish, crustaceans, insects, road-killed vertebrates, large carcasses and offal. Forages by

quartering and high soaring; drops on prey, hawks flying insects, snatches prey from water surface. Patrols roads, and fronts of grass fires; robs other raptors.

Breeding. Season long and variable; most of dry season (austral autumn to spring) in tropics; usually late winter and spring in S. Solitary, but sometimes near raptors of other species. Platform of sticks 60-150 cm wide, 30-100 cm deep, lined with green leaves; placed 3-62 m above ground in fork of live or dead tree. Usually 2 eggs (1-4); incubation 35-38 days; chicks have cream or fawn down; fledging 44-54 days; post-fledging dependence 6-8 weeks. Oldest ringed bird 11 years. Success variously measured as: 60% hatching success, and 1.0 young per nest; 1.5 young per clutch started, and 1.3 young fledged per pair per year; and 96% fledging success in nests with young.

Movements. Partly migratory and dispersive within Australia. Migratory in S and SE, wintering in milder coastal and N areas; some birds resident in both temperate and tropical areas.

Status and Conservation. Not globally threatened. CITES II. Common to abundant on coasts, and in tropics where benefits from human activity; locally declining in S through drainage of wetlands and reduction in food supply. Eggshell thickness significantly reduced by DDT use in S agricultural areas (use now curtailed); some birds poisoned.

Bibliography. Baker-Gabb (1984a), Beehler *et al.* (1986), Bell (1985), Coates (1985), Cupper & Cupper (1981), Debus (1983a), Gilliard & LeCroy (1966), Hannecart & Létocart (1980), Hollands (1984), Klapste (1983), Marchant & Higgins (1993), Martin, K. (1992), Newgrain *et al.* (1993a), Olsen (1991), Olsen & Marples (1992, 1993), Olsen & Olsen (1987a), Olsen, Crome & Olsen (1993), Olsen, Fuller & Marples (1993), Schodde & Tidemann (1986), Sontler (1987).

33. Brahminy Kite

Haliastur indus

French: Milan sacré **German:** Brahminenweih **Spanish:** Milano Brahmán
Other common names: Red-backed/White-headed Sea-eagle, Red-backed Kite, Whistling Eagle

Taxonomy. *Falco Indus* Boddaert, 1783, Pondicherry, India.

Placed in genus *Milvus* by some authorities, but differs in plumage, voice and behaviour. Four subspecies recognized.

Subspecies and Distribution.

H. i. indus (Boddaert, 1783) - Pakistan, India and Sri Lanka through SE Asia to S China.

H. i. intermedius Blyth, 1865 - Malay Peninsula, Greater and Lesser Sundas, Sulawesi and related small islands, Philippines and Sula Is (C Moluccas).

H. i. girrenera (Vieillot, 1822) - Moluccas, New Guinea, Bismarck Archipelago and Australia.

H. i. flavirostris Condon & Amadon, 1954 - Solomon Is.

Descriptive notes. 45-51 cm; 320-673 g; wingspan 109-124 cm. Adult unmistakable. Female larger and heavier. Juvenile streaky brown; similar to *H. sphenurus*, but with shorter wings and tail. Regional variation in plumage and bill colour: Australasian races have pure white head and breast; Solomon Is birds have yellow bill.

Habitat. Coasts, estuaries, terrestrial wetlands and urban areas; in tropics ranges over forest, farmland and grassland far from water; from sea-level to 1800 m (to c. 2000 m in WC Sumatra). Nests in trees, often mangroves, near water; occasionally on artificial structures.

Food and Feeding. Variety of small animals and carrion, including mammals, birds, reptiles, amphibians, fish, arthropods, crustaceans, shellfish, cuttlefish, road-killed vertebrates, large carcasses and offal; sometimes domestic poultry. Forages by quartering and high soaring, or still-hunting from prominent perch; sometimes searches on ground. Seizes prey by glide or dive that may become short chase; hawks flying insects, snatches prey from tree canopy and water surface, and robs other predators.

Breeding. Dry season in tropics, late winter and spring in subtropics. Solitary. Platform of sticks and other flotsam 40-60 cm wide, up to 20 cm deep, lined with leaves and other soft material including human rubbish; placed 2-30 m above ground in tree or artificial structure. Usually 1-2 eggs (1-4); incubation c. 35 days (28 days in Bangladesh), by female; chicks have cream to fawn down; fledging c. 50-56 days (40-44 days in Bangladesh). Age at first breeding probably at least 2 years. Usually 1 young raised to fledging, sometimes 2, occasionally 3; of 6 recorded nests, 3 successful (each producing 1 young). In Bangladesh, 63-33% success for eggs hatched.

Movements. In Australia and Asia mostly resident, with some local movement; congregates round abundant food. Breeding pairs sedentary. Occasional visitor to N Vanuatu.

Status and Conservation. Not globally threatened. CITES II. Common to abundant and widespread in tropics, where benefits from human activity. Range contracting northwards in E Australia, where eggshell thickness significantly reduced by DDT use (now ceased), and population affected by habitat disturbance. Has undergone dramatic decline throughout Java, with several possible causes: excessive use of pesticides; hunting pressure, for stuffing; collection of nestlings for sale in markets; loss of nesting habitat; and perhaps decreased food availability, with improved urban hygiene. Also declining in non-coastal parts of Thailand.

34. White-bellied Sea-eagle

Haliaeetus leucogaster

French: Pygargue blagre German: Weißbauch-Seeadler Spanish: Pigargo Oriental
Other common names: White-breasted Fish-eagle/Sea-eagle

Taxonomy. *Fulco leucogaster* Gmelin, 1788, no locality = Java. Forms superspecies with *H. sanfordi*. Monotypic.

Distribution. India and Sri Lanka through SE Asia, Philippines, Wallacea, New Guinea and Bismarcks to Australia and Tasmania.

Descriptive notes. 75-85 cm; male 2120-2900 g, larger female 2900-3400 g; wingspan 180-218 cm. Adult unmistakable. Juvenile mottled brown with white tail, which distinguishes it from dark-tailed adult and juvenile *H. sanfordi*. **Habitat.** Inshore seas and islands, coasts, estuaries and terrestrial wetlands, ranging over nearby wooded and open habitats; from sea-level up to 1400 m, or to 1700 m on Sulawesi. Nests in forest, woodland and rocky areas.

Food and Feeding. Mammals, birds, reptiles, fish, carrion and tideline offal. Live prey includes rabbits, fruit-bats (*Pteropus*), waterfowl and seabirds to size of gull, cormorant and gan-

net; takes spiny and poisonous fish and sea snakes. Forages by quartering, high soaring or still-hunting from perch. Attacks by shallow glide or dive to snatch prey from ground or water surface; harries aquatic birds to exhaustion, snatches fruit-bats from tree roosts, robs other predators, and attends foraging dolphins.

Breeding. May-Sept in Australia (May-Aug in N, June-Sept in S, where exceptionally to Nov); dry season in Asia and tropics. Solitary. Platform of sticks 120-170 cm wide, 50-180 cm deep, lined with leaves, grass and seaweed; placed on ground or cliff on offshore islands, otherwise 3-40 m above ground in tree. Usually 2 eggs (1-3); incubation c. 40 days; chicks have white down; fledging 65-70 days. Age at first breeding 7 years in captivity; not before assumption of adult plumage (at c. 5 years) in wild. Success in S Australia: 1-3 young per successful nest, 1-1 per active nest, 0-8 per occupied territory per year; 34% of successful nests raised 2 fledglings, 66% raised 1.

Movements. Breeding adults sedentary, juveniles dispersive. Some movement forced when inland waters dry up. Sometimes follows large rivers for some considerable distance inland.

Status and Conservation. Not globally threatened. CITES II. Generally common, though some localized declines in S Australia through habitat destruction or disturbance to nest-sites; also declining in Thailand. May have benefited from introduced prey and rubbish dumps in some areas. Eggshell thickness significantly reduced by DDT use in Australia (use now ceased).

(1985), Smythies (1981, 1986), Tarr (1962), White & Bruce (1986).

35. Sanford's Sea-eagle

Haliaeetus sanfordi

French: Pygargue de Sanford German: Salomonenseadler Spanish: Pigargo de las Salomón
Other common names: Solomons/Brown Sea-eagle

Taxonomy. *Haliaeetus sanfordi* Mayr, 1935, Choiseul Island, Solomons.

Has been confused with, or considered a race of, *H. leucogaster*, with which it forms superspecies; separated by plumage. Monotypic.

Distribution. Solomon Is, including Bougainville I and Buka I.

Descriptive notes. 70-90 cm; female 2270-2725 g. Adult similar to juvenile *H. leucogaster*, but more uniform, with pale buff head and dark eyeline, tawny underparts and dark tail; pale area on median coverts. Female larger than male. Juvenile mottled brown, similar to juvenile *H. leucogaster* but with dark tail and darker underwing.

Habitat. Occurs from inshore water and tideline to montane rain forest near freshwater lakes (1500 m), mostly over coastal habitats. Reputedly nests in hill forest, but pair also seen courting over mangroves of coastal islet.

Food and Feeding. Much like other *Haliaeetus*, contrary to reports that it is more of a forest eagle. Mostly fish and tideline offal; also cuscus (*Phalanger*), fruit-bats (*Pteropus*) and reportedly birds such as pigeons. Patrols or perches overlooking coastline; takes fish and fish discards from water surface in manner of other sea-eagles; scavenges on beaches. Arboreal prey apparently snatched from forest canopy.

Breeding. Courtship in Aug. No first-hand ornithological observations of breeding, but a large stick nest in a forest tree was said by natives to belong to this species.

Movements. Unknown. Adults presumably sedentary, as inferred from isolation, morphology and lack of records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Range and total population size small, biology little known; species formerly considered threatened. Moderately common locally in undisturbed habitats where not persecuted; scarce or absent where subject to hunting or deforestation. Possibly subject to breeding failure through eggshell thinning where DDT used, but data lacking.

Bibliography. Blaber (1990), Brown, L.H. (1976b), Brown & Amadon (1968), Coates (1985), Collar & Andrew (1988), Fentzloff (1989, 1990), Hadden (1981), Mayr (1935, 1936, 1945a), Schodde (1977).

36. African Fish-eagle

Haliaeetus vocifer

French: Pygargue vocifère German: Schreiseeadler Spanish: Pigargo Vocinglero
Other common names: Fish/River Eagle

Taxonomy. *Falco vocifer* Daudin, 1800, Keurboom River, Cape Province, South Africa.

In past, frequently placed in genus *Cuncuma*. Forms superspecies with *H. vociferoides*. Monotypic. **Distribution.** Sengambia E to Ethiopia and S to South Africa.

Descriptive notes. 63-73 cm; male 1986-2497 g, female 3170-3630 g; wingspan 190 cm. White on head and breast more extensive in female; this coloration is also main difference from Madagascar *H. vociferoides*. Loud yelping calls, uttered with head thrown back while perched or in flight, often by pair in duet, synonymous with African waterways. Juvenile mottled brown, black and white, with a distinct intermediate plumage before adult at about 5 years old.

Habitat. Margins of large lakes, rivers, swamps and reservoirs; visits seashores in vicinity of estuaries and ranges up to 4000 m; will sometimes breed at such sites.

Food and Feeding. Mainly fish of 200-1000 g, but up to 4200 g. Also takes carrion, waterbirds (especially young of colonial species), small mammals, reptiles (e.g. monitor lizards, terrapins or crocodiles), amphibians, and even insects; whatever is necessary or locally vulnerable. Hunts mainly from a perch by swooping down to pluck prey from near the surface, "rowing" larger prey to shore. Rarely hunts when soaring, but regularly pursues and pirates other piscivorous birds. Perches for 85-95% of day in productive tropical habitat. Usually solitary but over 100 may gather at concentrations of stranded fish.

Breeding. May lay in any month in most regions, but locally seasonal and generally favours low-water conditions, with peak in Oct-Dec/Jan in W Africa; Jul-Oct in Uganda; Jun-Aug in S Africa. Builds large stick nest in high fork of tree as close to water as possible, rarely on cliff or steep slope. Usually 2 eggs (1-4); incubation 42-45 days; chicks have white down; fledging 65-75 days; often only 1-2 chicks survive to independence, about 2 months after fledging.

Movements. Resident around many permanent waterbodies, usually as territorial pairs. However, rapidly colonizes new or ephemeral habitat, as in E Namibia, and some post-breeding dispersal, as in Kenya, suggesting mobile non-breeding sector of population. Juveniles often congregate in areas away from territorial adults. Vagrant to N Egypt (Sinai).

Status and Conservation. Not globally threatened. CITES II. Common on many major rivers and lakes, often at high densities for such a large predator, needing only 300-600 m of shore per pair, or 3-15 ha of fishing area; at lower densities along forested rivers (10-20 km per pair in Gabon). Locally vulnerable to river degradation and hunting (e.g. Ivory Coast), but also adaptable through flexible feeding habits and rapid exploitation of new impoundments or prey. Known to be contaminated with pesticides in some areas of Zimbabwe and South Africa, but no obvious population effects.

Bibliography. Benson & Benson (1975), Brosset & Erard (1986), Brown, L.H. (1976b, 1980), Brown & Cade (1972), Brown & Hopcraft (1973), Brown *et al.* (1982), Cramp & Simmons (1980), Culverwell (1985), Davies & Randall (1989), Douthwaite (1992), Geldenhuys (1984), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Hines & Raats (1989), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Morgan (1979), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Prout-Jones & Milstein (1986), Smart (1991), Steyn (1960, 1972b, 1982), Sumba (1986, 1988, 1989), Sumba & Pomeroy (1984), Tarboton & Allan (1984), Thiollay (1981, 1985d), Thiollay & Meyer (1978), Thomson (1984), Whitfield & Blaber (1978).

37. Madagascar Fish-eagle

Haliaeetus vociferoides

French: Pygargue de Madagascar German: Madagaskarseadler Spanish: Pigargo Malgache
Other common names: Madagascar Sea-eagle

Taxonomy. *Haliaeetus* [sic] *vociferoides* Des Murs, 1845, Madagascar.

Forms superspecies with African *H. vocifer*. Monotypic.

Distribution. Madagascar; originally in all W coast regions, and possibly on E coast, but now confined to NW coast. May also have extended to Mauritius historically.

Descriptive notes. 70-80 cm; wingspan 200 cm. White tail against overall brown plumage distinctive; sharply defined white mask with dark streak through eye. Sexes similar. Juvenile duller brown with dark terminal band to tail. Much duller than African congener *H. vocifer* but with similar distinctive vocal display.

Habitat. Shores of seas, lakes and large rivers, favouring rocky offshore islands and wooded perimeters, including mangroves; occurs up to 1200 m. Now mainly coastal.

Food and Feeding. Mostly surface-dwelling fish, including introduced *Tilapia*, and some crabs. Hunts from perches over water and

roosts in tall trees near the shore. Spends long periods perched interspersed with some soaring high over territory. Plunge-dives to take prey from water surface. Attacks, and probably pirates prey from other waterbirds. Usually encountered in pairs.

Breeding. Laying Jun-Jul. Builds large stick nest, lined with green leaves, on an island cliff, mangrove or tree near water. Usually 2 eggs; incubation c. 41 days; fledging c. 120 days; chicks have white down; elder chick may eliminate its younger sibling.

Movements. None recorded; range now much reduced. Previous records from E coast and Mauritius suggest considerable dispersion.

Status and Conservation. ENDANGERED. CITES II. Only 45-50 breeding pairs at 48 occupied territories estimated in 1985; some pairs with mean inter-nest distance of 1-48 km. More intensive recent surveys (1992) indicate twice the previous known density in S part of range (21 pairs, as opposed to 10); maximum total may be c. 100 pairs. Appears to have been recorded from all

W coastal regions until about 1940, and was still reported regularly in SW until 1975. Now restricted to 600 km of shoreline and to rocky islands and lakes in the Antsalova region, between Antsiranana and Belo-sur-Mer. Exact reasons for decline remain uncertain. Persecution of adults and nests remains a problem; not found to be affected by pesticides, but degradation of waterbodies through deforestation and poor agricultural practices leading to soil erosion in catchment areas may be a primary concern.

Bibliography. Collar & Andrew (1988), Collar & Stuart (1985), Dee (1986), Delacour (1932), Ferguson-Lees & Faull (1992), King (1978/79), Langrand (1987, 1990), Langrand & Meyburg (1984, 1989), Meyburg (1979a), Milon *et al.* (1973), Rand (1936), Salvan (1971), Thiollay & Meyburg (1981), Watson, Berkelman *et al.* (1993).

38. Pallas's Fish-eagle

Haliaeetus leucoryphus

French: Pygargue de Pallas **German:** Bindenseeadler **Spanish:** Pigargo de Pallas
Other common names: Ring-tailed/Band-tailed Fishing-eagle

Taxonomy. *Aquila leucorypha* Pallas, 1771, lower Ural river.

Monotypic.

Distribution. C & S Asia, from Kazakhstan (possibly extinct) to Mongolia and NE China, S to Pakistan, N India, Burma and SC China (Sichuan).

Descriptive notes. 72-84 cm; 2040-3700 g; wingspan 180-205 cm. Mainly brown plumage, with head and neck golden sandy buff; rounded tail dark brown with conspicuous broad white band. Female somewhat larger than male. Juvenile more uniformly brown, including all of tail, but has pale band on underwing-coverts and pale panel on inner primaries.

Habitat. Rivers and lakes, freshwater wetlands and pools; often in arid areas or steppe. In winter, may visit inland seas. Present in high plateaus and valleys, reaching 5200 m in Tibet.

Food and Feeding. Mainly fish; also waterbirds, rodents, lagomorphs, frogs, reptiles

(snakes, turtles) and carrion; even human bodies on occasions. Fish caught near surface, without plunge; alternatively taken as carrion; also steals from Ospreys (*Pandion haliaetus*) and other birds. Chicks of waterbirds sometimes stolen from colonies.

Breeding. Laying Oct-Feb in N India; later further N, formerly Mar in Kazakhstan and May in Tibet. Both adults build enormous nest of sticks and branches, lined with fresh leaves; normally in large tree near water, but, if necessary, can be built in reedbeds or on ground; same nest reused repeatedly. Normally 2-3 eggs, sometimes 4; incubation c. 40 days, mainly by female; chicks have first down brownish grey, second down greyish brown, long and woolly; chicks fed by both adults; normally maximum of 2 chicks raised to fledging.

Movements. Sedentary and dispersive, although mainly migratory in N, particularly where inland waters frozen over for long periods. Migrants reach Afghanistan, Iran and formerly Iraq; also very probably to Indian Subcontinent and Burma, where local populations basically sedentary.

Status and Conservation. RARE. CITES II. Formerly much more widespread; in first half of present century, breeding range stretched to Caspian Sea, where species last bred in 1947. Appears to have undergone a general decline, for causes that are not fully understood. Breeding population of former USSR may now be extinct; found only in Kazakhstan in 20th century. Scarce information available on status in Burma, Mongolia and China. Rare in Pakistan, with less than 40 pairs estimated in 1974; in rapid decline in Bangladesh; apparently more common in India, but fairly local.

Bibliography. Ali & Ripley (1978), Borodin (1984), Brown, L.H. (1976b), Cheng Tso-hin (1987), Collar & Andrew (1988), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Etchécopar & Hüe (1978), Flint *et al.* (1984), Günsel (1986), Inskipp & Inskipp (1985), Knyshtaus (1993), Liu Tsomo (1990), Love (1983), Mauersberger *et al.* (1982), Meyer de Schauensee (1984), Nanjappa (1989), Paz (1987), Patrikeev (1993), Roberts (1991), Sarker & Iqbal (1985), Smythies (1986).

39. White-tailed Sea-eagle

Haliaeetus albicilla

French: Pygargue à queue blanche **German:** Seeadler **Spanish:** Pigargo Europeo
Other common names: White-tailed Eagle

Taxonomy. *Falco Albicilla* Linnaeus, 1758, Sweden.

Forms superspecies with *H. leucocephalus*. Birds from Greenland sometimes separated in race *groenlandicus*, on grounds of larger average size. Monotypic.

Distribution. SW Greenland; W Iceland; N & C Eurasia S to Greece and Turkey, S Caspian Sea, L Balkash and Manchuria; formerly to lower R Yangtze; has bred on Attu I (W Aleutian Is). Winters S to N Mediterranean, Persian Gulf, Pakistan, N India and SE China.

Descriptive notes. 69-92 cm; male 4100 g, female 5500 g; wingspan 200-245 cm. White tail and yellow bill as in *H. leucocephalus*, but head and neck pale buff rather than pure white, contrasting much less with rest of plumage; upperparts fairly pale, wing-coverts and upper back yellowish brown; tail wedge-shaped. Female averages larger. Juvenile blackish brown, with tail, head, bill and iris all dark; whitish markings on axillaries; gradually attains adult plumage over 5-6 years, but tail not white until 8th year; bill yellow after 4-5 years.

Habitat. Diverse aquatic habitats, both freshwater and marine; coasts, rocky islands, lakes,

large rivers and large marshes. From desert to Arctic climates. For nesting and roosting requires proximity of sea cliffs or woods, ideally with high trees. Rarely far from coast or large stretches of water; normally in lowlands.

Food and Feeding. Wide range of food types, including fish, birds and, less importantly, mammals; prey normally medium-sized. Fish probably main prey in many areas; some taken dead or dying, rest normally caught without plunge; species which swim near surface most important, e.g. lump-sucker (*Cyclopterus lumpus*) and Gadidae at sea, pike (*Esox lucius*) in fresh water. Avian prey mainly seabirds and waterbirds; particularly species that dive, which are attacked on water, sometimes being chased to exhaustion by pair of eagles (see page 71); during breeding often steals chicks and

sometimes eggs from colonies, particularly of eiders and other Anatidae, auks, shags, gulls and coots. Mammals include rodents, rabbits and hares, and ungulates (sheep, goats and deer); almost exclusively taken as carrion, although young individuals sometimes hunted. Also steals from birds, e.g. Ospreys (*Pandion haliaetus*), other birds of prey, cormorants. Has learnt to take offal from fishing boats, and enjoys easy fishing in fish-breeding ponds.

Breeding. Laying dates vary considerably with latitude: Jan in S of range; Apr-May in Arctic regions. Nests mainly on ledges of sea cliffs or on high trees, rarely on ground; tree-nest placed in fork or touching trunk. Each pair normally has 2-3 nests, which are used alternately; enormous structures of sticks and branches, which in time can become several metres deep and wide; cup lined with materials such as moss, grass, lichens, ferns, seaweed or wool. Usually 2 eggs (1-3), laid at interval of 2-4 days; incubation 38 days (perhaps 34-46) per egg, starting with first egg; adults share incubation and care of young; chicks have first down grey, second down grey-brown; fledging 70-90 days; young depend on adults at least 30 days more. Breeding failure can be very high: 1-2 (very occasionally 3) chicks fledge, with averages of 0.2-1.1 per breeding pair, and 1.1-2.0 per successful pair. Low juvenile mortality. Sexual maturity at 5 years old, maybe younger. Can live to 27 years old (42 in captivity).

Movements. Mainly migratory in N and E of breeding range; sedentary elsewhere, including Greenland, Iceland and Norway. Juveniles more dispersive and gregarious; in winter can form flocks of 10's of birds (even 100) in good feeding or roosting areas, e.g. 72 on Hortobágy Plain, Hungary, in Dec 1993. In winter, straggles S from S Sweden through C Europe, rarely to S Europe; in Asia, movements poorly known, with birds occurring from Middle East to E China and Japan. Adults leave N breeding areas later (Oct) and return earlier (Feb-Apr) than juveniles.

Status and Conservation. VULNERABLE. CITES I. Marked decline historically from 19th century, with drastic reduction and extinction from extensive areas, including British Is, Faeroes, W Europe and most of Mediterranean. Trend reversed, with recolonizations in different periods of 20th century, becoming generalized from 1980's. By early 1990's, species on increase in most of Europe and stable or with slight increase in former USSR, but in decline and seriously threatened in SE Europe. Total numbers not accurately known, depending considerably on estimates from former USSR, with largest population of possibly 5000-7000 pairs. Figures available for early 1990's include: c. 1500 pairs in Norway; 1000 pairs in European Russia, where greatest density on lower Volga, with 250-300 pairs; 245+ pairs in Poland; c. 200 pairs in Germany; c. 100 pairs in Sweden; 80 pairs in Finland; 50-90 pairs in Byelorussia; and 50-60 pairs in Baltic republics. In 1980's; 160+ pairs in Greenland, and 30-40 pairs in Iceland. Asian populations little known, with maximum 20 pairs in Japan, and maybe 15-25 pairs in Turkey (1980's). Main causes of decline were direct persecution, use of poisoned baits and habitat destruction, especially drainage and forestry; from mid-20th century, seriously affected by pollution with organochlorine pesticides and heavy metals, particularly in Baltic, with significant reduction in breeding success. Recovery has been based on active protection, including guarding of nests and supply of uncontaminated food in winter; also favoured by drop in levels of some toxins. Threats continue to varying degrees, and habitat subject to tourist development and privatization of land for development. Various reintroduction projects successfully started: first breeding on Rhum (W Scotland) in 1985 and in S Bohemia in 1986; steady increase in breeding pairs, with 1988 totals of 11 in Scotland and 9 in Czechoslovakia; chicks have been successfully raised to fledging.

40. Bald Eagle

Haliaeetus leucocephalus

French: Pygargue à tête blanche **German:** Weißkopf-Seeadler **Spanish:** Pigargo Americano
Other common names: American Eagle, White-headed Sea-eagle

Taxonomy. *Falco leucocephalus* Linnaeus, 1766, America, Europe = South Carolina.

Forms superspecies with *H. albicilla*. Race *alascanus/alascensis* synonymous with *washingtoniensis*. Two subspecies recognized.

Subspecies and Distribution.

H. l. washingtoniensis (Audubon, 1827) - Aleutian Is, Alaska, Canada and N USA.

H. l. leucocephalus (Linnaeus, 1766) - S USA S to NW Mexico.

Descriptive notes. 71-96 cm; 3-6.3 kg; wingspan 168-244 cm. Adult dark brown with white head and tail. Female larger than male. Juvenile variable with age, all dark to mottled white to solid white belly; bill black, eye dark. Race *washingtoniensis* considerably larger.

Habitat. Generally prefers areas fringing water over considerable distance, e.g. coasts, estuaries, riparian habitats and lakes. From tundra (Aleutian Is) and conifer forests, to mangrove and cypress swamps (Florida), and even deserts (Mexico). In winter, also frequents arid sagebrush steppe and deserts far from water.

Food and Feeding. Great variation: carrion,

fish, birds, mammals, reptiles, invertebrates and garbage. In summer, largely fish and birds (e.g. seabirds, waterfowl), but reptiles can be important locally. During winter, mammals and carrion become important. Healthy birds caught; sometimes goose-size birds taken on the wing. Some auditory hunting; attracted to calls of prey (e.g. sea otters) out of visual field.

Breeding. Oct-Apr in S; Apr-Aug in N. Solitary; often aggregated, with small territories (20 ha). Nest location varied, depending on region, including ground, bluff, bush or tree, often on shoreline. If in tree, often placed on dead snag or at broken off top, conifer preferred over much of range. If on sea stack or hillside, usually easily accessible to humans. Often 2-4 unoccupied nests in territory. Nest may become huge (4 m deep, 2.5 m wide) with repeated use; central depression c. 10 cm deep lined with grass, seaweed or other vegetation. Usually 2 eggs (1-3, rarely 4). Incubation c. 35 days; chicks have dark grey down; fledging c. 70-92 days. Sexually maturity possibly at 4 years; will breed in year 4 but normally in year 5; few cases of successful breeding in years 3 (ringed birds) and 4. May form "breeding trios" of adults at nest-sites; in some populations c. 50% of adults are non-breeders. Oldest captive bird 47 years old, less in wild; first year mortality c. 75% in some

populations, and c. 10% reach year 5; adult mortality estimated at 6-8% in a stable population. Success varies regionally (data from 1970's and early 1980's): occupied territories 71%; successful territories 43%; successful nests 62%; hatching success 63-85% of attempts; 0-9 young fledged per occupied nest; 1-05 young fledged per active nest; 1-16 young fledged per successful nest. Fratricide occasionally occurs at 3-8 weeks.

Movements. In N: many resident on coast, and often large groups in coastal Alaska and British Columbia; inland, birds migrate Sept-Oct, arriving on wintering grounds in Nov, and some (with radio transmitters) known to move c. 2200 km. In S (e.g. California, Arizona and Florida), young birds move N in summer towards Canada, after fledging; adults in S may be sedentary.

Status and Conservation. Not globally threatened. CITES I. Complex situation: N populations not threatened and locally abundant, e.g. in coastal Alaska and British Columbia; but in lower Canada and most of contiguous 48 USA states, numbers reduced, and species often considered either threatened or endangered. Race *leucocephalus* listed as endangered in 1973, except in 5 states where listed as threatened. Bounty paid for eagles in Alaska in periods 1917-1945 and 1949-1953; c. 130,000-150,000 killed, and numbers there may still be recovering from that loss. Significantly affected by organochlorines in 1960's and 1970's, with losses of breeders of up to 50% in some areas, 90-100% in others; nesting failure 55-96%. Although DDT was banned, currently (1990's) lead poisoning is a problem in many areas. Numbers have increased in 1980's and 1990's, because of DDT ban, with 100-400% rise in breeders in some areas of W, e.g. Washington (from 99 to 398 pairs), Montana (22 to 93) and Idaho (12 to 53). Estimates of current populations are promising for some areas, poor in others: in early 1980's, total population estimated at c. 100,000 birds, based on Christmas bird counts, with over 60% in Alaska and British Columbia; certainly 10-15% more by 1990's. Because some regions have been relatively stable for past 2-3 decades (e.g. Saskatchewan), estimates from there are probably current; estimates for 1992 include c. 40,000-50,000 birds in Alaska, 20,000-30,000 in British Columbia, and c. 12,000 in Saskatchewan. In 48 contiguous states of USA, in 1993: c. 4016 breeding pairs, as opposed to 1188 pairs in 1980; 16,000 birds counted in winter, as opposed to 14,164 birds in 1980, although figures incomplete. No adequate surveys carried out in Mexico. In Jul 1994, proposal to reclassify in USA from endangered to threatened.

41. Steller's Sea-eagle

Haliaeetus pelagicus

French: Pygargue empereur **German:** Riesenseeadler **Spanish:** Pigargu Gigante
Other common names: White-shouldered Sea-eagle

Taxonomy. *Aquila pelagica* Pallas, 1811, islands on sea of Okhotsk. Possible race "niger" of Korea is probably only rare morph; not known in wild or captivity for five decades. Monotypic.
Distribution. Coastal regions along W Bering Sea, S of Paul's Bay (Koryakland), and Sea of Okhotsk; winters S to Ussuriland, Japan and Korea.

Descriptive notes. 85-94 cm; 4900-9000 g. Unmistakable, due to immense size, blackish brown plumage with white shoulders and wedged-shaped tail; very deep, strongly arched yellow bill. Immature has more sharply wedged-shaped tail and heavier bill than young *H. albicilla*. Morph, or possible race, "niger" differs in being all black except for white tail.
Habitat. Narrow strips of coast, together with forested valleys along lower reaches of rivers. Always nests near water containing fish, hence concentrated near mouths of rivers, or along sea coast; alternatively on rivers where salmon run, or by lakes, provided they offer conditions

necessary for the building of bulky nests. Most often river valleys, where almost all nests are built in trees. Also rocky coasts with terraced cliffs 100 m high or more. Also nests on cliffs far inland.
Food and Feeding. Principally fish, especially Pacific salmon (Salmonidae), taken alive or dead. Remainder of diet highly varied, but plays a subordinate role, only becoming important at times when main food source in short supply. Habitual method of catching fish is for species to wait perched 5-30 m above water, on tree or rocky ledge, from which swoops down in a dive. Also circles 6-7 m above water and dives down; or stands in shallow water, on sandbank, spit or ice floe, from which catches prey.

Breeding. Laying generally in second half of Apr and early May; varies from region to region, depending largely on climatic conditions at end of winter and in spring, and also on availability of food. Large stick nest, up to c. 2.5 m wide and c. 4 m deep, in tree or on cliff. 1-3 eggs, usually 2 (56%); incubation c. 38-45 days; chicks have white down; fledging c. 70 days. Breeding success 0.51-0.55 young per pair per year. Usually only one young reared. Chicks often fall from nest, or with it, or succumb to disease.

Movements. Chief overwintering areas outside breeding range are in S Primorski region, Kuril Is and Sakhalin; many birds overwinter on Hokkaido, particularly on E coast. However, estimated that major part of Kamchatkan sub-population does not leave peninsula, but merely moves to S parts of it. A young bird tracked by satellite remained in nest area in Kamchatka for nearly 2 months after fledging, up to mid-Oct; within 3 weeks it migrated 1360 km S through Kuril Is to Urup, NE of Hokkaido.

Status and Conservation. RARE. CITES II. Total world population c. 7500 birds, including 5600 adults; majority (1200-1500 pairs) breed in Kamchatka; c. 2200 birds winter on Hokkaido. Main problems include habitat alterations, with large-scale destruction of old forests; shooting by hunters, and natural collapse of eysies. Conservation measures recommended include payment of compensation to hunters for skins damaged by eagles; populations must be thoroughly monitored in future.

Genus *ICHTHYOPHAGA* Lesson, 1843

42. Lesser Fishing-eagle

Ichthyophaga humilis

French: Pygargue nain **German:** Braunschwanz-Seeadler **Spanish:** Pigarguillo Menor
Other common names: Himalayan Grey-headed Fishing-eagle, Lesser Fish Eagle

Taxonomy. *Falco (Pandion) humilis* S. Müller and Schlegel, 1841, Sumatra. In past, frequently listed as *I. nana*, but name *humilis* has priority. Two subspecies recognized.
Subspecies and Distribution.

I. h. plumbea (Jerdon, 1871) - Kashmir SE through Himalayas of India and Nepal to Burma. N Indochina and Hainan.

I. h. humilis (S. Müller & Schlegel, 1841) - Malay Peninsula (from Tenasserim) and Sumatra through Borneo to Sulawesi and Banggai Is; recently recorded on Buru (S Moluccas).

Descriptive notes. 51-64 cm; 780-785 g; wingspan 120-123 cm. Small greyish brown fishing-eagle; differs from larger *I. ichthyaetus*, in lacking white base to tail. Juvenile browner, with lightly streaked to unmarked pale underparts. Races differ only in size; *plumbea* larger.
Habitat. Forested margins of fast-flowing streams and rivers in foothills and mountains; sometimes found in more open areas, especially around forested lakes. Occurs from 200 to 1000 m, but also near sea-level in some areas, e.g. on Sulawesi.

Food and Feeding. Almost exclusively fish. Catches fish by means of short Sally from

streamside perch, sometimes snatching it off surface of water. Spends much of time moving about between favoured perches; occasionally soars.

Breeding. Little studied. Season Nov-Mar in Burma; Mar-May in India and Nepal. Builds large stick nest in tall tree in forest, near river or stream. Adults quite vocal during courtship. Usually 2-3 eggs. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Apparently uncommon in Sulawesi, Borneo and Sumatra, but common in reserve of Padang-Sugihan (S Sumatra) in mid-1980's; said to be locally common along forested streams in Burma; probably relatively secure in all of these areas. However, declining in Nepal and India, probably as result of overfishing, or silting up of streams due to loss of streamside forests, or both; deforestation may also affect species directly through loss of nesting habitat. Three recent nesting attempts in N India were unsuccessful.

Bibliography. Ali & Ripley (1978), Andrew (1992), Bishop *et al.* (1994), Brown, L.H. (1976b), Cheng Tso-hin (1987), Deignan (1945, 1963), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), van Marle & Voous (1988), Medway & Wells (1976), Mees (1967), Meyer de Schauensee (1984), Round (1988), Smythies (1981, 1986), Stresemann (1940a), White & Bruce (1986).

43. Grey-headed Fishing-eagle

Ichthyophaga ichthyaetus

French: Pygargue à tête grise **German:** Graukopf-Seeadler **Spanish:** Pigarguillo Común
Other common names: Greater Fish(ing) Eagle

Taxonomy. *Falco Ichthyaetus* Horsfield, 1821, Java. Population of Sri Lanka sometimes awarded separate race, *plumbeiceps*, which differs only in slightly smaller size; not normally accepted. Monotypic.

Distribution. India, Nepal and Sri Lanka E through Indochina and Malay Peninsula to Greater Sundas, N & E Philippines and Sulawesi.

Descriptive notes. 61-75 cm; 1600-2700 g; wingspan 155-170 cm. Medium-sized brownish grey fishing-eagle, with relatively small head and bill grey, and white belly; white base to tail. Darker and dusky than *I. humilis*. Juvenile brown, with underparts usually heavily streaked white; one specimen from Java was unstreaked.
Habitat. Lowland forests; closely associated with large bodies of fresh water, in particular sluggish streams, and large ponds; also rivers and marshes, and along sea coasts, sometimes near estuaries.

Food and Feeding. Almost exclusively fish; probably also some birds and small mammals. Catches fish from water surface by short flight

from hunting perch; fish too large to carry may be dragged to bank. Will also eat dead fish.

Breeding. Little studied. Season Dec-Mar in Sri Lanka; Nov-Jan in India; nests found in Jan and Mar in Burma; Apr in Sumatra. Builds huge stick nest 10-30 m up tall tree in forest, near lake or sluggish stream; nests used for several years in succession. Adults quite vocal during courtship. Usually 1-2 eggs, occasionally 3; incubation 28-30 days, by both sexes; fledging c. 10 weeks; fledgling dependency period unrecorded.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Apparently fairly common in Sri Lanka; uncommon in Philippines, Borneo, Burma and Sumatra, but common in reserve of Padang-Sugihan (S Sumatra) in mid-1980's; generally rare and local in SE Asia and Sulawesi; widely but sparsely distributed in India; no recent records from Thailand or Java. Species seems to be secure, but locally numbers reduced or species extirpated, primarily through loss of forests.

(1976b), Deignan (1945, 1963), Dickinson *et al.* (1991), Eve & Gurnee (1982), Hachisaka (1934), Henry (1971), Hoogerwerf (1948), Inskipp & Inskipp (1985), King, Buck & Yong (1990), King, Woskres & Dickinson (1975), Lekagul & Round (1991), Ma Kamoon (1980), Mees (1967), Mees & Voous (1988), Medway & Wells (1976), Riley (1938), Round (1988), Smythies (1981, 1986), Thiollay & Meyburg (1988), White & Bruce (1986).

Genus *GYPOHIERAX* Rüppell, 1836

44. Palm-nut Vulture

Gypohierax angolensis

French: Palmiste africain

German: Palmgeier

Spanish: Buitre Palmero

Other common names: Vulturine Fish-eagle

Taxonomy. *Falco angolensis* Gmelin, 1788, Angola.

Monotypic genus, apparently intermediate between fish-eagles and vultures. Monotypic.

Distribution. Senegambia E to Kenya coast and S to Angola and NE South Africa.**Descriptive notes.** 60 cm; 1361-1712 g, mean 1470 g; wingspan 150 cm. Bare red facial skin distinctive. Relatively short, rounded wings, black back, secondaries and primary tips, and short black tail with white tip notable in flight. Juvenile brown with yellow facial skin. Most similar to *Neophron percnopterus*, which has long pointed tail that is all white in adult; also recalls juvenile *Haliaeetus vocifer*.**Habitat.** Edges of tropical forests, large rivers, lakes, estuaries and seashore, where oil palms abound. Extends to drier areas where oil or raphia palms are planted.**Food and Feeding.** Mainly fleshy pericarp of*Elaeis guineensis* and *Raphia* palm fruits. May also survive on other fruits and grain, in addition to almost any small vertebrates and invertebrates, especially fish, crabs, amphibia and molluscs; even eats some larger vertebrates (medium-sized birds or mammals), if disabled or as carrion. Spends much of each day perched at palms or hanging below fruit, pulling off fruit with the bill, then holding it in the feet to rend. Takes some fish from water surface, even at sea, but collects much other food when paddling around shoreline.**Breeding.** Laying mainly Oct/Nov-Dec in W Africa; Jun-Aug in E Africa; May-Sept in S Africa. Builds large stick platform lined with leaves and palm fronds, in open fork or crown of tall tree, palm or euphorbia. Single egg; incubation at least 44 days; chick has brown down; fledging at least 90 days; both sexes incubate, brood and feed offspring.**Movements.** Sedentary in most areas with plentiful palm fruit. Also resident in some E African coastal areas with few palms, feeding mainly on crabs, fish and carrion. A regular vagrant to drier parts of S Africa, as well as to northern savannas of W Africa, suggesting some dispersal of non-breeding adults and juveniles; also vagrant to drier sub-Saharan areas outside normal range.**Status and Conservation.** Not globally threatened. CITES II. The commonest large raptor in many lowland forest areas of W and C Africa, at densities up to 1 pair/2 km², and with c. 50% of population made up of immatures. Less common in gallery forest and drier savannas. Abundant in swamps and along coast in Sierra Leone. Readily utilizes secondary habitats, which have extended its range, but does not favour extensive oil palm monoculture. Rarely persecuted due to mainly vegetarian diet; unlikely to be vulnerable to pesticides.**Bibliography.** Benson & Benson (1975), Brooke & Jeffery (1972), Brown, C.J. (1982), Brown, L.H. *et al.* (1982), Butchart (1989), Chapin (1932), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Moreau (1933), Mundy *et al.* (1992), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Serle (1954), Snow (1978), Tarboton & Allan (1984), Thiollay (1975a, 1975b, 1975c, 1976a, 1976b, 1977c, 1978a, 1978b, 1984), Thomson & Moreau (1957).Genus *GYPAETUS* Storr, 1784

45. Bearded Vulture

Gypaetus barbatus

French: Gypaète barbu

German: Bartgeier

Spanish: Quebrantahuesos

Other common names: Lammergeier

Taxonomy. *Vultur barbatus* Linnaeus, 1758, Santa Cruz, near Oran, Algeria.Monotypic genus, with doubtful affinities; usually considered closest to *Neophron*. Possible races *aureus* and *hemachalanus* doubtfully distinct. Two subspecies currently recognized.**Subspecies and Distribution.***G. b. barbatus* (Linnaeus, 1758) - NW Africa and SW Europe through Turkey, Egypt, Middle East, Iran and Afghanistan to Mongolia and C & NE China.*G. b. meridionalis* Keyserling & J. H. Blasius, 1840 - SW Arabia and very locally in E & S Africa.**Descriptive notes.** 100-115 cm; 4500-7100 g; wingspan 250-282 cm. Unmistakable large raptor with small "beard" of feathers, red eye-ring and long, wedge-shaped tail. Black wings and facial mask; rest of head, neck and underparts rich orange (resulting from impregnation by mineral particles; individuals very occasionally maintain original whitish coloration). Juvenile all dark, with broader wings; goes through various transitional plumages. Race *meridionalis* has lower tarsus unfeathered and lacks incipient breast band; facial pattern clearer, as lacks black markings and feathers on cheeks and crown.**Habitat.** Mountain ranges with rocky sites at which species nests and breaks bones; visits surrounding plains, and also areas of tableland. Requires large open areas with little or low vegetation, not continually covered with snow. Relies on thermals and wind for gliding flight, but to much lesser extent than most other vultures. Observed in Himalayas at over 8000 m, well above heights at which it can find food. Breeds at variable altitudes, e.g. 400-4400 m in Indian Subcontinent.**Food and Feeding.** Basically bones (up to 85% of diet), with preference for large bones. Particularly bones of medium-sized livestock (sheep, goats), on which diet is often based, or wild ungulates; eats both marrow and bone itself, and also bits of meat and skin; particularly partial to leg bones. To lesserextent feeds on carcasses of small and medium-sized animals; rodents, e.g. marmots in Europe and Asia, rock hyrax (*Procavia capensis*) in S Africa; lagomorphs; small carnivores and various birds and reptiles. On occasions, steals prey caught by other birds. Bones that it can not break are carried up into air and dropped from 20-80+ m onto particularly favoured rocky area (ossuary); bird then descends in spiral to eat. Recorded dropping tortoises in same way in SE Europe and Baluchistan. Surveys enormous areas; adult has home range of up to thousands of km² which may overlap with those of neighbouring adults. Stores food at nest, in cave or even at ossuary. Has significant relationship with man in many areas, visiting municipal carcass dumps or outskirts of farms or villages.**Breeding.** Early laying: Dec-Feb or early Mar in Europe, Asia and N Africa; May-Jul in South Africa. Monogamous, but polyandrous trios occur. Solitary, with average of 11 km between pairs on S face of Pyrenees. Nests on cliffs, mainly in caves, sometimes on ledges; large mass of sticks, c. 180 cm wide, 90 cm deep, lined with wool and other materials, e.g. animal skin and hair. Each pair normally alternates between various nests. 1-2 eggs, laid at interval of 4-5 days (3-8 in captivity); incubation 53-58 days, starting with first egg; only 1 chick hatches or survives; chick has white to pale grey down, latterly becoming browner; adults share incubation and feeding of chick; fledging 106-130 days; juvenile can receive food from parents for 7-12 months more. Average 0.6-0.9 birds fledge per clutch in Pyrenees. Sexual maturity at c. 7 years, although inexperienced pairs may not breed until 10-12 years (in captivity, has bred at 4 years old). Juvenile mortality apparently low. In captivity can live to more than 40 years old.**Movements.** Sedentary, although with enormous home range. Normally, neither adults nor juveniles seen in mountains outside normal range. Juveniles dispersive, particularly in summer, but less so than other vultures, usually not leaving natal mountain range: will visit regular feeding sites, sometimes near human settlements, and may settle temporarily near such sites; birds become sedentary with age.**Status and Conservation.** Not globally threatened. CITES II. Currently considered near-threatened. Massive decline in 19th and 20th centuries, particularly in Europe, but also in N and S Africa and W Asia; only small isolated populations survived. Little known populations of E Africa apparently still numerous, with rough estimate of 1400-2200 pairs in early 1990's; also seems numerous in C Asia and Himalayas, but rarer e.g. in Baluchistan (Pakistan). Stable and slightly increasing in Pyrenees, with 75 established pairs (including 14 trios) in 1993, of which to date only 60 breed; vestigial populations in Corsica (8 pairs in early 1990's) and Crete (perhaps 12-15 pairs in early 1980's, but with subsequent decline). Critical situation in SE Europe: perhaps 20 pairs in continental Greece in early 1980's, but in decline; virtually extinct in Macedonia by early 1990's. Current estimates of 30-40 pairs in Azerbaijan and perhaps 30 pairs in European Russia; 2 pairs in Israel in early 1980's. Also in 1980's, 204 pairs in Lesotho and E South Africa, and maximum 100 pairs in N Africa; probably extinct in Algeria and Tunisia. Project of reintroduction in Alps: 50 captive-bred young released in period 1986-1993; high survival rate, and some pairs established by early 1990's. Another conservation initiative that is becoming widespread is creation of feeding stations, which assist in survival of young. Main causes of decline were and still are poisoned baits set for carnivores, and direct persecution; robbing of nests particularly widespread in 19th century. By late 20th century degradation of habitat, disturbance in breeding areas and reduction of extensive livestock farming becoming increasingly important.**Bibliography.** Ali & Ripley (1978), Anderegg (1982), Attwell (1963), Bates (1939), Belik (1984, 1985, 1990), Bergier (1987), Blumstein (1990), Boshoff *et al.* (1978), Boswall (1970), Boudoint (1976), Bouvet (1985), Brooke (1984), Brown, C.J. 46. Egyptian Vulture

Neophron percnopterus

French: Vautour percnoptère

German: Schmutzgeier

Spanish: Alimoche Común

Other common names: (White) Scavenger Vulture

Taxonomy. *Vultur Perenopterus* [sic] Linnaeus, 1758, Egypt.Monotypic genus, possibly closest to *Gypaetus*, although has been combined with *Necrosyrtes*. Two subspecies recognized.**Subspecies and Distribution.***N. p. percnopterus* (Linnaeus, 1758) - S Europe E to C Asia (E Kazakhstan) and NW India, and S through N Africa, Arabia and Sahel zone to N Tanzania; SW Angola and NW Namibia; also Canary Is, Cape Verde Is and Socotra.*N. p. ginginianus* (Latham, 1790) - Nepal and India (except NW).**Descriptive notes.** 58-70 cm; 1600-2200 g; wingspan 155-170 cm. Small vulture with unique plumage, resembling that of European White Stork (*Ciconia ciconia*); marked contrast, especially in underparts, between overall white coloration and black flight-feathers; bare yellow face; short, wedge-shaped tail; legs greyish white, pink or pale yellow. Juvenile dark, particularly on underparts; intermediate plumages progressively lighter. Race *ginginianus* slightly smaller, with whole bill yellow.**Habitat.** Extensive open areas mainly in dry or arid regions, although sometimes around fringe areas of wet or cold climates; steppe,

desert, scrub, pastures and fields of cereals; requires rocky sites for nesting. Occurs in flat or mountainous regions, normally at low or medium altitudes, but occasionally higher up in mountainous

regions, e.g. seen at 4500 m in Ethiopia; nests from cliffs at sea-level up to sites at 2600 m in India. At present, range greatly affected by species' dependence for food on livestock and human waste; lives as scavenger near or even in towns, e.g. urban dweller in India and at beginning of century in Cairo. Normally solitary or in pairs; dozens of individuals, very occasionally 100+, may congregate at feeding points or at roosts on cliffs, buildings or trees.

Food and Feeding. Opportunist; able to take very varied types of food. Mainly carrion, including all sorts of dead vertebrates, from passerine birds and small mammals to livestock and large wild animals; normally eats only scraps of large carcasses, rejected by other vultures. To lesser degree, preys on small animals, often weak or injured ones, e.g. rabbits, chicks, spawning or dying fish, and terrapins; also insects, e.g. dung beetles (Coleoptera). Occasionally birds' eggs, notably *Ostrich* (*Struthio camelus*) eggs; breaks these by throwing stones at them, one of rare cases of tool use in avian world. Wide range of organic waste important, including excrement and rotting fruit and vegetables. Spots food from low surveying flight, higher soaring flight or from perch. Non-breeding birds travel up to 80 km daily from roost in search of food. Species heavily dependent on rubbish dumps and also traditional sites where carcasses of domestic animals dumped; commensal with man over extensive regions.

Breeding. Generally breeds later in year than other Palearctic vultures, although in S Sahara may breed from Jan or even earlier; Mar-Apr in Punjab, Canary Is and N Africa; Apr-May throughout Mediterranean range. Normally monogamous; rarely forms polyandrous trios. Solitary; in Europe normally at least 1.5 km between pairs; exceptionally 2 nests together, in Cape Verde Is; in Delhi, 0.5 pairs/km². Nests in cliffs, occupying caves or ledges protected by overhang; very occasionally nests in trees. Stick nest up to 1.5 m wide or more; usually lined abundantly with wool, hair, rags and remains of food, but sometimes with scarcely any material. Pairs often have several nests, alternating between them from year to year. Normally 2 eggs, occasionally only 1; incubation c. 42 days; both adults incubate eggs and feed chicks; chicks have white down; fledging c. 70-85 days; possibly only 1 month of dependency on adults. Great local variation in success: average 1.2-1.4 chicks (up to 1.75) fledge per successful pair; but some pairs (often 20-30% of potential breeders) do not lay. Sexual maturity at 4-5 years; known to live up to 37 years old in captivity.

Movements. Migratory in N of range; sedentary in Arabia, sub-Saharan Africa, Balearic Is and Canary Is; mainly sedentary in Indian Subcontinent, but locally migratory in some regions. Present in N breeding areas mainly Mar-Sept; winter sightings very rare, although species winters in small numbers in Coto de Doñana (SW Spain). Most migrants cross to Africa at Gibraltar; Suez and Bab al Mandab also important; nowadays, species winters only N of equator; some juveniles remain in Africa throughout second year.

Status and Conservation. Not globally threatened. CITES II. Has undergone fairly general decline, at least in Europe; population now more stable, and even recovering in some areas. Total population of Africa may number 7500 pairs and up to 20,000 birds, with largest concentration in Ethiopia; isolated nucleus of maybe only 10 pairs in Angola and Namibia; relict population may hang on in South Africa (2 birds seen in Transvaal in 1989). Main European population in Spain, with at least 1324-1373 pairs in late 1980's, including c. 35 pairs in Canary Is; in 1980's, perhaps over 100 pairs in Portugal, c. 50 pairs in former Yugoslavia, and 200-250 pairs in Greece; in early 1990's, 67 pairs in France, maximum 13-14 pairs in Italy, c. 100 pairs in Bulgaria, a few pairs in Crimea, and possibly 50 pairs in European Russia. Asian populations certainly sizeable, especially those of India and Pakistan, but generally little known, with no figures available; at least 80-100 pairs in Azerbaijan; 90 pairs in Israel in 1982, with increase following serious decline caused by rodenticide poisoning; sizeable population on Socotra. Factors responsible for some declines include strychnine and pesticide poisoning, and direct persecution; reduction in availability of food, due to decrease in amount of large-scale livestock farming, and also in traditional use of local municipal carcass dumps; decline in populations of small prey species; and increasing vulnerability of breeding areas.

Genus *NECROSYRTES* Gloger, 1841

47. Hooded Vulture

Necrosyrtes monachus

French: Vautour charognard **German:** Kappengeier **Spanish:** Alimoche Sombrio

Taxonomy. *Cathartes monachus* Temminck, 1823, Senegal.

Monotypic genus sometimes combined with *Neophron*, but differs markedly in morphology and e.g. nesting behaviour. Two subspecies sometimes recognized, with nominate race in W Africa, and rest of range covered by race *pileatus*; but variation only in size, and clinal from small in W to large in S. Monotypic.

Distribution. Mauritania E to Ethiopia and S to Namibia and South Africa, except areas of uninterplanted forest or desert.

Descriptive notes. 67-70 cm; 1530-2600 g, mean 2028 g; wingspan 170-182 cm. Small vulture with long thin bill and pink face that can flush bright purple. Sexes alike. Juvenile usually with face pale blue and hood of short down dark brown rather than beige; similar to juvenile *Neophron percnopterus*, but head has covering of down, as opposed to contour feathers and tail not pointed. Overall most resembles *Torgos tracheliotus*, but much smaller and finer-billed.

Habitat. Mainly open woodland and savanna; absent from desert and dense forest, except where enters secondary forest, clearings, settlements and urban areas, in W and NE Africa, as commensal with man.

Food and Feeding. Carrion and some small insects; also food scraps and excreta around human habitation. Locates small items from low flights, that are early relative to those of larger vultures. Gregarious at larger carcasses but unable to compete with larger species, usually taking scraps and fighting with conspecifics around edges of the fray. Uses fine bill to pick meat from between bones after larger species have left, and to extract insects from soil and dung.

Breeding. Laying usually after rainy season: Oct-Mar in W and NE Africa; Jan and Apr-Jul in E Africa; May-Aug in S Africa. Builds small stick nest in upper fork of large tree, usually deep within foliage and not on the crown as in other vulture species; rarely on building or cliff. Single egg; incubation 48-54 days; chick has brown first down, darker second down; fledging 89-130 days; parents alternate roles in raising offspring, for up to c. 4 months after first flight.

Movements. No regular movements reported except for Jun-Sept wet season extension into S Sahara. Probably sedentary in most areas, but may range over 200 km when not breeding, especially juveniles. Vagrant to Morocco.

Status and Conservation. Not globally threatened. CITES II. Common to locally abundant in many areas of W and NE Africa, where well integrated with human development and agriculture; has expanded range considerably in Sierra Leone, with destruction of forest. Much less common in wilderness areas further S where not commensal with man, e.g. 50 pairs in Transvaal lowveld, South Africa. Recently subjected to some persecution and poisoning in W and S Africa.

Bibliography. Bannerman (1953), Benson & Benson (1975), Brown *et al.* (1982), Cramp & Simmons (1980), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Houston (1989), Hustler & Howells (1988a), Kruuk (1967), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Mundy & Cook (1972, 1975), Mundy *et al.* (1992), Pickford *et al.* (1989), Pinto (1983), Serle (1943), Snow (1978), van Someren (1956), Tarboton & Allan (1984), Thiollay (1978c, 1985d), Wilson, R.T. (1982).

Genus *GYPs* Savigny, 1809

48. African White-backed Vulture

Gyps africanus

French: Vautour africain **German:** Weißrückengeier **Spanish:** Buitre Dorsiblanco Africano
Other common names: White-backed (Griffon) Vulture

Taxonomy. *Gyps africanus* Salvadori, 1865, Sennar, Sudan.

Forms superspecies with *G. bengalensis*, with which has been considered conspecific; these two sometimes partitioned off in genus *Pseudogyps*, on grounds of usually having 12 not 14 rectrices. Possibility of three geographically discrete populations that differ on size, but not named. Monotypic.

Distribution. Mauritania E to Ethiopia and S to N and E South Africa.

Descriptive notes. 94 cm; 4150-7200 g, mean 5450 g; wingspan 218 cm. White lower back and underwing-coverts conspicuous against dark brown plumage and black skin on neck and head of adult. Becomes paler and plainer with age, especially female. Dark eye and neck separate from adult of larger, paler *G. coprotheres*. Juvenile always darker, each contour feather streaked with lighter brown, and ruff feathers long and lanceolate.

Habitat. Various open woodlands, savannas and steppes; only absent from extreme desert and dense forest.

Food and Feeding. Carrion and bone fragments of larger carcasses, mainly soft muscle and organ tissue. Usually gregarious, feeding and fighting amidst a hectic scrumage to obtain flesh, even thrusting the long bare neck under the skin or crawling into the rib-cage. May also come down to small dead animals and afterbirth. Soars together with other vultures, using their behaviour and that of carnivores, including man, to locate food. After feeding, usually bathes together with other species at favourite sites.

Breeding. Laying usually at start of dry season: Oct-Jan in W and NE Africa; all months in E Africa; Apr-Jun in C and S Africa. Builds platform of sticks, lined with grass and green leaves, on crown of large tree or less often in an open fork, frequently along a watercourse; rarely nests on a pylon. Frequently clumped in loose colonies of 2-13 nests, some of which only persist for a few years. Single egg (rarely 2-3); incubation 56 days; chicks have pale grey down; parents take turns to incubate, brood and feed offspring; fledging 120-130 days.

Movements. Sedentary in many areas, but in W Africa moves N in the Jul-Sept wet season to less densely vegetated areas, and S again in dry season. Possibly migrates down Rift Valley of Uganda in Jul. Marked birds indicate some long-distance movements, mainly dispersive, but also to exploit new food sources.

Status and Conservation. Not globally threatened. CITES II. The commonest African griffon-like vulture of savanna and woodland by 4-5 times, e.g. in many large reserves and ranches, with 2500 breeding pairs estimated for Transvaal alone. Subject to some persecution, poisoning and range reduction in parts of S, C and NE Africa, but has also expanded to adopt power pylons as nest-sites in S Africa.

Bibliography. Allan (1988b), Bannerman (1953), Benson & Benson (1975), Brown *et al.* (1982), Dowsett & Dowsett-Lemaire (1980), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Houston, D.C. (1974a, 1974b, 1975, 1976, 1989, 1993), Howells & Hustler (1984), Kemp & Kemp (1975a), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Mundy (1982), Mundy *et al.* (1992), North (1944), Pickford *et al.* (1989), Pinto (1983), Tarboton & Allan (1984), Thiollay (1978b, 1978c).

49. Indian White-backed Vulture

Gyps bengalensis

French: Vautour chaugoun **German:** Bengelengeier **Spanish:** Buitre Dorsiblanco Bengali
Other common names: (Oriental) White-backed/White-rumped Vulture

Taxonomy. *Vultur bengalensis* Gmelin, 1788, Bengal.

Forms superspecies with *G. africanus*, with which sometimes considered conspecific; these two sometimes separated off in genus *Pseudogyps*. Monotypic.

Distribution. SE Iran, Afghanistan (perhaps irregularly) and Pakistan through Nepal and India to SC China (Yunnan), Indochina and N Malay Peninsula.

Descriptive notes. 76-93 cm; 3500-6000 g; wingspan 205-220 cm. Blackish, medium-sized vulture with white lower back; underwing-coverts conspicuously all white; bill and cere dark. Juvenile dark brown, with streaked underparts.

Habitat. Inhabits open country near villages, towns and cities, as well as parks and sanctuaries, in lowlands and Himalayan foothills up to 4500 m. Often closely associated with man, large numbers congregating in and around towns, especially by rubbish dumps and slaughterhouses. Often gathers

to roost in large numbers for long periods in trees; repeated use of same trees can lead to trees being killed by accumulation of droppings, sometimes causing problems thus in groves of coconut palms, mangos, etc.

Food and Feeding. Exclusively carrion, especially remains of cattle. Regularly feeds in company of other vultures, especially *G. indicus*, and also other scavengers, e.g. jackals, corvids and dogs. Carrion located by means of keen eyesight; soaring vultures also watch other flying vultures and other scavengers; when one drops to carcass, all birds in sight follow suit, and many can gather in short time.

As in other vulture species, birds tend to gorge themselves, then rest for long period nearby, on ground or tree, while food is digested.

Breeding. Season Oct-Mar. Sometimes forms small colony in grove of trees. Large stick nest built by pair 5-30 m up large tree, often in village, town or even city, and usually next to road, stream or canal. Display flights consist of close mutual soaring of pair. 1 egg (reports of 2 eggs probably involve two females laying in same nest); incubation at least 45 days, by both sexes; fledging c. 3 months; period of post-fledging dependency unknown. High density of 2-7 pairs/km² in Delhi, N India.

Movements. Mainly sedentary. Vagrant in past to Borneo, presumably from Malay Peninsula, in period when more numerous there.

Status and Conservation. Not globally threatened. CITES II. Common to abundant throughout most of range; less common in S India and W Pakistan; rare in W Yunnan (S China); in most of Thailand and Malay Peninsula relatively common in past, but now rare or absent. Well adapted to living in close proximity to humans, feeding extensively at rubbish dumps, where frequently ignores human presence; can cause conflict.

Bibliography. Ali & Ripley (1978), Cheng Tso-hin (1987), Deignan (1945, 1963), Etchécopar & Hùe (1978), Galushin (1971), Grubb (1980), Gyldestolpe (1920), Hollom *et al.* (1988), Holmes & Wells (1975), Hùe & Etchécopar (1970), Humphrey & Bain (1990), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), MacKinnon & Philipps (1993), Medway & Wells (1976), Meyer de Schauensee (1984), Proud (1949), Roberts (1991), Riley (1938), Round (1988), Sathesan (1989, 1989e), Smythies (1981, 1986).

50. Long-billed Vulture

Gyps indicus

French: Vautour indien

German: Dünnschnabelgeier

Spanish: Buitre Picofino

Taxonomy. *Vultur indicus* Scopoli, 1786, India.

May form superspecies with *G. himalayensis*, *G. fulvus*, *G. coprotheres* and *G. rueppellii*. Race *tenuirostris* sometimes considered separate species because of differences in plumage and nest substrate, but further research required to justify this split. Birds of Punjab hills erroneously ascribed separate race, *jonesi*; this population actually belongs to *G. fulvus*. Two subspecies recognized.

Subspecies and Distribution.

G. t. tenuirostris G. R. Gray, 1844 - lower Himalayas, from Kashmir through Nepal to Assam, and SE into Indochina and N Malay Peninsula.

G. i. indicus (Scopoli, 1786) - SE Pakistan and India S of R Ganges, except extreme S.

Descriptive notes. 80-100 cm; 5500-6300 g; wingspan 205-229 cm. Medium-sized vulture with pale body and wing-coverts; blackish neck, with whitish down; bill mostly pale yellow. Paler than *G. bengalensis*, somewhat sligher than most other congeners, with bill more slender. Juvenile darker. Race *tenuirostris* larger; head and neck darker, lacking whitish down; also darker above, especially on wings; only culmen of bill is pale.

Habitat. Inhabits open country near villages, towns and cities, as well as parks and sanctuaries; usually in company of *G. bengalensis*, but in lower numbers. Race *indicus* occurs on

plains, nesting on cliffs; race *tenuirostris* occurs in Himalayan foothills and nests on trees.

Food and Feeding. Feeds exclusively on carrion, mostly cattle. Feeds in company of other vultures, especially more numerous *G. bengalensis*, with which often joins in carrion feeding guild. Carrion located by means of keen eyesight; soaring vultures also watch other flying vultures and other scavengers; when one drops to carcass, all birds in sight follow suit, and many can gather in short time. Feeding sessions can be raucous at times, with many grunts and hisses, as vultures fight over place to feed.

Breeding. Season Nov-Mar. Often colonial. Races differ in nesting substrate. Widespread race *indicus* breeds in small to large colonies on cliffs; nest is loose platform of sticks lined with straw; usually destroyed by nestling which pushes sticks off ledge. Himalayan race *tenuirostris* nests in trees; builds compact nest 7-15 m up large leafy tree; often nests in small group or colony, usually near village. Display flight not described, but probably, as in other *Gyps*, includes mutual soaring. 1 egg; adults share nesting duties; chick has yellowish brown down. No further information available.

Movements.

Status and Conservation. Not globally threatened. CITES II. Fairly common throughout most of range, although usually less numerous than sympatric *G. bengalensis*. Rare and local throughout SE Asia, but reasons for decline unknown; may now be extinct in Thailand.

Bibliography. Ali & Ripley (1978), Deignan (1963), Grubb (1980), Humphrey & Bain (1990), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), Medway & Wells (1976), Ripley (1982), Roberts (1991), Round (1988), Smythies (1986).

51. Rüppell's Griffon

Gyps rueppellii

French: Vautour de Rüppell

German: Sperbergeier

Spanish: Buitre Moteado

Other common names: Rüppell's Vulture

Taxonomy. *Vultur Rueppellii* A. E. Brehm, 1852, Khartoum, Sudan.

Forms superspecies with *G. fulvus* and *G. coprotheres*, and possibly also with *G. himalayensis* and *G. indicus*. Two subspecies recognized.

Subspecies and Distribution.

G. r. rueppellii (A. E. Brehm, 1852) - SW Mauritania E to Sudan, N to Aïr Massif (NW Niger) and S to Uganda, Kenya and N Tanzania.

G. r. erlangeri Salvadori, 1908 - Ethiopia, Eritrea and NW Somalia, possibly ranging to S Arabia.

Descriptive notes. 101 cm; 6800-9000 g, mean 7570 g; wingspan 241 cm. Pale tips to contour feathers give scaled appearance (individually variable); yellow eye and orangish bill also distinctive. Juvenile with black bill and eye; paler with broadly streaked plumage. Races separated on size and colour, but may intergrade.

Habitat. Open sub-Saharan habitats of arid steppe and grassland up to 4500 m; occurs in or around mountains for orographic lift, and cliffs and gorges for roosting and breeding.

Food and Feeding. Carrion and bone fragments of larger carcasses, mainly soft muscle and organ tissue. Roosts, soars and feeds com-

munity, fighting with other vulture species to obtain flesh and often inserting the strong bare neck under the skin or crawling into the rib-cage. Follows other vultures and migrant game or stock herds to locate much of its food. Rarely comes down to small carrion.

Breeding. Laying usually after long rainy season: Oct-Dec in W and NE Africa; Jun-Aug in Kenya; enigmatically, Dec-Jan in one decade, then Jul-Sept in another in Tanzania. Breeds on cliff faces in colonies of 10-1000 pairs; builds platform of sticks, lined with grass and placed on an open ledge; in N Cameroon, also nests in trees, alone or in small nuclei. Single egg; incubation c. 55 days; chick has grey down; parents share care of egg and chick; fledging c. 150 days.

Movements. No regular movements in most areas, although may wander daily 150-200 km from nesting and roosting cliffs. In W Africa moves S in dry season to edge of Guinea woodlands. In E Africa juveniles may move to areas outside range of breeding colonies. Vagrant to Egypt.

Status and Conservation. Not globally threatened. CITES II. Total population estimated at 30,000 birds, including 3000 pairs in Tanzania, and 2000 pairs each in Kenya, Ethiopia, Sudan and W Africa. Less studied than other griffons; several colonies in Kenya reported to have declined through agricultural encroachment and poisoning. Widely killed for use in traditional medicines.

Bibliography. Bannerman (1953), Brown & Britton (1980), Brown *et al.* (1982), Cramp & Simmons (1980), Etchécopar & Hùe (1964), Gallagher & Woodcock (1980), Gore (1990), Hollom *et al.* (1988), Houston, D.C. (1974a, 1974b, 1975, 1976, 1989, 1990, 1993), Jensen & Kirkeby (1980), Kruuk (1967), Lippens & Wille (1976), Mackworth-Præd & Grant (1975-1973), Morel & Morel (1990), Mundy *et al.* (1992), Nikolaus (1987), Pennycook (1983), Thiollay (1978c).

52. Himalayan Griffon

Gyps himalayensis

French: Vautour de l'Himalaya

German: Schneegeier

Spanish: Buitre del Himalaya

Other common names: Himalayan Griffon Vulture

Taxonomy. *Gyps himalayensis* Hume, 1869, Himalayas.

Sometimes considered a race of *G. fulvus*, but ranges overlap and plumages distinct. May form superspecies with *G. indicus*, *G. fulvus*, *G. coprotheres* and *G. rueppellii*. Monotypic.

Distribution. Himalayas from N Pakistan and N India through S Tibet and Nepal to Bhutan, N Assam and C China; also NE through Pamirs to Tien Shan, and possibly also into Tarbagatai and Altai.

Descriptive notes. 116-150 cm; 8000-12,000 g; wingspan 260-310 cm. Large, pale vulture; largest *Gyps*; great individual variation in size, with some birds huge. Purplish pink patch of bare skin at base of neck. Body and wing-coverts whitish, lacking tawny tones of *G. fulvus*. Generally tends to be paler than *G. indicus*; palish bill, largely yellowish. Juvenile dark, with narrow pale streaks on underparts and upperwing-coverts; immature plumages progressively paler overall.

Habitat. Mountains, mostly 1500-4000 m, but down to 900 m in Himalayas, and even recorded up to 5000 m in Nepal. In winter, generally somewhat lower, a few juveniles wandering down onto plains.

Food and Feeding. Feeds exclusively on carrion. Soars and glides over vast areas, searching for carcasses and watching other vultures. Gathers in small numbers at carcasses; these can be devoured very rapidly. At carcasses, dominant over other vultures, except *Aegypius monachus*. Feeding at times can be raucous, with many grunts and hisses, as vultures fight over a place to feed. Reported to follow caravans and domestic flocks in high mountains.

Breeding. Nest building or repair usually begins in late winter; laying generally in Jan, but Feb-Mar in Russia. Nests may be solitary or in small groups with up to 6 pairs. Large, loose nest on cliff face built or simply repaired by pair. Display flights consist of close mutual soaring of pair. Almost invariably 1 egg; incubation c. 50 days; fledging and dependency periods unknown, but entire nest cycle extends for 7 months or more.

Movements. Sedentary, with limited altitudinal movements; a few juveniles straggle S onto plains of N India in winter. Vagrant to Afghanistan and Turkmenistan.

Status and Conservation. Not globally threatened. CITES II. Apparently common in W China and throughout Himalayas of Pakistan, India, Tibet and Nepal, e.g. common in Great Himalayan National Park, Himachal Pradesh (N India); uncommon in mountains of C China.

Bibliography. Ali & Ripley (1978), Cheng Tso-hin (1987), Dementiev & Gladkov (1951), Etchécopar & Hùe (1978), Flint *et al.* (1984), Inskipp & Inskipp (1985), Krystautas (1993), Meyer de Schauensee (1984), Ripley (1982), Roberts (1991).

53. Eurasian Griffon

Gyps fulvus

French: Vautour fauve

German: Gänsegeier

Spanish: Buitre Leonado

Other common names: Griffon Vulture

Taxonomy. *Vultur fulvus* Hablizl, 1783, Samamisia Alps, Gilan, Iran.

Sometimes considered conspecific with *G. coprotheres*; also occasionally with *G. himalayensis*. Forms superspecies with *G. coprotheres* and probably with *G. rueppellii*; possibly also with *G. himalayensis* and *G. indicus*. Population of Punjab Salt Range (Pakistan), erroneously described as *G. indicus jonesi*, actually belongs to race *fulvescens* of present species. Two subspecies recognized.

Subspecies and Distribution.

Gyps f. fulvus (Hablizl, 1783) - NW Africa and Iberian Peninsula E through Balkans, Turkey, Middle East, Arabia and Iran to Pamirs and Altai.

Gyps f. fulvescens Hume, 1869 - Afghanistan, Pakistan and N India E to Assam.

Descriptive notes. 95-110 cm; 6000-11,000 g; wingspan 240-280 cm. Whitish head, neck and collar; dark centres to greater upperwing-coverts. Similar to the other griffon vultures: smaller and somewhat browner than *G. himalayensis*; larger and normally paler than *G. bengalensis*, *G. indicus* and *G. africanus*. Juvenile has brown collar and darker back than adult.

Habitat. Expansive open areas; wide range of habitats, including mountains, plateaux, steppe and even semi-desert, with abrupt rocky areas such as crags and canyons for nesting and roosting. Soaring flight requires updraughts associated with slopes and cliffs, or thermals;

generally prefers dry, sunny areas; also dependent on presence of livestock. Breeds at wide range of altitudes, from cliffs at sea-level, e.g. Sardinia and Croatia, up to 2750 m in Caucasus; recorded considerably higher.

Food and Feeding. Exclusively, or almost exclusively, carrion; feeds mainly on muscles and viscera of medium-sized and large mammals, especially ungulates. Original wild prey species (mountain goats, deer, gazelles) now replaced to greater or lesser extent by domestic species (sheep, goats, cows, horses), on which present species has often become totally dependent; sometimes eats other mammals (carnivores, rabbits and hares, cetaceans, etc). Birds co-operate in search for food, dispersing up to 10's of km from colony or roost, exploring wide areas meticulously; when individual locates carrion, other birds within sight will congregate. Regularly visits traditional municipal carcass dumps, where these still exist.

Breeding. Laying Dec-Mar or later; replacement clutches till May; laying can be spread over 3 months at any given colony. Colonial; normally under 20 pairs, though most breeding pairs may concentrate in largest colonies of up to 150 pairs. Nests on crag or cliff, preferring protected ledge or small cave; thin, fairly small platform of branches, sometimes stolen from other large raptors, e.g. eagles, *Gypaetus barbatus*, occasionally tree-nesting *Aegypius monachus*. 1 egg; incubation 50-58 days; both adults incubate egg, and feed chick by regurgitating semi-digested food; first down short and white, second down longer and creamy white to pale grey; fledging 110-130 days; chicks may receive food from parents for 3 months more. Breeding success in Spain 0.76 chicks fledged per clutch (similar in French Pyrenees). First breeding can occur at 4 years old, but normally older. Known to live up to 37 years old in captivity.

Movements. Sedentary and partly migratory; juveniles disperse widely, accounting for most sightings outside normal range, e.g. vagrants in C & N Europe. A few thousand birds, mainly juveniles, winter in Africa, with crossings at Straits of Gibraltar (peak Oct-Nov), Bosphorus and Suez; occur S to Senegal, Mali and Niger; in smaller numbers, E to Sudan and Ethiopia; mainly visit zones of savanna and steppe. Not all of these birds return to Europe in spring; peak crossing into Iberian Peninsula in Apr-May. Shorter seasonal or nomadic movements also occur, in relation to climate and movements of livestock herds.

Status and Conservation. Not globally threatened. CITES II. Favoured in past by increases in livestock farming and also in extent of pastures. Widespread decline in most of 20th century in Europe, N Africa and Middle East, mainly due to poisoned baits set for carnivores, direct persecution, and in some areas reduction in available food supplies. Very little information available on population trends in Asia, but probably more stable in E parts of range. Spectacular recent recoveries in places; notably in Spain, main population of W, with at least 8100 pairs and 23,000-24,500 individuals in 1989; significant increase in French Pyrenees, with c. 300 pairs in early 1990's; successful reintroduction in Massif Central (SE France), with first birds released in 1981, but over 30 pairs breeding by early 1990's (see page 103). In 1980's, c. 1100 pairs in rest of Europe: c. 300 pairs in European Russia (1990's); 100-150 pairs in Portugal; 30 pairs on Sardinia; c. 450 pairs in mainland Greece and Crete; c. 200 pairs in former Yugoslavia; up to 10 pairs in Bulgaria. In same period: perhaps 100-150 pairs in NW Africa, where considered very rare; c. 500-1000 pairs in Turkey; c. 70 pairs in Israel; c. 100-120 pairs in Azerbaijan. Species readily capable of recovery, if efficiently protected, with reliable food sources accessible.

Bibliography. Ali & Ripley (1978), Arroyo *et al.* (1990a), Ben-Zohar (1986), Bergier (1987), Bijlsma (1983), Bonnet *et al.* (1990), Brown *et al.* (1982), Bundy (1976), Christensen *et al.* (1981), Cramp & Simmons (1980), Dendaletche (1988), Donazar (1993), Donazar *et al.* (1987), Elósegui (1987, 1989), Etchecopar & Húe (1978), Finlayson (1992), Flint *et al.* (1984), Frumkin (1986), Genaro (1985), Génsbol (1986), Glutz von Blotzheim *et al.* (1971), Goodman *et al.* (1989), Habbizl (1983), Handrinos (1985), Handrinos & Demetropoulos (1983), Jaubert (1989), Jennings (1987), Leconte (1977, 1985), Mackworth-Præd & Grant (1957-1973), Marinovic & Örländic (1994), Marinovic *et al.* (1985), Mundy (1985b), Mundy *et al.* (1992), Natorp (1986), Nikolaus (1987), Nogué (1982), Paz (1987), Perco *et al.* (1983), Polo *et al.* (1992), Popov & Verzhutskii (1990), Roberts (1991), Rufino *et al.* (1985), Simeonov *et al.* (1990), Soto (1986), Terrasse (1977), Terrasse & Thauront (1988), Terrasse, Bagnolini *et al.* (1994), Terrasse, Terrasse & Budoint (1961), Thaler *et al.* (1986), Valverde & Bemis (1960), Welch & Welch (1988), Wilbur & Jackson (1983), Whympner (1909).

54. Cape Griffon

Gyps coprotheres

French: Vautour chasseur

German: Kapgeier

Spanish: Buitre de El Cabo

Other common names: Cape/Kolbe's Vulture

Taxonomy. *Vultur Coprotheres* J. R. Forster, 1798, South Africa.

Forms superspecies with *G. fulvus* and *G. rueppellii*, and possibly also with *G. himalayensis* and *G. indicus*. Sometimes considered conspecific with *G. fulvus*. Monotypic.

Distribution. Centred on Lesotho and South Africa, extending to Namibia, Botswana, Zimbabwe, S Mozambique and Swaziland, rarely wandering N to Zambia.

Descriptive notes. 110 cm; 7070-10,900 g, mean 9350 g; wingspan 255 cm. Pale plumage contrasts with dark spots along trailing edge of wing-coverts and dark flight-feathers. Most like *G. fulvus* but neck and bill colour differ. Bill black at all ages; adult has eye golden and neck and coracoid skin patches blue. Juvenile has eye brown and neck pink.

Habitat. Open grassland, steppe and, historically, karoooid vegetation, in the proximity of mountains for orographic lift and cliffs for roosting and nesting sites. Peripheral N colonies in bush savanna.

Food and Feeding. Carrion and bone fragments of larger carcasses, mainly soft muscle and organ tissue. Colonial and gregarious, feeding and fighting among other vultures to obtain flesh, even inserting the long bare neck under the skin or crawling into the rib-cage. Often soars in groups, using behaviour of conspecifics to help locate food. After feeding, usually bathes communally at favourite sites.

Breeding. Laying Apr-Jul. Breeds colonially on cliff faces with 1-1000 pairs building stick platforms lined with grass on open ledges. Single egg (rarely 2); incubation 55 days; chick has white down; parents take turns with care of egg and chick; fledging mean 140 days. Known to have lived over 11 years.

Movements. Most birds remain within foraging range of about 100 km of nesting and roosting colonies. Some disperse over long distances throughout S African subcontinent (e.g. into Zambia and C Mozambique), especially juveniles which concentrate in nursery areas remote from colonies.

Status and Conservation. RARE. CITES II. At least 83 colonies and 4400 breeding pairs estimated to remain, but has undergone range retraction and loss of peripheral colonies; declines continue at some major colonies. Most studied, monitored and conserved of African vulture species. Historically affected by elimination of carnivores and game, possibly initiating skeletal abnormalities in chicks, through lack of bone flakes in diet. Has recently been suffering from persecution and poisoning, collection for traditional medicines, electrocution and drowning in water tanks. Conservation efforts include provision of food and bone flakes at "vulture restaurants" and attempts to control limiting agents. Not obviously affected by pesticides.

Bibliography. Benson *et al.* (1990), Borello (1985, 1986), Borello & Borello (1993), Boshoff & Currie (1981), Boshoff & Robertson (1985), Boshoff & Vernon (1980b), Brooke (1984), Brown, C.J. Genus AEGYPIUS Savigny, 1809

55. Eurasian Black Vulture

Aegypius monachus

French: Vautour moine

German: Mönchsgeier

Spanish: Buitre Negro

Other common names: Cinereous Vulture, (European) Black Vulture(!)

Taxonomy. *Vultur Monachus* Linnaeus, 1766, Arabia.

Sometimes considered to be congeneric with genera *Torgos*, *Sarcogyps* and *Trigonoceps*. Possible races *chincoulchinou* of China and *danieli* of Mongolia not generally recognized. Monotypic.

Distribution. S Palearctic, from Spain, Balearic Is and Balkans through Turkey, Caucasus, Iran and Afghanistan to S Siberia, Mongolia, N China and extreme N India. Winters S to Sudan, Middle East, Pakistan, NW India and Korea.

Descriptive notes. 98-107 cm; 7000-12,500 g; wingspan 250-295 cm. Huge, broad-winged vulture, often slightly wedge-shaped tail; all dark sooty to black. One of largest Old World vultures. Bare skin of head and neck bluish grey; head covered with blackish down; neck ruff paler in older birds. Immature somewhat blacker, and top of head covered with black down; juvenile has bare skin pink.

Habitat. Forested areas in hills and mountains, at 300-1400 m in Spain, but higher in Asia. In Tibet and China, two different eco-geographical types: mountainous forest and scrub between 780 m and 3800 m; and arid and

semi-arid alpine meadows and grassland, between 3800 m and 4500 m. In Nurata Mts, Uzbekistan, breeds at altitude of 900-1900 m. Forages over forested areas, but also over many kinds of open terrain from steppe to upland grasslands.

Food and Feeding. Feeds on carrion, from medium-sized to large carcasses; only rarely takes live prey, e.g. lizards and tortoises. In S Spain, feeds basically on mammals, including 90% rabbits and sheep, but insects and lizards also appear in diet; here, increase of wild ungulate populations has changed diet, so that such species are now important. In Mongolia, sometimes found in large numbers in areas affected by Tarbagan pest, a disease of Bobak marmot (*Marmota bobak siberica*); also takes prey from *Aquila nipalensis*. In Tibet, feeds on carcasses of wild yaks, blue sheep, Tibetan gazelles, kiang, woolly hare and Himalayan marmots, together with domestic yak, sheep, and sometimes even corpses of human beings put out on "celestial burial platforms". Generally dominant at carcasses; heavy bill capable of tearing through muscles, tendons and skin.

Breeding. Laying in Feb-Apr. Tends to congregate in very loose colonies or nuclei; in Spain occupied nests 30 m to 2 km apart; density of 1.7-2.0 pairs/1000 ha in Nurata Reserve, 300 km SE of Tashkent (Uzbekistan); 5 pairs in 100 km² in Kentei Mts, Mongolia. Nests usually (1.5-5 m up) in trees: in Spain, mainly evergreen oaks (*Quercus*) and pines (*Pinus*); in Armenia, Azerbaijan, Kopet-Dag, Tien Shan and Baluchistan, mainly junipers (*Juniperus*); in Uzbekistan, often on Buchara almond (*Amygdalus bucharica*); nests on rocks extremely rarely in Europe, but more often in parts of Asia, e.g. Tien Shan. Enormous stick nest 145-190 cm wide, 95-300 cm deep, often occupying much of tree. 1 egg, extremely rarely 2 (0.76%); in C Asia, clutch size averages 1.01 eggs (per laying); incubation usually 54-56 days (50-62); chicks have grey down, paler on head; fledging 95-110 days in Spain, 104-120 days in C Asia. Hatching success 90%, and high overall nesting success in Spain, but much pairs do not breed every year. Breeding success in Nurata Mts (Uzbekistan) 0.57 young per pair. In captivity has lived to 39 years old.

Movements. In S Europe adults non-migratory, in C Asia semi-resident, often following nomads and their domestic herds. Partly migratory in Asia: most birds leave Mongolia and other N breeding areas for winter; migrants winter from NE Africa and Middle East through N India to Korea; some birds reach Arabia and S China.

Status and Conservation. VULNERABLE. CITES II. Threatened at world level, partly because nests on trees which are often easily accessible. In many areas, the forests where it breeds have been cut down or will be destroyed in near future. Also suffering from lack of food, poisoning, direct persecution, etc. Has declined or disappeared from much of former range in W; exception is Spain, where species increased from 200 pairs in 1970 to 900-1000 pairs in 1992, after major conservation efforts; 85% of population now in protected areas. In Mallorca (Balearic Is), increased from 20-22 birds in 1966 to 57 birds in 1991, as result of releases. In France, 9 birds released in 1992 and 1993. Now extinct in Morocco, Portugal, Italy, former Yugoslavia, Albania, Romania, Moldova and Israel. Tiny remnant populations in Greece (c. 16 pairs), Bulgaria (1 pair), Ukraine, in Crimea (3-6 pairs, from 15-20 in 1950's) and Turkey (very rare). Presently c. 50 pairs in European Russia; 60-80 pairs in Azerbaijan, and probably c. 40-70 pairs in Georgia and Armenia. No exact information further E, but probably over 1000 pairs in Asian part of former USSR; regularly observed in C Asia and Mongolia. Even in Tibet, where Qinghai, Xizang and Ganan are refuge areas for species because Tibetans protect it, chemical pesticides used against rodents have led to poisoning of vultures and decline in breeding rates. Many vultures also trapped or shot in China

for trade in their feathers. Problem of collecting live specimens is becoming especially acute in former USSR.

Genus *TORGOS* Kaup, 1828

56. Lappet-faced Vulture

Torgos tracheliotus

French: Vautour oricou **German:** Ohrengerier **Spanish:** Buitre Orejudo
Other common names: African Black/King Vulture, Nubian Vulture

Taxonomy. *Vultur tracheliotus* J. R. Forster, 1791, Great Namaqualand, South Africa. Usually considered sufficiently distinctive to merit monotypic genus, but sometimes placed in *Aegypius* along with *A. monachus*, *T. occipitalis* and *S. calvus*, and in superspecies with *A. monachus*. Validity of races questionable, as variation may be largely individual and clinal. Three subspecies recognized.

Subspecies and Distribution.
T. t. tracheliotus (J. R. Forster, 1791) - extreme SW Morocco; S Mauritania E to Ethiopia and Kenya, S to South Africa.
T. t. nubicus (H. Smith, 1829) - Egypt and N Sudan.
T. t. negevensis Bruun *et al.*, 1981 - S Israel and Arabian Peninsula.

Descriptive notes. 115 cm; 5400-9400 g, mean 6780 g; wingspan 280 cm. Very large, although size often exaggerated: in E Africa, averages considerably lighter (6200 g) than sympatric *G. rueppellii* (7400 g). Colour of head and exposure of lappets partly dependent on mood and temperature. White down on adult's patagia and thighs forms distinctive flight pattern. Juvenile brown with some down on head, dark horn-coloured head and no pale areas on underparts. Races recognized on extent of lappets and bald head, and on colour of bill and thighs, but considerable individual variation may be clinal; *negevensis* has patagia buff-coloured.

Habitat. Steppe and desert, where isolated flat-topped trees provide nest-sites; also extends into more mesic open savanna and woodland, breeding up to 2800 m.

Food and Feeding. Carrion, skin and bone fragments from large and small carcasses; takes up to 1450 g in one meal. Mainly scavenges; credited with killing some small animals but may pirate from other raptors. Usually in pairs, but up to 50 birds may gather with other vultures at larger carcasses or at water. Large, broad wings with low wing-loading allow relatively early ascent and slow searching flights. May dominate all other scavenging birds at a carcass, with bounding attack display, but often spends more time in social interaction than feeding, returning later to use heavy bill for rending skin and sinew.

Breeding. Laying usually in dry season: Oct-Jan in W Africa, Dec-Feb in NE Africa and Middle East, Feb-Jul in E Africa, Apr-Aug in S Africa. Builds extensive platform of sticks, lined with dry grass, usually on a short, exposed thorny tree. Several nests from previous attempts may be found nearby, and pairs nest either alone or somewhat clumped within an area of suitable habitat. Single egg (rarely 2); incubation 54-56 days; chick has first down white and second down grey; fledging 125-135 days; may still be fed regularly by parents a year after fledging.

Movements. No regular movements described, except for W Africa where apparent shift N during the rains and S during the dry season. Adults may forage over 200 km from the nest, and juveniles known to have dispersed at least 700 km.

Status and Conservation. Not globally threatened. CITES II. Thinly scattered as a breeding species throughout its wide range, with concentrations of up to c. 40 pairs found only in Namibia, Botswana, Zimbabwe, South Africa, Tanzania and possibly Arabia. Decline in NE Africa during 1930's, and more recently in Algeria, and now extinct in both areas; also range reduction in South Africa and Namibia, where poisoning implicated, and in Sudan. Only one pair out of at least 30 remained in Israel by 1989, and only 10 pairs in Upper Egypt, suggesting that the relatively small population of race *negevensis* might be vulnerable, but a good number of breeding pairs recently discovered occupying substantial part of interior of Saudi Arabia. A small captive breeding population exists at Tel Aviv (Israel).

Bibliography. Anthony (1976), Bannerman (1953), Benson & Benson (1975), Bergier (1987), Brown, C.J. (1986b, 1988b), Brown, L.H. *et al.* (1982), Bruun (1981), Bruun *et al.* (1981), Cramp & Simmons (1980), Gënsbøl (1986), Ginn *et al.* (1989), Goodman *et al.* (1989), Gore (1990), Herholdt & de Villiers (1989), Houston (1989), Hustler & Howells (1988a), Jennings (1982), Leshem (1984), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Mundy (1982), Mundy *et al.* (1992), Newton & Shobrak (1993), Paz (1987), Pennycook (1976), Pickford *et al.* (1989), Pinto (1983), Richardson (1990), Shirihai & Yekutieli (1991), Steyn (1982), Tarboton & Allan (1984), Weigelt & Schulz (1992), Wilson, R.T. (1982).

Genus *TRIGONOCEPS* Lesson, 1842

57. White-headed Vulture

Trigonoceph occipitalis

French: Vautour à tête blanche **German:** Wollkopfgeier **Spanish:** Buitre Cabeciblanco

Taxonomy. *Vultur occipitalis* Burchell, 1824, Matlowing River, Botswana.

Usually considered sufficiently distinctive to merit monotypic genus, but sometimes placed in genus *Aegypius* with *A. monachus*, *T. tracheliotus* and *S. calvus*. Monotypic.

Distribution. Senegal E to Ethiopia (including Dahak Archipelago) and Somalia, then S to Namibia and N South Africa.

Descriptive notes. 85 cm; 3300-5300 g, mean 4260 g; wingspan 230 cm. Pied plumage, angular head, high neck ruff and bright facial colours notable. Both sexes have greater underwing-coverts tipped white, but only female has white inner secondaries (from first post-juvenile moult; most evident in flight. Juvenile fledges with white down on head, which then becomes dark brown all over, with paler facial colours than adult, somewhat like juvenile *Torgos tracheliotus*.

Habitat. Dry woodland and tree savanna, not extending into drier steppe or denser forest areas.

Food and Feeding. Carrion and bone fragments from carcasses large and small. Feeds alone or in pairs, rarely more than two pairs congregating at larger carcasses; prefers to snatch a chunk from another species and then feed sedately nearby. Often first at a kill, or follows an eagle or another early-arriving scavenger e.g. *Terathopus ecaudatus*. Credited with killing some small or weak prey, but may also rob or scavenge from other raptorial birds. Includes termite alates or locusts in the diet when available.

Breeding. Laying usually in the dry season: Oct-Jan in W and NE Africa; all months in E Africa, depending on rainfall patterns; May-Aug in S Africa. Builds rather deep stick platform on crown or open upper fork of a tall tree, often in a conspicuous position, made more so by the adults perching on the nest for long periods. Single egg; incubation 55-56 days; chick has white down; fledging 115-120 days. One remarkable record of incubation and rearing in wild by *Torgos tracheliotus*.

Movements. No regular movements of adults reported, even in W Africa. Adult pairs apparently sedentary within a limited home range, possibly territorial. Adults may be most sedentary of African vultures, but wide juvenile dispersal expected and indication of juvenile movements with rains in W Africa and Chad.

Status and Conservation. Not globally threatened. CITES II. Generally uncommon, at 0.25-1.2 birds/100 km of road counts, with highest values of up to 9.3 birds/100 km from woodland-grassland mosaic in Cameroon and Uganda. Estimated 130 pairs in South Africa, 80 in Hwange National Park, Zimbabwe. Up to 61% of pairs do not attempt breeding every year, especially during periods of below average rainfall.

Bibliography. Anthony *et al.* (1980), Bannerman (1953), Benson & Benson (1975), Brooke (1984), Brown *et al.* (1982), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Houston (1989), Howells & Hustler (1984), Hustler & Howells (1988b), Koenig (1979), Kruuk (1967), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Mundy (1982, 1985a, 1987), Mundy *et al.* (1992), Pennycook (1976), Pickford *et al.* (1989), Pinto (1983), Richardson (1984), Steyn (1982), Tarboton & Allan (1984), Thiollay (1978c).

Genus *SARCOGYPS* Lesson, 1842

58. Red-headed Vulture

Sarcogyps calvus

French: Vautour royal **German:** Kahlkopfgeier **Spanish:** Buitre Cabecirrojo
Other common names: (Indian/Asian) King/Black Vulture, Pondicherry Vulture

Taxonomy. *Vultur calvus* Scopoli, 1786, Pondicherry, India.

Sometimes placed in *Aegypius* or *Torgos*, but probably distinctive enough to merit its own monotypic genus. Monotypic.

Distribution. E Pakistan through India, except extreme S, and Nepal to SC China (S Yunnan). Burma, Indochina and N Malay Peninsula.

Descriptive notes. 76-84 cm; 3600-5400 g; wingspan 218-229 cm. Medium-sized, jet black vulture; pale grey band across base of flight-feathers from above and below. Red head and legs; lappets on sides of neck; in flight, white flank spots and tapered wing shape distinctive. Iris pale (white to yellowish) in adult male, dark in female. Juvenile dark brown with dark eye; in flight, shows distinctive white patches, while wing shape similar to *Gyps* vultures.

Habitat. Wide variety of habitats, including open countryside, cultivated areas, savanna woodland, and foothills up to 2000 m; often in proximity of human habitation.

Food and Feeding. Usually feeds on carrion; also pirates food from other vultures, especially *Neophron perenopator*, and perhaps from other raptors. Attends carcasses in company of other vultures, but usually less numerous; generally rather timid at carcasses.

Breeding. Season mainly Dec-Apr, with most laying in Jan-Feb. Large nest built by pair 9-12 m up large tree, often at top; in desert areas, nest placed 2-3 m up on top of smaller bushes; nest is lined with green leaves. Display flights more acrobatic than those of other Asian vultures, with mutual soaring and cartwheeling. Pairs territorial, excluding conspecifics. Usually 1 egg; incubation c. 45 days, by both sexes; chick has greyish white down; fledging and dependency periods unknown.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Because territorial, never as numerous as other sympatric vulture species. Fairly common in Nepal and in many parts of India. Declining in Gujarat (W India), Malay Peninsula and perhaps elsewhere; most likely causes are decrease in availability of food and also direct persecution. Apparently rare on periphery of range in Yunnan (SC China) and Pakistan.

Genus *CIRCAETUS* Vieillot, 1816

59. Short-toed Snake-eagle

Circaetus gallicus

French: Circaète Jean-le-Blanc **German:** Schlangenadler **Spanish:** Culebrera Europea
Other common names: Short-toed Eagle

Taxonomy. *Falco gallicus* Gmelin, 1788, France.

Forms superspecies with *C. beaudouini* and *C. pectoralis*, both of which are frequently considered races of present species, due to occurrence of mixed pairs in zones of overlap. Population of Lesser Sunda is racially distinct; averages somewhat smaller and may have different timing of moult, but remains little known at present. Name *C. ferox* formerly applied, but is unidentifiable. Monotypic. **Distribution.** NW Africa and SW Europe N to Gulf of Finland and E to L Balkash and Iran; Indian Subcontinent; Lesser Sunda (from Lombok to Timor). W populations winter in Sahel zone.

Descriptive notes. 62-67 cm; male 1200-2000 g, female 1300-2300 g; wingspan 170-185 cm. Plumage rather variable; typical contrast of dark head and upper breast with white underparts ranges from very conspicuous (re-calling *C. pectoralis*) to non-existent; brown barring on underparts equally variable. Large head; yellow iris; 3-4 bands on tail; upperparts mainly greyish brown, generally paler than in *C. beaudouini* and much paler than *C. pectoralis*. Juvenile similar to adult.

Habitat. Varied habitats mainly in warm temperate and tropical zones; from open woodland and even fairly dense forest to semi-desert.

Often occurs in areas with mixed habitats: requires fairly open areas rich in reptiles, e.g. stony areas with sparse vegetation cover, pastures, scrub; also, nearly always requires tree cover of some sort, e.g. small woods or scattered trees. From plains and hilly country to mountains; hunts up to tree-line and above; in Morocco breeds up to 2300 m. Nests in very wide range of woodland types, including both coniferous and deciduous. Perches on vantage points, e.g. trees, bluffs, pylons.

Food and Feeding. Specializes in reptiles, particularly snakes, which constitute 70-80% of prey or more. Regional variation in species: mainly non-venomous species, especially Colubridae, up to 150+ cm in length. Also takes other reptiles, particularly lizards, including monitors (*Varanus*), chameleons, geckos, slow-worms and skinks; occasionally mammals, e.g. rodents, shrews, rabbits, hares, hedgehogs; also amphibians; few birds and invertebrates. Probably takes fewer reptiles during bad weather and when recently arrived on breeding grounds. Normally hunts in open areas, but sometimes in dense vegetation; forages at medium height or remarkably high up (normally 20-150 m), with gliding or soaring flight; to survey terrain more closely, hovers on wind or with wings beating, "parachuting" down on prey, once located, often with a brief final hover. Swallows snakes and lizards whole, head first; but head may be crushed or torn off prior to consumption, and large snakes can be torn to pieces before being eaten; part of prey sometimes sticks out of bill, when bird already in flight.

Breeding. Lays in Apr in S Europe and Morocco; Jan-Feb in Indian Subcontinent; young bird in Oct in Lesser Sunda. Nests almost exclusively in trees, rarely very tall, often only a few metres in height; very rarely nests on cliff ledges; sometimes uses nest of other raptors or corvids. Nest built on crown of tree or on lateral branch; small for size of species, often no more than 50 cm wide, c. 30 cm deep; built of sticks and twigs, and lined with green leaves or grass. Pair-bond probably maintained in both migratory and sedentary populations, but new nest normally built each year. 1 egg; replacement clutch rare; incubation 45-47 days, mainly by female; chick has white down; cared for and fed by both adults; at first given small bits of food, but later learns to pull prey out of adult's crop, and swallow it whole; fledging 60-80 days; independent, leaving parents' territory soon after. Breeding success in C Italy of 0.75 chicks fledged per pair. Oldest recorded bird 17 years old.

Movements. Migratory in Palearctic; sedentary in India, Pakistan and Lesser Sunda. Most migrants winter in tropical N Africa, from Senegambia to Ethiopia; E birds winter in Indian Subcontinent, occasionally in SE Asia. Exceptional in winter in S Europe, N Africa and Middle East; more common in Arabian Peninsula. Most birds leave Europe from mid-Sept to mid-Oct, returning during Mar and first half of Apr. Birds gather at crossing points: main route between Africa and Europe passes over Straits of Gibraltar; between Africa and Asia over Gulf of Suez. Vagrant to Malay Peninsula; one probable record from E Java.

Status and Conservation. Not globally threatened. CITES II. Declined markedly in past, disappearing from most of C & N Europe in 19th century; possibly stable at end of 20th century. In Europe and Asia, affected very little by pesticides, and generally suffers less from shooting than sedentary raptors, although on Malta even in 1993 all 50 birds that arrived on single day were shot. Long-term population trends probably depend on habitat changes resulting from intensification of farming, etc. Estimates in 1980's: 1000-2000 pairs in Spain; 80-100 pairs in Portugal; c. 1000 pairs in France; 380-415 pairs in Italy; perhaps 200 pairs in former Yugoslavia; over 300 pairs in Greece; c. 50-70 pairs in Bulgaria; c. 30-100 pairs in Romania; c. 45-50 pairs in Hungary; c. 20-30 pairs in Poland; over 1000 pairs in Morocco; and over 200 pairs in Tunisia. Estimates from early 1990's include: 1000 pairs in European Russia; 200-250 pairs in Byelorussia; and sizeable population in Ukraine, where declining due in part to deforestation. Very little information on Asian populations: perhaps 100-200 pairs in Israel; and 100-1000 pairs in Turkey, although maximum alternatively estimated at c. 8000 pairs; the 12,000 birds seen in Suez in autumn 1984 must correspond to populations occupying E Europe and most of Asia. In Pakistan, widespread and locally quite common, but generally rather sparsely distributed. Status in Lesser Sunda virtually unknown, but very few records, so species almost certainly uncommon, at best; until recently thought to be mere migrant to these islands, but breeding proved in 1971.

Bibliography. Ali & Ripley (1978), Amores & Franco (1981), van Balen & Compost (1989), Bergier (1987), Boudouin (1953), Boudouin *et al.* (1953), Brown, L.H. (1974a, 1976b), Brown *et al.* (1982), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Eichécopar & Hude (1978), Flint *et al.* (1984), Gensbøl (1986), Goodman *et al.* (1989), Handrinos & Demetropoulos (1983), Knystautas (1993), Król (1983), Mackworth-Præd & Grant (1957-1973), Olech (1991), Paz (1987), Petreñ (1988), Richardson (1990), Roberts (1991), Rocamora (1994b), Shirahai & Christie (1992), Simeonov *et al.* (1990), Thiollay (1989), White & Bruce (1986).

60. Beaudouin's Snake-eagle

Circaetus beaudouini

French: Circaète de Beaudouin **Spanish:** Culebrera Sudanesa
German: Beaudouin-Schlangenadler
Other common names: Beaudouin's Harrier-eagle

Taxonomy. *Circaetus beaudouini* J. Verreaux and Des Murs, 1862, Bissau, Guinea-Bissau.

Often considered conspecific with *C. gallicus* and *C. pectoralis*, as some mixed pairs occur; these three species form superspecies. Monotypic.

Distribution. S Mauritania and Senegambia E to SW Sudan, N Uganda and NW Kenya.

Descriptive notes. 60 cm. Generally shows darker upperparts and bolder flight-feather markings than *C. gallicus*, while dark bars in tail tend to be more pronounced; underparts pale grey-brown with fine white barring. Most resembles intermediate immature plumage of *C. pectoralis*, of which adult much darker and more pied, and which may confound reports of hybridization. Juvenile much paler than congeners, almost white on head and neck.

Habitat. Open woodland and tree savanna, possibly overlapping in NW Kenya with *C. pectoralis*, which tends to occur in more open habitats.

Food and Feeding. Mainly snakes, but also other small vertebrates when necessary. Hunts from a prominent perch more often than its nearest relatives; also forages by means of soaring flight that is interrupted at intervals to hover. Often perches on edge of woodland, and generally more static in behaviour than its close relatives.

Breeding. Laying Nov. Virtually unstudied but probably similar to *C. gallicus* and *C. pectoralis*. Builds small inconspicuous stick nest on crown of tree. Single egg; other details unrecorded.

Movements. A regular seasonal migrant between moist wooded savannas and the Sahel; most birds move N in rains and S in dry season, in association with grass fires and reduced ground cover. In some areas, patterns of movement have been masked by confusion with *C. gallicus*.

Status and Conservation. Not globally threatened. CITES II. Generally uncommon. Most limited range of any *Circaetus* eagle, and if a good species must be considered vulnerable as it inhabits the generally degraded habitats of the Sahel zone. Not known to be affected by pesticides or seriously persecuted.

Bibliography. Brown, L.H. (1974a), Brown *et al.* (1982), Browne (1981), Gore (1990), Grimes (1987), Lewis & Pomeroy (1989), Morel & Morel (1990), Serle (1943), Serle *et al.* (1977), Snow (1978), Thiollay (1975c, 1978c, 1985d).

61. Black-breasted Snake-eagle

Circaetus pectoralis

French: Circaète à poitrine noire **Spanish:** Culebrera Pechinegra
German: Schwarzbrust-Schlangenadler
Other common names: Black-chested Snake-eagle, Black-breasted Harrier-eagle

Taxonomy. *Circaetus* [sic] *Pectoralis* A. Smith, 1829, South Africa.

Often considered conspecific with *C. gallicus* and *C. beaudouini*; these three species form superspecies. Monotypic.

Distribution. E Sudan and Ethiopia S to South Africa.

Descriptive notes. 65 cm; 1178-2260 g; wingspan 178 cm. Pied plumage of adult and yellow eye similar to adult *Polemaeus bellicosus*, but underwing mainly white not black and underparts unspotted. Juvenile plumage brown, similar to *C. cinereus* but more cinnamon below; present species usually perches more horizontally. Intermediate immature plumage similar to adult, but browner with brown scallions on white underparts.

Habitat. Open areas of savanna and steppe, extending into deserts and clearings in woodland, but absent from forested areas.

Food and Feeding. Mainly snakes and lizards but takes rodents, amphibia, arthropods, even small birds, bats and fish, more than other snake-eagles. Perch-hunts for long periods but also spends much time on the wing soaring in search of prey, interspersed with bouts of hovering. Up to 200 individuals may roost communally when not breeding, spreading out during the day to hunt solitary, less often gregariously when prey locally abundant e.g. rodents or locusts. Often consumes prey in flight; snakes swallowed but left hanging from bill, when delivered to nest.

Breeding. Laying during dry season: Nov-May in NE and E Africa; May-Jan in C Africa; Mar-Oct in S Africa. Builds small platform of thin sticks on the crown of a tree, often a small, isolated one and generally secretive when nesting; rarely nests on a power pylon. Single egg; incubation 51-52 days; chick has white down; fledging 89-90 days.

Movements. Known to be highly nomadic and possibly even makes regular intra-African migrations: a non-breeding visitor, moving regularly into several areas, or numbers fluctuating considerably in others, but details unclear.

Status and Conservation. Not globally threatened. CITES II. Widespread and often locally common. Broad habitat tolerance, mobility, secretive breeding and use of man-modified areas all bode well for its future. Not known to be affected by pesticides.

(1974a), Brown *et al.* (1982), Colebrook-Robjent & Aspinwall (1986), Dowsett & Dowsett-Lemaire (1980), Ginn *et al.* (1989), Lewis & Pomeroy (1989), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Steyn (1966, 1982), Turboton & Allan (1984).

62. Brown Snake-eagle

Circaetus cinereus

French: Circaète brun **German:** Einfarb-Schlangennadler **Spanish:** Culebrera Sombria
Other common names: Brown Harrier-eagle

Taxonomy. *Circaetus cinereus* Vieillot, 1818, Senegal. Monotypic.

Distribution. Senegambia E to N Ethiopia and S to South Africa.

Descriptive notes. 75 cm; 1540-2465 g; wingspan 164 cm. Dark brown colour and upright stance distinguish from juvenile *C. pectoralis* or from *C. beudouini*. Underside of flight-feathers silvery white against dark coverts. Juvenile slightly paler; intermediate immature plumage with few spots and bars of white on underparts.

Habitat. Woodland and tree savanna, especially where low hills protrude, less often extending into drier steppes.

Food and Feeding. Snakes, including large and poisonous species, and a few large lizards; rarely rodents or gamebirds. Hunts primarily from a perch on top of a prominent tree, often on a hill, making long strikes at prey or infrequent changes of perch. Only rarely hunts from foraging flight or after hovering briefly. Usually consumes prey on the ground. Sometimes attracted by small birds mobbing a predator.

Breeding. Laying Nov-Feb in W Africa and NE Zaire; Feb-May in E and C Africa; Jul-Mar in S Africa. Builds small platform of thin sticks on crown of tree, succulent plant, epiphyte, buffalo-weaver (*Bubalornithinae*) nest, or rarely a power pylon, often on the old nest of another raptor. Secretive when breeding. Single egg; incubation 48-50 days; chick has white down; fledging 97-113 days.

Movements. Resident and sedentary in many areas, but long distance ringing recoveries (up to 2100 km) and fluctuations in numbers in S and E Africa suggest some intra-African movements. In W Africa may move S in dry season and N when rains increase ground cover.

Status and Conservation. Not globally threatened. CITES II. Widespread and conspicuous but often at low density, such as 1 pair/200 km² in Kenya. Vulnerable to clearing of woodland and lowering of primary productivity through overgrazing. Not known to be affected by pesticides.

Bibliography. Allan (1988b), Benson & Benson (1975), Britton (1980), Brown, L.H. (1976b), Brown *et al.* (1982), Colebrook-Robjent & Aspinwall (1986), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Steyn (1964, 1972a, 1975a, 1982), Turboton & Allan (1984), Thiollay (1978c).

63. Southern Banded Snake-eagle

Circaetus fasciolatus

French: Circaète barré **German:** Graubrust-Schlangennadler **Spanish:** Culebrera Barreada
Other common names: Fasciolated/Fasciated/East African Snake-eagle

Taxonomy. *Circaetus fasciolatus* Kaup, 1847, Natal, South Africa. Monotypic.

Distribution. Kenya to NE South Africa along the E coast of Africa and further inland along major rivers.

Descriptive notes. 60 cm; 908-1110 g. Barred underparts and three white bars on long tail distinguish from *C. cinerascens*. A highly vocal species, especially when adult. Juvenile dark brown above and white below, flecked with buff and streaked with black respectively. Intermediate plumage not described.

Habitat. Dense coastal and riverine forest, ranging into savanna adjoining marshes and floodplains.

Food and Feeding. Mainly small snakes and lizards, also some rodents, amphibians, arthropods and birds. Secretive and solitary, usually perching within the canopy when hunting, less often in the open. Changes perch infrequently and rarely soars above forest.

Breeding. Laying Jul, Oct in E Africa; Sept-Oct in S Africa. Builds small stick nest in upper fork of forest tree, deep within canopy, and often well hidden among creepers. Single egg; incubation and fledging periods unrecorded.

Movements. Sedentary and resident throughout limited range, except for some movement N into Kenya in dry season May-Sept.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Locally common, but habitat often patchy and restricted. Secretive nature and reptilian diet do not attract persecution; often hunts on edges of small agricultural clearings. Vulnerable to cutting and degradation of forest habitat, especially along rivers. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Britton (1980), Brown, L.H. (1969, 1976b), Brown *et al.* (1982), Clancey (1987a, 1990), Danell (1965, 1966a), Ginn *et al.* (1989), Krueger (1967), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Steyn (1982), Zimmerman (1970).

64. Western Banded Snake-eagle

Circaetus cinerascens

French: Circaète cendré **German:** Bandschlangennadler **Spanish:** Culebrera Coliblanca
Other common names: (Smaller) Banded Snake-eagle, Banded Harrier-eagle

Taxonomy. *Circaetus* [sic] *cinerascens* J. W. von Müller, 1851, Sennar, Sudan. Monotypic.

Distribution. Senegambia E to S Sudan and W Ethiopia, then S to R Zambezi, occurring S to Angola and Namibia in W, and Zimbabwe and Zambia in E.

Descriptive notes. 60 cm; 1126 g; wingspan 114 cm. Stocky appearance with slightly barred underparts and single pale bar across short tail distinguish from *C. fasciolatus*. Individually variable in colour and barring. Juvenile brown above and on tail with white head and underparts; intermediate plumage all dark brown.

Habitat. Riverine forest, gallery forest and woodland associated with riparian systems; does not enter lowland rain forest.

Food and Feeding. Mainly snakes but also small monitor lizards, small tortoises, rodents, amphibians and some fish and insects. Perches

on open limbs among forest trees, taking most prey from the ground but some from foliage and trunks. Sedentary in small area of forest, making only short flights when changing perch.

Breeding. Laying Dec-Apr in Zambia; Mar in Zimbabwe; suspected Jan-Feb in NE Africa and Jul in NE Zaire; no breeding recorded in W Africa, but suspected breeding pair in Mar in Ghana. Vocal within forest, especially prior to nesting, and may also perform diving flight display. Builds small platform of sticks well concealed within canopy, often on a thorny tree and almost invariably among creepers. Single egg; incubation unrecorded; chick has first down white, second down fawn; fledging c. 56 days.

Movements. Usually sedentary within linear riverine forest habitats, but may move seasonally into adjacent parts of E Africa or S in wet season into Guinea woodland of W Africa.

Status and Conservation. Not globally threatened. CITES II. Locally common but with patchy linear distribution. Vulnerable to degradation of riverine habitat, e.g. in NE Namibia, where only 14 pairs now estimated to occur. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Brown, C.J. & Hines (1987), Brown, L.H. (1976b), Brown, L.H. *et al.* (1982), Colebrook-Robjent & Aspinwall (1986), Edwards (1985), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Steyn (1982), Thiollay (1975b, 1978c).

Genus *TERATHOPIUS* Lesson, 1830

65. Bateleur

Terathopus ecaudatus

French: Bateleur des savanes **German:** Gaukler **Spanish:** Aguila Volatinera
Other common names: Bateleur Eagle

Taxonomy. *Falco ecaudatus* Daudin, 1800, Knysna district, Cape province, South Africa.

Monotypic genus. Several features of morphology, in addition to juvenile plumage and feeding habits, indicate links with *Circaetus*. Monotypic.

Distribution. Senegambia E to Sudan and Ethiopia then S to Namibia and South Africa.

Descriptive notes. 60 cm; 1820-2950 g; wingspan 187 cm. Very short tail and long primaries distinctive, especially in low rocking flight with upturned wing tips. In male, secondaries mostly black; female has secondaries grey above, mostly white below with black trailing edge; sexes separable perched and in flight, even as subadults; c. 7% of adults have back cream, not chestnut. Juvenile brown with blue-green facial skin and legs, similar to several snake-eagle plumages; becomes sooty brown with basic adult patterns in intermediate plumage, face and legs turning orange before assuming adult scarlet.

Habitat. Open woodland and tree savanna, extending into bush savanna but less into scrubby steppe and grassland.

Food and Feeding. Various small animals, taken live or as carrion. Mainly small mammals and birds, also reptiles, fish, birds' eggs, crabs and insects. Hunts from characteristic low searching flight, gliding back and forth about 50 m above ground. Usually descends on prey in tight spiral. Up to 50 may gather at emergences of termite alates, especially immatures.

Breeding. Laying Sept-Dec in W Africa; all months in E Africa (peak Feb-Mar) and S Africa (peak Dec-Mar). Performs acrobatic rocking display flight. Builds large nest of sticks in open fork of large tree, sometimes on old structure of another bird species, often along a watercourse. Single egg; incubation 52-59 days; chick's down dark brown, with cream head and thighs; fledging extremely variable at 93-194 days; post-fledging dependence of up to 4 months; parents share rearing of young and extra juvenile or adult may attend some nests.

Movements. Adult pairs territorial and resident in most areas, but juveniles excluded, becoming highly mobile and nomadic, with concentrations developing in some areas such as SW and E Africa. May move N in rainy season in W Africa during Jul-Sept. Vagrant to Tunisia, Israel, SW Arabian Peninsula and Iraq.

Status and Conservation. Not globally threatened. CITES II. Widespread and common at densities of 1 pair/140-200 km² in Kenya, or 1 pair/30-60 km² in Transvaal (estimated total of 600 pairs). Suffered extensive range retraction in many areas of South Africa, Namibia and Zimbabwe through poisoning and nest disturbance, and now only common in larger nature reserves. Also declining in W Africa (Ivory Coast) and in Sudan. Some evidence for pesticide contamination in S Africa but no population effects described.

Bibliography. Benson & Benson (1975), Britton (1980), Brown, L.H. (1955), Brown & Cade (1972), Brown *et al.* (1982), Colebrook-Robjent & Aspinwall (1986), Cramp & Simmons (1980), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Herholdt & de Villiers (1989, 1991), Hustler (1985), de Kock & Watson (1985), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1962), Maclean (1993), Moreau (1945), Nikolaus (1987), Orosion (1993), Pap (1987), Smock (1973), Snelling (1970), Snelling *et al.* (1984), Steyn (1965a, 1980b, 1982), Turboton & Allan (1984), Thiollay (1978c, 1985d), Tree (1978), Watson (1985, 1987, 1988, 1989, 1990a, 1990b), Wilson, R.T. (1982).

Genus *SPILORNIS* G. R. Gray, 1840

66. Crested Serpent-eagle

Spilornis cheela

French: Serpenteaire bacha **German:** Schlangenweihe **Spanish:** Culebrera Chifla
Other common names: Small/Nicobar (Crested) Serpent-eagle (*minimus*); Ryukyu Serpent-eagle (*perplexus*); Simeulue Serpent-eagle (*abbotti*); Nias Serpent-eagle (*asturinus*); Mentawai Serpent-eagle (*sipora*); Natuna Serpent-eagle (*naturensis*)

Taxonomy. *Falco Cheela* Latham, 1790, India = Lucknow. Complex genus, with taxonomy extremely confused and tentative; complete revision and extensive study of relationships and species limits required; research priorities include field work on biology, especially with regard to prey and vocalizations, and laboratory analyses of DNA. Present species currently considered to form superspecies with *S. klossi*, *S. kinabaluensis*, *S. rufipectus* and *S. holospilus*, but may be conspecific with any or all of these taxa; any or all of races *perplexus*, *abbotti*, *asturinus*, *sipora* and *naturensis* may be valid species; different treatment of these two groups is essentially arbitrary in most cases; extraordinary size differences suggest that some island races probably merit recognition as full species. Situation in Nicobar Is particularly complicated and uncertain, although presence of two different species of *Spilornis* generally agreed upon: race *davisoni* said to occur by some authors; race *minimus* often considered separate species, usually including *S. klossi*. Several further races have been described. Twenty-one subspecies currently recognized.

Subspecies and Distribution.

- S. c. cheela* (Latham, 1790) - N India and Nepal.
- S. c. melanotis* (Jerdon, 1844) - India S from Gujarat and Gangetic Plain.
- S. c. spilogaster* (Blyth, 1852) - Sri Lanka.
- S. c. burmanicus* Swann, 1920 - Burma, SW China, Thailand and Indochina.
- S. c. davisoni* Hume, 1873 - Andaman Is; possibly also Nicobar Is.
- S. c. minimus* Hume, 1873 - C Nicobar Is.
- S. c. ricketti* W. L. Slater, 1919 - N Vietnam and SC & SE China.
- S. c. perplexus* Swann, 1922 - S Ryukyu Is.
- S. c. hoyi* Swinhoe, 1866 - Taiwan.
- S. c. rutherfordi* Swinhoe, 1870 - Hainan.
- S. c. palawanensis* W. L. Slater, 1919 - Palawan group (Philippines).
- S. c. pallidus* Walden, 1872 - lowlands of N Borneo.
- S. c. richmondi* Swann, 1922 - S Borneo.
- S. c. naturensis* Chasen, 1934 - Natuna Is and Belitang I (off W & SW Borneo).
- S. c. malayensis* Swann, 1920 - Malay Peninsula (from S Tenasserim), nearby Anambas Is and N Sumatra.
- S. c. batu* Meyer de Schauensee & Ripley, 1939 - S Sumatra and Batu Is (off W Sumatra).
- S. c. abbotti* Richmond, 1903 - Simeulue I (off W Sumatra).
- S. c. asturinus* A. B. Meyer, 1884 - Nias I (off W Sumatra).
- S. c. sipora* Chasen & Kloss, 1926 - Mentawai Is (off W Sumatra).
- S. c. bido* (Horsfield, 1821) - Java and Bali.
- S. c. haweanus* Oberholser, 1917 - Bawean I (off N Java).

Habitat. Occurs in a wide variety of habitats, including dry to wet forests, tea plantations, wooded savannas and mangroves. Frequents open or closed forest, but not in dense forest interior; only secondary or partly open forest, clearings, gaps and forest edge; also plantations, e.g. of teak. Occurs from sea-level to 1900 m.

Food and Feeding. Preys mainly on reptiles, especially tree snakes; also a few mammals, crabs, eels and birds. Hunts almost exclusively from exposed perch near open glade, along stream or along forest edge. Snakes taken on ground or in trees, after short stoop. Much time spent soaring, and individuals soar and call throughout year.

Breeding. Season varies with locality, depending on timing of rainy season (laying mostly in dry season in N of range): Dec-Mar in S India; Feb-May in N India, and also in Sri Lanka; Feb-Apr in Burma and Sumatra; record of second brood in Jun in Burma. Rather small nest lined with grass, built by pair 7-12 m up large tree; often near clearing or stream. Spectacular display flights include mutual soaring, undulations and threat display, with wings bowed upwards and head and tail raised; also accompanied by loud vocalizations. 1 egg (reports of 2 eggs should be verified); incubation c. 35+ days, by female; chick has white down; both parents feed chick; fledging and dependency periods unknown. A fledgling being fed in Sept in Malaysia may indicate late nesting or long dependency period.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Throughout extensive range generally widespread and common, sometimes abundant, but locally uncommon. No threats known at present, and species appears to be quite adaptable to disturbed habitats. Surveys required, in order to establish conservation status of well marked island races, especially as some (or all) of these may subsequently prove to be distinct species.

Bibliography. Ali & Ripley (1978), Amadon (1964, 1974), Brazil (1991), Brown, L.H. (1976b), Cheng Tso-hin (1987), Deignan (1945, 1963), Dickinson *et al.* (1991), Etchécopar & Hue (1978), Henry (1971), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Philipps (1993), van Marle & Vooijs (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Naoraji (1985), Naoraji & Monga (1983), Parkes (1973), Rand & Rabot (1960), Roberts (1991), Severinghaus & Blackshaw (1976), Smythies (1981, 1986), Thiollay & Meyburg (1988), Tikader (1988), Wilkinson *et al.* (1991a, 1991b).

67. Great Nicobar Serpent-eagle

Spilornis klossi

French: Serpenteaire menu **German:** Kloss-Schlangenweihe **Spanish:** Culebrera de Nicobar
Other common names: (Great) Nicobar (Crested) Serpent-eagle

Taxonomy. *Spilornis klossi* Richmond, 1902, Great Nicobar Island. Taxonomic status uncertain, although existence of two species of *Spilornis* in Nicobar Is generally agreed upon: present species sometimes considered conspecific with *S. cheela*; *S. (cheela) minimus* often awarded full species status, in which case usually considered to include *S. klossi* as race. Currently considered to form superspecies with *S. cheela*, *S. kinabaluensis*, *S. rufipectus* and *S. holospilus*. Monotypic.

Distribution. Great Nicobar I (Nicobar Is).

Descriptive notes. 38-41 cm. Small, secretive, but confiding serpent-eagle; pale, uniformly coloured underparts; in contrast to *S. cheela* (in its various forms), tail presents several much narrower bands. Juvenile has broad buffy edging on feathers of crown, back and upperwing- and upper-tail-coverts; subadult has brownish grey iris.

Habitat. Apparently found mainly, or exclusively, in interior of rain forest.

Food and Feeding. Little studied; lizards, rats, Emerald Dove (*Chalcophaps indica*) and small birds recorded. Habits presumably similar to congeners.

Breeding. No information available. Apparently no display flight, as species was not seen flying during recent raptor survey in period Mar-Apr, when species is thought to be breeding.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Seen only twice during recent raptor survey, on both occasions perched inside forest. Reported by one source to be common. More than 80% of island still covered with undisturbed primary forest; two new national parks proposed, covering 536 km² of island. Intensive survey work required to determine status; general research also needed.

Bibliography. Ali & Ripley (1978), Amadon (1964, 1974), Amadon & Bull (1988), Brown & Amadon (1968), Richmond (1903), Tikader (1988).

68. Kinabalu Serpent-eagle

Spilornis kinabaluensis

French: Serpenteaire de Kinabalu **German:** Bergschlangenweihe **Spanish:** Culebrera del Kinabalu

Other common names: Mountain Serpent Eagle

Taxonomy. *Spilornis cheela kinabaluensis* W. L. Slater, 1919, Mount Kinabalu, north Borneo. Taxonomic status uncertain: sometimes regarded as race of *S. cheela*, but apparently does not intergrade with sympatric *S. cheela pallidus*; also altitudinally segregated and vocalizations quite different. Present species currently considered to form superspecies with *S. cheela*, *S. klossi*, *S. rufipectus* and *S. holospilus*. Monotypic.

Distribution. Mountains of N Borneo, recorded on Mt Mulu (NE Sarawak), Mt Murud (NE Kalimantan) and Mt Kinabalu (W Sabah).

Descriptive notes. c. 51-55 cm. Large, dark serpent-eagle; differs from *S. cheela* in darker overall coloration, longer wings and markedly different vocalizations. Larger and darker than sympatric *S. cheela pallidus*. Juvenile presumably similar to that of *S. cheela*.

Habitat. Montane forests; occupies higher altitudes than sympatric *S. cheela pallidus*, which inhabits adjacent lowlands.

Food and Feeding. Particularly snakes and lizards; generally similar to *S. cheela*.

Breeding. No information available.

Movements. Apparently sedentary.

Status and Conservation. RARE. CITES

II. Status very poorly known. May be threatened in long term by clear-felling of forests. Surveys required to determine conservation status; research on biology also highly desirable.

Bibliography. Amadon (1964, 1974), Brown & Amadon (1968), Collar & Andrew (1988), MacKinnon & Philipps (1993), Smythies (1981).

69. Sulawesi Serpent-eagle

Spilornis rufipectus

French: Serpenteaire des Célèbes **German:** Celebesschlangenweihe **Spanish:** Culebrera de Célebes

Other common names: Celebes Serpent-eagle

Taxonomy. *Spilornis rufipectus* Gould, 1858, vicinity of Macassar, Sulawesi. Taxonomic status uncertain: sometimes considered conspecific with *S. cheela*. Currently considered to form superspecies with *S. cheela*, *S. klossi*, *S. kinabaluensis* and *S. holospilus*. Race *sulaensis* poorly differentiated, and perhaps of questionable validity. Two subspecies normally recognized.

Subspecies and Distribution. *S. r. rufipectus* Gould, 1858 - Sulawesi, and islands of Salayar, Muna and Butung, off S Sulawesi. *S. r. sulaensis* (Schlegel, 1866) - Banggai and Sula Is, off E Sulawesi.

Descriptive notes. 41-50 cm. Medium-sized serpent-eagle; similar to *S. cheela*, especially in being vocal and conspicuous, but has completely dark hood, with barred belly and flanks, and rather narrow pale bar in tail. Race *sulaensis* generally smaller and paler than nominate, with bolder barring on underparts.

Habitat. Forest edge and openings, secondary forest and grassy savannas, from 300 to 1000 m.

Food and Feeding. Virtually nothing known; diet and habits most likely similar to *S. cheela*. Readily attracted to grass fires; often forages over open grassland.

Ruiter (1947), Stresmann (1940a), White & Bruce (1986).

70. Philippine Serpent-eagle

Spilornis holospilus

French: Serpente des Philippines

German: Philippinenschlangenweihe

Spanish: Culebrera Filipina

Taxonomy. *Buteo holospilus* Vigors, 1831, near Manila.

Taxonomic status uncertain: sometimes classified as race of *S. cheela*; shares Philippines with *S. cheela palawanensis*, but without sympatry. Currently considered to form superspecies with *S. cheela*, *S. klossi*, *S. kinabaluensis* and *S. rufipectus*. Proposed race *panayensis* not valid. Monotypic.

Distribution. N & E Philippine Is, from Luzon S to Mindanao.

Descriptive notes. c. 47-5-64 cm; 604-762 g (2 birds). Medium-sized serpent-eagle, with relatively longer tail than most congeners; similar to *S. cheela*, but has underparts uniformly coloured, with markings generally more clearly defined; lacks dark crown. Juvenile similar to juvenile *S. cheela*. Purported race *panayensis* said to be smaller and paler, but differences might be due to individual variation.

Habitat. Forests and forest edge; also in open country.

Food and Feeding. Observed feeding on snake. No further information available; diet

and habits presumably similar to those of *S. cheela*.

Breeding. Female with egg in oviduct collected in Apr. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Fairly common. Apparent adaptability to open and secondary habitats suggests species not seriously threatened despite rampant deforestation throughout much of limited range.

Bibliography. Amadon (1964, 1974), Brown, L.H. (1976b), Brown & Amadon (1968), Dickinson *et al.* (1991), Gilliard (1950), McGregor (1909-1910), Rand & Rabor (1960).

71. Andaman Serpent-eagle

Spilornis elgini

French: Serpente des Andaman

German: Andamanenschlangenweihe

Spanish: Culebrera de Andamán

Other common names: Andaman Dark Serpent Eagle

Taxonomy. *Haematornis elgini* Blyth, 1863, South Andaman Island.

The only taxon in the *Spilornis* complex that is definitely separate species and not race of *S. cheela*, as occurs in sympatry with *S. cheela davisoni*. Monotypic.

Distribution. Andaman Is.

Descriptive notes. 49-54 cm; 790-1000 g; wingspan 115-123 cm. Medium-sized dark serpent-eagle. Overall, very dark brown with numerous small white spots. Vocalizations consist of clear whistles, differing markedly from calls of *S. cheela*. Juvenile similarly dark overall, but with paler head.

Habitat. Forest, typically in clearings; also on open hillsides with scattered trees. Traditionally said to be ecologically segregated from sympatric *S. cheela davisoni*, which has been claimed to stick mainly to coastal forest, especially tidal creeks and mangrove swamps, while present species normally occurs inland;

however, both species occur and even display near each other in inland areas, although present species is more numerous.

Food and Feeding. Apparently takes variety of prey, especially birds; also frogs, lizards, rats and snakes. Hunts from perch in typical style of genus.

Breeding. Quite vocal during display flights, which include mutual soaring over territory. No further information available.

Movements. Sedentary.

Status and Conservation. RARE CITES II. Common, sometimes reaching surprisingly high densities; most numerous raptor on Andaman Is. Probably should not be classed as threatened, but rapidly growing human population may encroach on forest habitat in future.

Bibliography. Ali & Ripley (1978), Amadon (1964, 1974), Brown, L.H. (1976b), Brown & Amadon (1968), Butler (1899), Collar & Andrew (1988), Ripley (1982), Tikader (1988).

Genus *DRYOTRIORCHIS* Shelley, 1874

72. Congo Serpent-eagle

Dryotriorchis spectabilis

French: Serpente du Congo

German: Schlangenbussard

Spanish: Culebrera Congoleña

Other common names: African Serpent-eagle

Taxonomy. *Astur spectabilis* Schlegel, 1863, St George Elmina, Ghana.

Monotypic genus, may be most related to Asian *Spilornis* species and Madagascan *Eutriorchis*. Two subspecies recognized.

Subspecies and Distribution.

D. s. spectabilis (Schlegel, 1863) - Sierra Leone E to S Nigeria and NW Cameroon.

D. s. batesi Sharpe, 1904 - S Cameroon E to W Uganda and S to Gabon and SC Zaire; N Angola.

Descriptive notes. 50 cm. Short, rounded wings and long, rounded tail distinctive. Eye yellow in adult male, brown in female. Juvenile similar to adult but for pale head and neck; heavily spotted underparts similar to juveniles of African forest *Accipiter* and *Aviceda* species; separate morph or intermediate plumage with fine black streaks below. Race *batesi* browner, and much less spotted and marked below.

Habitat. Lowland tropical rain forest.

Food and Feeding. Mainly reptiles, especially snakes (with their prey), chameleons and lizards, and some toads. Hunts from a perch, dropping down to take prey from foliage or the ground

below, sometimes striking repeatedly at prey with the feet almost like a Secretarybird (*Sagittarius serpentarius*). Mainly within forest understorey, to which its large eyes appear well suited.

Breeding. Unrecorded. Indications of breeding Oct-Dec in Gabon, sometime during period Jun-Nov in Zaire. Regularly utters loud crowing calls.

Movements. No movements recorded.

Status and Conservation. Not globally threatened. CITES II. Appears to be rather common in many larger tracts of forest, judging from calls, but inconspicuous except for persistent calling. Vulnerable to deforestation, due to intolerance of secondary habitats, which now dominate much of its range in W Africa. Not known to be affected by pesticides.

Bibliography. Brosset & Erard (1986), Brown *et al.* (1982), Chapin (1932), Ferguson-Lees & Faull (1992), Gatter (1988), Grimes (1987), Lippens & Wille (1976), Louette (1981), Mackworth-Praed & Grant (1957-1973), Pinio (1983), Rodewald *et al.* (1994), Serle *et al.* (1977), Snow (1978), Thiollay (1975a, 1978c).

Genus *EUTRIORCHIS* Sharpe, 1875

73. Madagascar Serpent-eagle

Eutriorchis astur

French: Serpente de Madagascar

German: Schlangenhacht

Spanish: Culebrera Azor

Other common names: Long-tailed Serpent-eagle

Taxonomy. *Eutriorchis astur* Sharpe, 1875, southern Madagascar.

Monotypic genus, most similar to monotypic African *Dryotriorchis*. Monotypic.

Distribution. Madagascar, originally along all moist eastern regions, but now confined to NE.

Descriptive notes. 66 cm. Upperparts and underparts clearly barred, wing feathers and long tail distinctively banded. Voluminous crest and yellow eye and legs notable; said to erect crest when excited. Juvenile with white edging to feathers giving scaly effect dorsally. Closely resembles sympatric *Accipiter henstii* in size and colour, but breast more broadly barred and latter has white eyebrow.

Habitat. Primary rain forest up to 1000 m; also around ecotone with secondary forest.

Food and Feeding. Large chameleon found in stomach of collected specimen; also reported to eat lemurs and poultry. Descends to forest floor, or flies from branch to branch within forest.

Breeding. Unrecorded.

Movements. None recorded.

Status and Conservation. ENDANGERED. CITES II. Species not recorded by scientists between 1935, when two specimens were collected, and 1988, although 5 possible sightings were made by foresters over the period 1964-1977. Only known previously from 11 museum specimens collected between 1875 and 1935 from 4 main areas, of which 3 remain more or less intact. Recently sighted and even trapped alive; projects currently being run in Madagascar by WWF and Peregrine Fund should help to ascertain conservation status of species and also promote environmental awareness. Its future depends on preservation of adequate rain forest in NE of the island, especially the Marojejy, Masaola, Ambutovaky, Zhamane and Mantady tracts, and possibly also the Mangoro Valley tract.

Genus *CIRCUS* Lacépède, 1799

74. Western Marsh-harrier

Circus aeruginosus

French: Busard des roseaux **German:** Rohrweihe **Spanish:** Aguilucho Lagunero Occidental
Other common names: Eurasian Marsh-harrier, Marsh Harrier

Taxonomy. *Falco aeruginosus* Linnaeus, 1758, Sweden.

Forms superspecies with *C. ranivorus*, *C. spilonotus*, *C. approximans* and *C. maillardi*, all of which have frequently been lumped within present species. Two subspecies currently recognized.

Subspecies and Distribution.

C. a. aeruginosus (Linnaeus, 1758) - Europe and Asia Minor E into C Asia, E to upper R Yenisey and Mongolia; winters in W & S Europe, Africa S of Sahara, and in Indian Subcontinent and Sri Lanka.

C. a. harterti Zedlitz, 1914 - NW Africa, from Morocco to Tunisia.

Descriptive notes. 48-56 cm; male 405-667 g, female 540-800 g; wingspan 110-130 cm. Plumage rather variable. Male generally brown above, particularly on back; underparts streaked, but solid dark brown at least on belly and vent; plumage becomes progressively paler with age. Female averages larger; usually brown with yellowish cream crown, throat and forewing. All dark or melanistic morph in some adults. Juvenile similar to female, but lacks pale shoulder; often all dark chocolate. Race *harterti* has much paler underparts than nominate.

Habitat. Typically in extensive areas of dense marsh vegetation, especially reeds and reedmace, in aquatic habitats of both fresh and brackish water, e.g. marshes, swamps, lagoons, etc.; sometimes in areas lacking stretches of open water. Also in other aquatic habitats, e.g. lakes, reservoirs and rivers typically with reedbeds along margins. Sometimes in other open areas, normally in or near wetlands, e.g. grassland and other low vegetation, salt-pans, paddyfields and other cereal fields. Generally in lowland plains, although up to 2000 m in Asia. On migration and in winter quarters, can occur in less typical habitats, e.g. over forest and mountains above 3000 m in W Cameroon. On occasions, hundreds of birds gather in roosts, mainly in reedbeds.

Food and Feeding. Great opportunist, lacks specialization; very wide range of prey, varying with local availability. Prefers small or medium-sized birds, and often their chicks and eggs; also mammals, especially rodents and rabbits; to much lesser extent, fish, reptiles (e.g. lizards, snakes), frogs and some invertebrates. Birds taken are mainly aquatic, e.g. ducks, rails and waders, and marsh passerines; larger birds tend to be those that are vulnerable, e.g. ducks that are wounded or in eclipse. Also takes carrion, especially in winter, from small animals to cetaceans and large herbivores. In C Europe, voles can dominate in diet, during years of plenty; in C & S Spain, rabbits and rats important. Characteristic low, buoyant flight over marshy vegetation; attempts to surprise prey, diving on it on ground or water.

Breeding. Laying mainly in Apr-May, till Jun in N Europe. Generally monogamous, but males sometimes polygynous. Solitary or in small, loose colonies; almost always in dense marsh vegetation, such as reedbeds. If pair-bond is maintained, pair tends to nest near previous year's site. Nest is pile of reeds, reedmace and rushes, c. 60-80 cm wide and of variable depth (deeper if base touches water); built by female, but both adults add material throughout breeding. Normally 3-6 eggs (2-7), at intervals of 1-2 days; replacement laying can occur; incubation 31-38 days per egg, by female; both adults hunt for chicks (at first just male); fledging c. 35-40 days; young remain with adults 2-3 weeks more. Sexual maturity at 2-3 years. Rate of hatching failure varies, but can be very high: normally 2-4 chicks fledge (up to 5), mean 1.8-3.2 per breeding pair, and 2-7-3.5 per successful pair. Oldest recorded bird 16 years.

Movements. Mainly migratory in N & E Europe and C Asia; sedentary and dispersive in S of breeding range. N breeders winter from France and N Africa through Mediterranean to Turkey, Middle East and Nile Valley, and S to sub-Saharan Africa; easternmost Asian populations winter in Indian Subcontinent and Sri Lanka; also said to winter in SE China and Greater Sundas, but considerable confusion in this zone with *C. spilonotus*. Migrants start to arrive on breeding grounds in Mar, or Apr in N of range; leave mainly in Sept-Oct, although juveniles start dispersal earlier.

Status and Conservation. Not globally threatened. CITES II. Population trends have varied in Europe throughout 20th century, but overall decline in numbers and range; from 1980's, generalized recovery, with populations of N & C Europe increasing, and to lesser degree those of S Europe. In 1980's, possibly c. 10,000 pairs in Europe (excluding former USSR, where species also on increase); largest populations in Germany with 2225-2350 pairs, Poland 1500-2000 pairs, Hungary over 1000 pairs, France 700-1000 pairs, Netherlands 800-900 pairs, Czechoslovakia 600 pairs, Sweden 520 pairs, Denmark 500 pairs and Spain 480-520 pairs. In early 1990's estimates of 30,000 pairs in European Russia, 2200-3000 pairs in Byelorussia, and over 150 pairs in Azerbaijan. In 1980's, estimates of 100's of pairs in Morocco (*harterti*), and perhaps 100-250 pairs in Turkey. Main factors in decline, most of which continue to affect species, include: drying out of wetlands; direct persecution, especially shooting; poisoning by pesticides applied liberally in wetlands and nearby crop fields; contamination by lead shot consumed from wounded waterbirds; and more generalized poisoning by heavy metals.

75. African Marsh-harrier

Circus ranivorus

French: Busard grenouillard **German:** Froschweihe **Spanish:** Aguilucho Lagunero Etiópico

Taxonomy. *Falco ranivorus* Daudin, 1800, South Africa.

Forms superspecies with *C. aeruginosus*, *C. maillardi*, *C. spilonotus* and *C. approximans*; sometimes all considered conspecific, but present species differs from closest ally, *C. aeruginosus*, in some aspects of plumage and morphology, probably in breeding behaviour and display, and in lack of pronounced sexual dimorphism in plumage. Birds of E & C Africa sometimes placed in separate race, *aequatorialis*, on grounds of smaller size, but validity very doubtful. Monotypic.

Distribution. Zaire, Uganda and Kenya S to South Africa; ranges NE to Ethiopia and Somalia.

Descriptive notes. 44-49 cm; 382-590 g. Individually variable. Female larger and often darker above and more rufous below than male. Separable from *C. aeruginosus*, in which male has plain grey areas in wing and tail, while female has pale crown and forewing. Juvenile of present species darker brown than adults, with plain underparts and usually pale band across breast.

Habitat. Marshes and adjacent grassland and cropland.

Food and Feeding. Small rodents and birds, up to size of 600 g teal (*Anas*); also nestlings, eggs, frogs, insects and some carrion. Hunts

upwind with low, slow coursing flight, checking and hovering before a swift turn onto prey, alternating with fast sweeps downward to surprise and snatch up prey in flight, especially birds.

Breeding. Laying mainly in dry season: Jun-Jul in Kenya; all months in S Africa (peak Jun-Nov in Cape winter-rainfall zone, Dec-Jun in summer-rainfall areas). Distinctive sky-dancing courtship display. Builds nest platform of weeds and reeds lined with dry grass; scanty when built on ground, grass or sedges in small marsh, but deeper when among reeds and rushes over open water. Usually 3-4 eggs (3-6); incubation 31-34 days; chicks have white down; fledging 38-41 days.

Movements. No regular movements described. Resident around perennial water bodies; nomadic to ephemeral wetlands, with considerable local dispersal, especially of juveniles.

Status and Conservation. Not globally threatened. CITES II. Common on major wetlands of E and S Africa, especially in Botswana, Zambia and Uganda. 500-1000 pairs in Transvaal, South Africa. Vulnerable to drainage, burning and grazing of more seasonal wetlands, where generally local or uncommon, and declining, in most parts of E and S Africa. Slightly contaminated but not obviously affected by pesticides.

Bibliography. Benson & Benson (1975), Britton (1980), Brown *et al.* (1982), Ginn *et al.* (1989), Kemp & Dean (1988), de Kock & Simmons (1988), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957, 1962), Maclean (1993), Malherbe (1970), Nichol (1963), Pickford *et al.* (1989), Pinto (1983), Simmons (1990, 1991a, 1991d, 1992a), Snow (1978), Steyn (1982), Tarboton & Allan (1984).

76. Eastern Marsh-harrier

Circus spilonotus

French: Busard d'Orient **German:** Mangroveweihe **Spanish:** Aguilucho Lagunero Oriental
Other common names: Spotted Marsh-harrier; Spotted-backed/Papuan Harrier (*spilothorax*)

Taxonomy. *Circus spilonotus* Kaup, 1847, Asia.

Often considered a race of *C. aeruginosus*, with which it forms superspecies, along with *C. ranivorus*, *C. approximans* and *C. maillardi*. Race *spilothorax* possibly approaching species level. Two subspecies normally recognized.

Subspecies and Distribution.

C. s. spilonotus Kaup, 1847 - SE Siberia and Mongolia to Ussuriland, Sakhalin, NE China and N Japan; winters from S Japan and SE Asia and S China to Indonesia and Philippines.
C. s. spilothorax Salvadori & D'Alberty, 1875 - C & E New Guinea.

Descriptive notes. 47-55 cm; 370-780 g. Male similar to that of *C. aeruginosus*, but paler and more finely streaked. Female differs from that of *C. aeruginosus* in dark streaking on crown and nape. Immature said to be darker than that of *C. aeruginosus*. Race *spilothorax* polymorphic; normal morph usually has heavier streaking on head and neck, but birds from Central Highlands of New Guinea have solid blackish throat; dark morph mostly blackish with some pale streaking, pale primary windows and grey tail.

Habitat. Marshes, swamps, lake edges, and especially large reedbeds; also other open

areas, e.g. paddyfields and grassland, particularly outside breeding season. In New Guinea, mainly in highlands.

Food and Feeding. Opportunist hunter, like *C. aeruginosus*; captures disabled aquatic birds, or those caught unawares; takes small terrestrial passerines, nestlings and eggs; sometimes rodents, e.g. voles, ground squirrels, mice, although normally to lesser degree; also frogs and fish. Forages in typical manner of harriers, floating low over open habitats, attempting to surprise prey.

Breeding. Laying from mid-May to early Jun. Nests on ground in marshes, mainly in reedbeds. Nest is fairly large; built of reeds and sticks, without any special lining. Lays 3-7 eggs, at intervals of 3-3 days; incubation 33-48 days; fledging 35-40 days. Low hatching success in Hokkaido (Japan). Sexually mature probably at 2-3 years old.

Movements. Mostly migratory; apparently sedentary in New Guinea. Populations from SE Siberia, Mongolia and NE China winter from Burma to S China and S to Malay Peninsula, Indochina, Sumatra, N Borneo and Philippines; in Japan, winters in C & S Honshu and Kyushu. Reaches breeding areas during Apr and early May; leaves mainly Sept-Oct.

On following pages: 77. Pacific Marsh-harrier (*Circus approximans*); 78. Madagascar Marsh-harrier (*Circus maillardi*); 79. Long-winged Harrier (*Circus buffoni*); 80. Spotted Harrier (*Circus assimilis*); 81. Black Harrier (*Circus maurus*); 82. Hen Harrier (*Circus cyaneus*); 83. Cinereous Harrier (*Circus cinereus*); 84. Pallid Harrier (*Circus macrourus*); 85. Pied Harrier (*Circus melanoleucos*); 86. Montagu's Harrier (*Circus pygargus*).

Status and Conservation. Not globally threatened. CITES II. Very little information available about population sizes and trends. Generally rare and patchily distributed in former USSR; uncommon breeder in N Japan. Presumably affected by degradation of wetlands throughout much of extensive range.

Bibliography. Ali & Ripley (1978), Austin (1948), Austin & Kuroda (1953), Beehler (1978), Brazil (1991), Brazil & Hanawa (1991), Cheng Tso-hin (1987), Clarke (1993), Coates (1985), Deignan (1945), Dickinson *et al.* (1991), Eichécopar & Hue (1978), Lekagul & Round (1991), Lever (1987), Mackay (1991), MacKinnon & Phillips (1993), van Marle & Vocus (1988), Medway & Wells (1976), Nishide (1979), Peckover & Filewood (1976), Ripley (1982), Smythies (1981, 1986).

77. Pacific Marsh-harrier

Circus approximans

French: Busard de Gould **German:** Sumpfweihe **Spanish:** Aguilucho Lagunero del Pacífico
Other common names: Australasian/Swamp Harrier

Taxonomy. *Circus approximans* Peale, 1848, Vanua Levu, Fiji.

Has been considered a race of *C. aeruginosus*, with which it forms superspecies, along with *C. ranivorus*, *C. spilonotus* and *C. maillardi*; separated by plumage. Supposedly larger race *gouldi* of New Guinea, Australia and New Zealand shown by recent work not to differ. Monotypic.

Distribution. S New Guinea (breeding uncertain), Melanesia, Australia, New Zealand and Polynesia E to Tonga. Introduced to Society Is.

Descriptive notes. 50-61 cm; male 392-726 g, larger female 622-1080 g; wingspan 121-142 cm. A typical marsh-harrier, duller than *C. aeruginosus*. Female darker and browner, and more rufous ventrally. Juvenile solid dark brown, with trace of pale rump. Adult greyer, juvenile darker and browner than juvenile *C. assimilis*.

Habitat. Terrestrial, estuarine and coastal wetlands, grasslands, crops and pasture, from sea-level up to 1700 m. Nests in tall reeds, grass, crops and other dense ground cover.

Food and Feeding. Mammals, birds and eggs, reptiles, amphibians, fish, insects and carrion.

Forages by low, slow quartering; also by soaring. Seizes prey by diving or dropping to ground or water surface; harries aquatic birds to exhaustion or sometimes drowns them. Robs other raptors. **Breeding.** Sept-Dec. Solitary; rarely polygynous. Nest is a platform of sticks, reeds, grass and other plants on ground or over water among tall grass, reeds or shrubs. Usually 3-4 eggs (2-7); incubation 31-34 days; chicks have white down; fledging c. 43-46 days; post-fledging dependence 4-6 weeks. Oldest ringed bird 18 years. Success 1.05-1.75 young fledged per nest, 1.82-2.15 per successful nest.

Movements. Migratory in S; resident at lower latitudes where numbers swelled by wintering birds. Winter migrants reach N Australia and New Guinea.

Status and Conservation. Not globally threatened. CITES II. Common in suitable habitat, but local declines where wetlands drained. Nests vulnerable to human disturbance. Eggshell thickness significantly reduced by DDT use (now ceased) in S agricultural areas of Australia. Sometimes shot.

Bibliography. Baker-Gabb (1978, 1979, 1981a, 1981b, 1982a, 1982b, 1983, 1984a, 1985b, 1986, 1993), Baker-Gabb & Fitzherbert (1989), Beehler *et al.* (1986), Bregulla (1992), Coates (1985), Copper & Copper (1981), Gurr (1968), Hedley (1976), Hollands (1984), Holyoak & Thibault (1984), Mackay (1991), Marchant & Higgins (1993), Newgrain *et al.* (1993b), Olsen & Marples (1993), Olsen, Crome & Olsen (1993), Olsen, Fuller & Marples (1993), Pierce & Maloney (1989), Schodde & Tidemann (1988), Tollan (1988).

78. Madagascar Marsh-harrier

Circus maillardi

French: Busard de Maillard **Spanish:** Aguilucho Lagunero Malgache

German: Madagaskarweihe

Other common names: Madagascar Harrier, Malagasy Marsh-harrier; Reunion Marsh-harrier/Harrier (*maillardi*)

Taxonomy. *Circus Maillardi* J. Verreaux, 1862, Reunion.

Forms superspecies with *C. aeruginosus*, *C. ranivorus*, *C. approximans* and Asian *C. spilonotus*; most closely linked with last. Two subspecies recognized.

Subspecies and Distribution.

C. m. maillardi J. Verreaux, 1862 - Reunion I.

C. m. macroseles Newton, 1863 - Madagascar and Comoro Is.

Descriptive notes. 54-59 cm. White underparts, streaked with black, and grey secondaries distinctive in flight. Female larger than male and brown, but both have white upper-tail-coverts, which are tinged brown in female-like juveniles. Races differ in size and intensity of plumage colours.

Habitat. Marshy edges of lakes and rivers, also rice paddies and adjacent open grassland. On Reunion and in the Comoros uses hillsides and clearings in forest up to mountain peaks, but rarely above 2000 m on Madagascar.

Food and Feeding. Mainly small vertebrates such as frogs, reptiles, rats, birds or nestlings;

also shrews, insects and tenrecs on Reunion. Seen in vicinity of active heronry. Courses low over vegetation, dropping onto prey detected on the ground or foliage below, sometimes standing on ground or perching on low stump. Hunts over forest canopy and along cliff faces, especially on Reunion and in the Comoros.

Breeding. Laying Dec-May on Reunion; Oct in Comoros. Performs twisting aerial display with culling. Builds a nest of grass and weed stems on the ground or on low vegetation. Usually 2-3 eggs (2-6); incubation 33-36 days; chicks have pale grey down; fledging 45-50 days.

Movements. Sedentary on permanent marshes, but nomadic to ephemeral habitats. Used to migrate to lower altitudes during winter on Reunion, but such movements less marked in recent times.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Widely distributed on Madagascar, both coastally and inland, but nowhere common and not present on all wetlands. Exact status on Madagascar undetermined, but total population expected to be larger than those of Reunion or the Comoros. Widespread and common on Reunion, with territory size of 3-6 km² and about 130 pairs; now well adapted to man-altered habitats, although declined up to 1966-1974 due to persecution, some of which continues. In the Comoros, uncommon on Ngazidja and Ndzuani, commoner on Mwali and adjacent islets (possibly 25 pairs, with territory size about 35 km²), and recorded for Maore.

Bibliography. Benson (1960a), Clouet (1976, 1978), Dee (1986), Diamond (1987), Jones, C.G. (1989), Langrand (1990), Langrand & Meyburg (1984), Lever (1987), Louette (1988), Milon *et al.* (1973), Simmons (1991a), Staub (1976), Thibault & Guyot (1988).

79. Long-winged Harrier

Circus buffoni

French: Busard de Buffon

German: Weißbrauenweihe

Spanish: Aguilucho de Azara

Taxonomy. *Falco Buffoni* Gmelin, 1788, northeastern Brazil.

Formerly used name *C. brasiliensis* has page priority, but unidentifiable. Monotypic.

Distribution. SW Colombia to the Guianas, Trinidad and Tobago, and NE Brazil (Pará and Maranhão), then S to E Bolivia, N & C Argentina and C Chile.

Descriptive notes. 48-56 cm; male c. 397 g, female c. 605 g. Particularly long wings and tail, white rump; like other *Circus*, wings held in slight dihedral in coursing flight; has longer wings and more buoyant flight than sympatric congeners. Polymorphic, with melanistic morph. Normal morph male has head and back black, with white supercilium and white dappling on throat; below white with black breast band; underwing pale brownish grey, with black barring and black wingtips; tail grey with white tip and blackish bands, above wing-coverts and flight-feathers grey, remiges tipped black. Female like male, but brown

above, with tawny dappling on throat, brown streaking ventrally and tawny thighs; slightly larger than male. Melanistic morph (both sexes) shows sooty black body and white rump; tail, primaries and underwing as in normal colour morph. Legs and feet pale orange-yellow. Immature, normal morph, as normal morph female, but underparts more broadly streaked brown; dark morph similar to adults, but sooty with white streaking below, thighs and undertail-coverts rufous.

Habitat. Lowland tropical zone, in open fields, marshes, grassland and savanna; usually moderately wet areas. Normally below 690 m, but one record at 2000 m in Argentina; 300-1000 m in Colombia.

Food and Feeding. Birds, reptiles, frogs and mammals; principal prey in Surinam seems to be mammals, but two birds seen eating eggs at a heronry. Hunts by coursing over open country in typical style of harriers.

Breeding. Eggs in Jun, Trinidad; possible nest building in Aug, Colombia. Nests on the ground in rushes. 3-4 eggs in Argentina; 2 eggs in Trinidad. No further information available.

Movements. Migratory, at least in southernmost populations; insufficient data to assess status (resident, migratory or wintering) throughout Brazilian distribution. Birds in N South America were thought to be all migrants from S, but breeding record from Trinidad suggests that others may breed in appropriate habitat in this region. Records from Pacific slope in Colombia and Chile suggest species may occasionally cross Andes. Occasional visitor to Tierra del Fuego; recently recorded on Falkland Is.

Status and Conservation. Not globally threatened. CITES II. Widespread, but apparently rather local. Very poorly known. Rare and local in E Brazil, more frequent in S Brazil. In Colombia, fairly common in NE Meta, less numerous in W Meta, rare in Cauca Valley. Likely to be affected by degradation of wetland habitats.

Bibliography. Amadon (1954, 1964), Banks & Dove (1992), Belton (1984), Blake (1977), Clark, R. (1986), Contreras *et al.* (1990), French (1973), Fjeldså & Krabbe (1990), Haverschmidt (1962), Herklots (1961), Hilty & Brown (1986), Jaksic & Jiménez (1986), Johnson (1965), Meyer de Schauensee & Phelps (1978), de la Peña (1992), Pinto (1964), Rensen & Traylor (1989), Snyder (1966).

80. Spotted Harrier

Circus assimilis

French: Busard tacheté

German: Fleckenweihe

Spanish: Aguilucho Moteado

Other common names: Jardine's/Allied Harrier

Taxonomy. *Circus assimilis* Jardine and Selby, 1828, Sydney, New South Wales.

Formerly recognized race *quirindus* of Sulawesi doubtfully valid. Monotypic.

Distribution. Australia; Sulawesi and Sula Is (C Moluccas); also recorded on Sumba and Timor (Lesser Sundas), but probably migrants.

Descriptive notes. 50-61 cm; male 407-537 g, larger female 540-745 g; wingspan 121-147 cm. Adult plumage unmistakable and unique in genus. Juvenile ginger with dark wings and tail, and prominent rusty shoulders; these features and strongly barred tail distinguish it from greyer or much darker *C. approximans*. Negligible regional variation.

Habitat. Treeless or sparsely wooded grasslands, savannas, plains and cropland; from sea-level to at least 1000 m. Nests in woodland.

Food and Feeding. Terrestrial birds (quails, larks, pipits), mammals (mice) and reptiles; rarely carrion. Forages by low, slow quartering; seizes prey by diving to ground, or by short chase if prey flushed.

Breeding. Usually Sept-Oct in S Australia, exceptionally Mar-Jun; Jun-Sept in N; may rear 2 broods in single year. Solitary. Platform of sticks lined with green leaves, 40-70 cm wide, 16-30 cm deep; placed 2-15 m above ground in live tree (this habit unique in genus). Usually 3 eggs (2-4); incubation 32-34 days; chicks have pale grey down; fledging 36-43 days; post-fledging

dependence at least 6 weeks. Age at first breeding 2 years. Of eggs laid, 56-75% hatching success and 44-57% fledging success; 2-17 per successful nest, 1-3 young per nest, 0.9 per territorial pair. **Movements.** Partly migratory in S, some birds wintering in tropics; status uncertain in Sula Is and Lesser Sundas, but probably only migrant to latter. In S, departure and locality of subsequent return determined by local rainfall: birds leave in dry conditions, return to areas with good rains and plagues of prey.

Status and Conservation. Not globally threatened, CITES II. Generally uncommon but widespread; may have benefited locally in S by creation of habitat, and increase in native and introduced prey. Eggshell thickness not significantly reduced by DDT.

Bibliography. Baker-Gabb (1982a, 1984b, 1984c, 1985a), Baker-Gabb & Fitzherbert (1989), Cupper & Cupper (1981), Hollands (1984), Klapste & Klapste (1982), Klau (1985), Lowe & Lowe (1976), Marchant & Higgins (1993), Olsen & Marples (1993), Olsen, Crome & Olsen (1993), Schodde & Tidemann (1988), Schrader (1985), Tiley (1985), White & Bruce (1986).

81. Black Harrier

Circus maurus

French: Busard maure

German: Mohrenweihe

Spanish: Aguilucho Negro

Taxonomy. *Falco maurus* Temminck, 1828, Cape of Good Hope, South Africa. Monotypic.

Distribution. S South Africa, ranging N to Transvaal, Lesotho, S Namibia and S Botswana.

Descriptive notes. 50 cm. White rump and bands across tail and flight-feathers conspicuous at all ages. Female larger than male. Juvenile brown, with buff edges to dorsal feathers and dark mottling on pale underparts, most similar to female and juvenile of *C. pygargus* and *C. macrourus*. Eye brown in nestling but yellow in juvenile and adult.

Habitat. Breeds in Mediterranean-like fynbos habitat of Cape Floral Kingdom and adjacent karoo scrub and grasslands. Outside breeding season, moves N into drier grassland, scrub and steppe.

Food and Feeding. Mainly small birds, up to

350 g, including nestlings; also eggs, rodents, insects and frogs, rarely carrion. Courses low over vegetation, often checking or hovering before plunging down on prey. Usually rests on ground, sometimes on low perch.

Breeding. Breeds mainly in wet season within winter-rainfall zone of S Cape, also in dry season of adjacent summer-rainfall areas of E Orange Free State and E Natal, South Africa; laying Jul-Sept. 3-4 pairs may nest close to one another with nests only 50 m apart. Makes undulating courtship flight. Builds untidy pad of grass on base of stems, reeds or weeds. Usually 3-4 eggs (2-5); incubation 34 days; chicks have first down white, second down buff; fledging 36-41 days.

Movements. Most birds migrate N in winter to dry steppe and grassland areas of S Namibia, S Botswana and S Transvaal.

Status and Conservation. Not globally threatened, CITES II. Currently considered near-threatened. Widespread and locally common within restricted breeding habitat. An endemic breeding species of South Africa, vulnerable due to limited range and widespread degradation of fynbos breeding habitat. Has adapted well to agricultural croplands, even nesting in wheatfields. Vulnerable to pesticides and rodenticides used on croplands.

Bibliography. Brown *et al.* (1982), Ginn *et al.* (1989), Howe (1989), Hustler (1976), Mackworth-Præd & Grant (1962), Maclean (1993), van der Merwe (1981), Pickford *et al.* (1989), Sinclair *et al.* (1993), Snow (1978), Steyn (1982), Steyn & Meyburg (1989), Tarboton & Allan (1984).

82. Hen Harrier

Circus cyaneus

French: Busard Saint-Martin

German: Kornweihe

Spanish: Aguilucho Pálido

Other common names: Northern Harrier, Marsh Hawk

Taxonomy. *Falco cyaneus* Linnaeus, 1766, Europe, Africa = near London.

Forms superspecies with *C. cinereus*, with which it has been considered conspecific. Race *hudsonius* may be separate species. Two subspecies recognized.

Subspecies and Distribution.

C. c. cyaneus (Linnaeus, 1766) - Europe and N Asia E to Kamchatka; winters from Europe and NW Africa through S Asia to SE China and Japan.

C. c. hudsonius (Linnaeus, 1766) - North America, S to NW Mexico and SE Virginia (USA); winters S to N South America.

Descriptive notes. 43-52 cm; male 350 g, female 530 g; wingspan 99-121 cm. Larger and broader-winged than *C. pygargus* and *C. macrourus*, with white rump and dark grey band along trailing edge of secondaries; lacks black bar on upperwing of *C. pygargus*. Female averages larger; dark brown above, pale below with dark streaks; from below, dark bands on primaries, secondaries and rectrices. Juvenile very similar to female, but slightly darker above and more rufous below. Race *hudsonius* has rusty markings on underparts.

Habitat. Open country with some grass or shrub cover, especially grassland, steppe,

meadows, moorland, scrub and cultivation (rye, wheat, alfalfa); also wetlands, especially in North America, and young conifer plantations, in winter more widespread, e.g. over ploughed land. Prefers flat or gently sloping land, although also present on mountain slopes, up to 2500 m and jibow. Range includes colder and more northerly areas than other harriers, N into tundra. Commonly perches on ground, but also on poles, trees or rocks; sleeps on ground, and outside breeding season often gathers in numbers at roosts, which may be traditional; typically 10's of birds, very occasionally up to 200.

Food and Feeding. Small vertebrates: mainly mammals, e.g. voles, mice, cotton rats (*Sigmodon*), ground squirrels, and up to size of young rabbits and hares; also birds of open areas, low vegetation

and wetlands, particularly passerines, e.g. larks, very occasionally up to size of adult Galliformes and ducks. Birds often predominate, in breeding season making up 80% of prey, with many chicks taken; in some moorland areas of Scotland, nearly 30% of prey brought to nest comprises chicks of grouse (*Lagopus*). Also takes some invertebrates, e.g. grasshoppers, crickets; reptiles; amphibians; bird eggs; and, especially in winter, carrion. Normally slow, low foraging flight, relying heavily on hearing prey, which is mainly captured on ground; generally hunts alone; may travel some distance from nest or roost, outside breeding season up to 10 km or more.

Breeding. Laying mid-Apr to early Jul, varying with latitude; normally peaks in May in North America and Europe. Marked tendency locally towards polygyny of males: 2-3 females per breeding male, sometimes more, with up to 7 reported; possibly caused by lack of males, or because species breeds in loose colonies. Nests on ground, in dense grass or scrub, crops or marshy vegetation. Nest is pile of small sticks and grass, 30-60 cm wide, built normally by female. Normally 3-6 eggs (1-7), at interval of 1-3 days; clutch size can vary between good and bad vole years; replacement laying occurs; incubation 29-31 days per egg, by female; chicks brooded continuously at first, with only male bringing food; female also hunts later, but generally closer to nest; chicks have buffy white first down, buffy brown second down; fledging 29-38 days, with males 2-3 days earlier than females; chicks fed several weeks more, with decreasing frequency. Fledging success 1-6 chicks per breeding pair, and 2-4 per successful pair, in Orkney Is, Scotland; respectively 2-2 and 3 in Wisconsin, USA; in Orkney Is 41% of nests fail, largely due to sizeable number of females abandoned in midst of breeding attempt by polygamous males. Sexual maturity normally at 2-3 years, although perhaps 30% of breeding birds breed at one year old. Apparently at least 60% mortality in first year; greater survival rate in females. Some birds live up to 12 years or more; oldest recorded bird 16 years.

Movements. Completely migratory in N of range, in N & NE Europe, Asia, N North America; partially migratory and dispersive in rest of breeding range. Winters from Scotland and S Sweden southwards, with very few birds reaching N Africa; in Asia, winters in area well separated from breeding range, from Turkey to E China and Japan; in America, from British Columbia and New Brunswick (Canada) through Central America to Panama and S to N Colombia, Venezuela and irregularly in Greater Antilles. Leaves for winter quarters from Aug-Oct, or even Nov; arrives in breeding range Mar-May, varying with latitude; migrates on wide fronts.

Status and Conservation. Not globally threatened, CITES II. Population trends vary regionally, but generally seems to be in decline. Notable changes since 19th century: population has increased and expanded widely in British Is, where in early 20th century nested only in Orkney Is and Outer Hebrides; however, in other regions, such as Poland and Ukraine, species has become local. Estimates in 1980's of 2800-3800 pairs in France, 1000-2000 pairs in Sweden, 3000 pairs in Finland, and 300-400 pairs in Spain; in late 1980's, c. 500 pairs in Scotland, and 80-120 pairs in Netherlands; in early 1990's, estimates of 300-500 pairs in Byelorussia, and perhaps 15,000 pairs in European Russia; large numbers in rest of former USSR, particularly in Asian sectors. In North America, stable or with slight decline in 1980's, more notably in E; large reduction in population between 1950's and 1960's, due, at least in part, to organochlorine pesticides; winter population in 1986 in S Canada and USA (most of N American population) reckoned to number c. 110,000 birds. Main threat at present seems to be transformation of habitat, due to intensified agriculture, disappearance of marshes, reforestation, etc.; persecution still severe locally, e.g. on managed grouse moors of Scotland.

Bibliography. Ali & Ripley (1978), Armstrong (1983), Balfour (1957), Balfour & Cadbury (1979), Balfour & Macdonald (1970), Barnard (1982), Belton (1984), Berger (1987), Biaggi (1983), Biedstein (1978), Blake (1977), Brazil (1991), Brazil & Hanawa (1991), Brown *et al.* (1982), Cheng Tso-hin (1987), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Ehrlich *et al.* (1992), Eichecopar & Hüb (1978), Flint *et al.* (1984), Friedmann (1950), Gensbol (1986), Hamerstrom (1986), Handrinos & Demetropoulos (1983), Hilly & Brown (1986), Hou *et al.* (1990), Johnsgard (1990), Kjellen (1992), Marchant *et al.* (1990), Martin, B.P. 83. Cinereous Harrier

Circus cinereus

French: Busard bariolé

German: Grauweihe

Spanish: Aguilucho Vari

Taxonomy. *Circus cinereus* Vieillot, 1816, Paraguay and near Río de la Plata.

Formerly considered race of *C. cyaneus*, with which it forms superspecies. Monotypic.

Distribution. Colombia and Ecuador (above treeline) S through Peru, Bolivia and Paraguay to extreme S Brazil, then S to Tierra del Fuego and Falkland Is.

Descriptive notes. 40-50 cm; male 340 g, female 500 g. Both sexes have prominent white rump; distinctive rufous barring below. Male pearly grey above, with grey upper breast; otherwise whitish below, boldly barred with bright rufous brown; underwing whitish with black trailing edge and wingtips; tail with conspicuous dark bars below. Iris and legs yellow. Female dark brown above, nape streaked with white; tail greyish; with four narrow blackish bands and broad blackish terminal band; outer rectrices have rufous wash; white below, with irregular grey barring on breast and chestnut barring on belly and undertail-coverts; larger than male.

Immature similar to female, but browner above and mostly whitish below, with dusky vertical streaking particularly on breast and flanks; eye reddish brown.

Habitat. Savannas, pastures and wetlands, near marshes, rivers or streams; in N Argentinian Patagonia, mostly recorded in shrub-steppe, but also river valleys, grassy foothills, shrubland, sedge communities and clearings in *Nothofagus* forest. In Colombia occurs at 1700-3000 m; in Andes, in puna zone up to 4500 m; in S occurs down to sea-level.

Food and Feeding. Mainly birds and other small vertebrates. Diet in Torres del Paine National Park: mostly avian prey, 42%; also small reptiles (Iguanidae), 29%; and mammals, 29%. Takes frogs and some insects; insects can represent large proportion of prey items, but total biomass consumed is small. In Tierra del Fuego, mostly lizards and mammals, very few birds. Hunting technique is typical harrier coursing (flight less than 10 m above ground over open fields, marsh country or scrubland). Said to take some birds on the wing, but most avian prey probably nestlings.

Breeding. In S, nesting reported in Oct-Jan, later than other local raptors, as occurs in *C. cyaneus*; may be timed so that abundance of nestling or fledgling passerines is available when nestling

barriers are being fed. Nest of rushes lined with grass, built on the ground in marshes and pastures. 3-4 eggs, rarely 5; no further information available. Will nest in fairly close proximity to conspecifics, but defends its territory against intrusion by *Circus buffoni*.

Movements. Migratory and resident, but transition between these populations not known. Southernmost birds move N to N Argentina, Paraguay and S Brazil; no records in austral winter (May-Aug) from Isla Grande (Tierra del Fuego). Birds appear erratically in Bolivia, perhaps from S part of range.

Status and Conservation. Not globally threatened. CITES II. Overall in no danger; in S portions of range can be fairly common, in some areas second most abundant raptor after Chimango Caracara (*Milvago chimango*). Particularly common in Tierra del Fuego. Apparently has suffered some decline in Chile and Argentina; in contrast, has increased elsewhere, where forest has been removed. Almost extirpated from Falkland Is, probably as result of destruction of natural grasslands, and also shooting; now seen only rarely, and may no longer breed. Thought to be very local in upland Colombia.

Bibliography. Amadon (1961a), Blake (1977), Cabot & Serrano (1986), Contreras *et al.* (1990), Donazar, Ceballos *et al.* (1993), Field & Krabbe (1990), Goodall *et al.* (1957), Hilly & Brown (1986), Housse (1945), Humphrey *et al.* (1970), Iriarte *et al.* (1990), Jaksic & Jiménez (1986), Jiménez & Jaksic (1988), Johnson (1965), Nores & Yzurieta (1980), de la Peña (1992), Pinto (1964), Sick (1985a, 1993), Thiollay (1991a).

84. Pallid Harrier

Circus macrourus

French: Busard pâle

German: Steppenweihe

Spanish: Aguilucho Papialbo

Taxonomy. *Falco macrourus* S. G. Gmelin, 1770, Voronezh, Russia.

Known to have hybridized with *C. pygargus*. Monotypic.

Distribution. Ukraine and SW Russia E to L Balkash region, NW China and perhaps N Mongolia; irregularly breeds farther W to Sweden and Germany. Winters mainly in Africa S of Sahara, and from Pakistan, India and Sri Lanka E to S China, and irregularly to E China.

Descriptive notes. 40-48 cm; male 315 g, female 445 g; wingspan 95-120 cm. Male very pale; only four primaries black. Female similar to females of *C. cyaneus* and especially *C. pygargus*; paler belly, contrasting with more heavily marked breast and head; more defined facial pattern. Juvenile very similar to juvenile *C. pygargus*, with rusty underbody and underwing-coverts, but generally paler; narrow whitish collar.

Habitat. Mainly in natural grassy plains and dry steppes in flat or undulating terrain or on slopes, valleys with steppe vegetation and semi-desert. In winter, uses similar habitats, but also others, e.g. unirrigated wheat fields or sandy islands in Indus Delta (Pakistan), open woodland and mountain plateaux in W Africa; infrequently visits marshes and rice paddies. Outside breeding season may reach up to 3000 m in Himalayas, and rarely over 4000 m in Africa. Roosts colonially during migration and in winter quarters, normally in grass, but also in open; up to 100's of birds together, sometimes along with *C. pygargus* and *C. cyaneus*.

Food and Feeding. Small mammals and birds and, especially in winter quarters, large insects. Takes advantage of demographic explosions of rodents, feeding on voles, mice, gerbils, steppe lemmings (*Lagurus lagurus*) and ground squirrels; birds can be of greater importance, particularly small terrestrial passerines e.g. larks and pipits, and also partridge chicks. Insects include grasshoppers and locusts, and to lesser degree beetles, crickets, dragonflies and others. Reptiles and frogs less often, although lizards (*Lacerta*) common in areas of sand dunes in Pakistan. Flies low, 1-5 m above ground, into wind, dropping onto small prey spotted on ground; spends large part of day hunting. Captures insects fleeing from grass fires.

Breeding. Laying in May-Jun. Solitary or in loose colonies of 3-5 pairs, occasionally up to 30; sometimes with *C. pygargus*. May change breeding area from year to year, with fluctuations in vole populations. Nests on ground, protected by vegetation, e.g. in dry meadows, weeds, low scrub or swamps; nest is pile of grass. Normally 4-5 eggs (3-6); replacement laying can occur; incubation 29-30 days per egg, by female; food brought by male during incubation and early brooding; chicks have buffy white first down, pale cinnamon second down; fledging 35-45 days; chicks stay with adults 2-3 weeks more. Sexual maturity probably at 2-3 years, but sometimes before reaching adult plumage. Oldest recorded bird 13 years.

Movements. Migratory, wintering mainly in sub-Saharan Africa, Indian Subcontinent, Sri Lanka and Burma; rare, or much less common, in Mediterranean Basin, Middle East, Arabia, Iran and S & E China; some birds may remain in S of breeding range. Migrates on broad front; leaves for winter quarters from Aug, mainly in Sept, arriving up to Oct-Nov. Leaves for breeding areas in Mar-Apr; African wintering population moves farther W than in autumn, with some of passage through Maghreb and C Mediterranean. In winter quarters, may make nomadic movements in search of concentrations of food, e.g. locust swarms.

Status and Conservation. Not globally threatened. CITES II. Drastically declining, particularly in Europe. Total population in early 1990's no higher than 20,000 pairs; c. 2000 in European Russia, where spottily distributed, and maximum 5 pairs in Byelorussia; most of population in Asia. Marked reduction in breeding range; in S Ukraine and SW Russia, few breeding sites left in early 1990's, with decline due to exploitation of steppes. Still relatively numerous in part of Asian range and in steppes S of Ural Mts, with 2-2.6-2 pairs per 100 km²; but also reduction in numbers and range, e.g. SC Siberia; estimated c. 90% of population of former USSR occurs in Kazakhstan and S Siberia. No longer nests in Romania; last reported breeding 1956 in Bulgaria, where species had been commonest harrier. Occasional breeder in C Europe; in 1952, invasion year, even bred in Sweden. Decline also evident in fewer birds wintering in Africa; up to 1950's fairly common and locally abundant, particularly in W Africa, where was commonest harrier. Still widespread and fairly common, in Indian Subcontinent and Burma, corresponding to better conservation of E populations. Decline caused by intensification of agriculture, with transformation of natural habitat; also by excessive use of pesticides.

Bibliography. Ali (1979), Ali & Ripley (1978), Benson (1970), Bergier (1987), Brown *et al.* (1982), Cheng Tso-hin (1987), Clarke (1993), Cramp & Simmons (1980), Davygora & Belik (1994), Dementiev & Gladkov (1951), Eidecopar & Hie (1964, 1978), Flint *et al.* (1984), Gallagher & Woodcock (1980), Genschel (1986), Ginn *et al.* (1989), Grimes (1987), Handrinos & Demetropoulos (1983), Henry (1971), Hollom *et al.* (1988), Hie & Eidecopar (1970), Knyshtaus (1993), Lundevall & Rosenberg (1954), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Meyer de Schauensee (1984), Paz (1987), Pickford *et al.* (1989), Pinto (1983), Richardson (1990), Roberts (1991), Rogacheva (1992), Shirihai & Christie (1992), Simeonov *et al.* (1990), Smythies (1986), Svensson (1991), Thiollay (1989).

85. Pied Harrier

Circus melanoleucos

French: Busard tchoug

German: Elsterweihe

Spanish: Aguilucho Pío

Taxonomy. *Falco melanoleucos* Pennant, 1769, Sri Lanka. Monotypic.

Distribution. S Siberia (L. Baikal) and Mongolia E to Amurland, Manchuria and N Korea; has bred in N Burma and NE India (Assam). Winters from India and Sri Lanka to S China, Borneo and Philippines.

Descriptive notes. 41-49 cm; male 265-325 g, female 390-455 g; wingspan 103-116 cm. Male strikingly coloured, with extensive black on head, neck, back, breast, broad wingbar and primaries; forewing, rump and rest of underparts white. Female similar to those of *C. cyaneus*, *C. macrourus* and *C. pygargus*, but generally whiter below and extensively grey on upperwing and uppertail. Juvenile rich cinnamon below, very similar to juveniles of *C. macrourus* and *C. pygargus*.

Habitat. Open ground, including grassland and water meadows, areas of reeds and rushes, semi-steppe, river valleys, swamps, marshes

and bogs; tolerates certain degree of bush cover. In S Asia often in flooded and unflooded paddyfields.

Food and Feeding. Small mammals, especially voles, but also mice and shrews; more occasionally small terrestrial birds and their nestlings, e.g. larks, pipits; also frogs, lizards and insects, e.g. grasshoppers, beetles. Surveys terrain meticulously, using low, buoyant flight typical of genus.

Breeding. Laying in May in Siberia, probably in Apr in N Burma. Nests on ground, in long grass, reedbeds, rushes or sometimes in bushes; nest is thin structure c. 40-50 cm wide, built of grass and other available plant matter. Lays 4-5 eggs, at interval of 2 days; incubation, starting with first egg, mainly by female. Asynchronous hatching, leading to notable size differences between chicks. In Siberia, chicks hunt for themselves from late Aug, when dispersal starts.

Movements. Migratory, except in Assam and Burma, where may well only breed irregularly. Reaches N breeding areas in Apr, males sometimes in first week; leaves for winter quarters mainly in Oct, although starts to disperse earlier, especially juveniles; winters mainly in India and Burma between Sept/Oct and Apr; recorded on migration at Beidaihe (NE China) Aug-Oct, with peak numbers in mid-Sept. In years when rodents plentiful, some birds may spend winter in S Ussuriland and NE China; sometimes winters in Taiwan.

Status and Conservation. Not globally threatened. CITES II. Relatively small range, apparently with limited numbers; population size and trends poorly known; total of 14,534 birds counted migrating over Beidaihe (NE China) in autumn 1986. Rare or even occasional breeder in Assam and N Burma; locally common in SE Siberia and Russian Far East, although in decline due to developing agriculture.

Bibliography. Ali (1979), Ali & Ripley (1978), Austin (1948), Brazil (1991), Brazil & Hanawa (1991), Cheng Tso-hin (1987), Deignan (1945), Dementiev & Gladkov (1951), Dickinson (1986), Dickinson *et al.* (1991), Eidecopar & Hie (1978), Flint *et al.* (1984), Gore & Won (1971), Henry (1971), Inskipp & Inskipp (1985), King *et al.* (1975), Knyshtaus (1993), Lekagul & Round (1991), Long Guo-zhen (1982), MacKinnon & Philipps (1993), Madoc (1976), Medway & Wells (1976), Meyer de Schauensee (1984), Neufeldt (1964), Smythies (1981, 1986).

86. Montagu's Harrier

Circus pygargus

French: Busard cendré

German: Wiesenweihe

Spanish: Aguilucho Cenizo

Taxonomy. *Falco Pygargus* Linnaeus, 1758, England.

Known to have hybridized with *C. macrourus*. Monotypic.

Distribution. NW Africa and S & C Europe E through Caspian lowlands to Kazakhstan and upper R Yenisey. Winters in Africa S of Sahara and Indian Subcontinent S to Sri Lanka.

Descriptive notes. 43-50 cm; male 227-305 g, female 319-445; wingspan 97-115 cm. Normal male has black primaries and black bands across secondaries (1 above, 2 below); narrow white rump. Female slightly paler above than those of *C. macrourus* and *C. cyaneus*. Melanistic morph in male blackish, in female chocolate-coloured. Juvenile darker above than female, with rufous underbody and underwing-coverts; unstreaked below.

Habitat. Open areas with grass or shrubs; generally flat or undulating ground, less often in steeper terrain; from totally undisturbed habitats to those heavily transformed. Grasslands, meadows, fields of cereals (wheat, barley, rye), fallow fields, heath, moor, scrubland, marshes, bogs, peatland, young conifer plantations. Mainly at low altitudes, but up to 1500 m in C Asia, and in African winter quarters recorded up to 4000 m. Perches on small knolls, rocks or trees; roosts on ground, amidst vegetation; may roost colonially; exceptional winter roost in NW India c. 1500 birds.

Food and Feeding. Small ground birds, including many of their young in breeding season; small mammals, mainly voles, which when abundant can constitute nearly all diet; lizards and large insects (e.g. locusts, grasshoppers, mantids) important locally and in winter quarters. Avian prey mostly small passerines, especially larks, and some partridge chicks. Hunts like other harriers, with low, slow flight, quartering narrow strip of land in straight line upwind, and dropping onto prey; nearly always captures prey on ground.

Breeding. Laying mostly in May-Jun; from mid-April in Morocco. Solitary, or in loose groups of up to 10's of pairs; males occasionally bigamous. Nests on ground, in tall, dense vegetation, e.g. grassland, cereal fields, reedbeds, bushy scrub and young conifer plantations. Nest is small, narrow platform, 20-40 cm wide, made of grass stems or thin twigs. Normally 3-5 eggs (1-6), laid at interval of 1-5.3 days; replacement clutch can occur; incubation 28-29 days per egg, by female; chicks fed by female, but prey mostly caught by male; chicks have first and second down white, variably tinged buff; fledging 30-40 days; c. 2 weeks later chicks start to hunt alone, initially

catching insects. Sexual maturity normally at 2-3 years, sometimes in 1st year. Up to 4 chicks fledge; breeding success very variable and highly influenced by human interference, predation and availability of prey, particularly voles. Oldest recorded bird 16 years.

Movements. Migratory; winters in sub-Saharan Africa, Indian Subcontinent and Sri Lanka; few winter records in Europe and Middle East. Leaves European breeding grounds mainly in Aug-Sept, and returns in Apr-May; migrates on broad fronts.

Status and Conservation. Not globally threatened. CITES II. In decline, mainly due to transformation of natural or semi-natural habitats and high rate of breeding failure in agricultural areas, in turn caused by nestlings dying following harvesting of crops. In some areas stable (perhaps in parts of former USSR), even with local increases. Nowadays highly dependent on cultivation and very vulnerable to changes in agricultural practices. In early 1990's, possibly c. 7000 pairs in W Europe; c. 3000 pairs in France, c. 2000 pairs in Spain, 900-1200 pairs in Portugal, c. 110 pairs in Germany, 50-60 pairs in Sweden, 25-30 pairs in Denmark; also c. 150 pairs in Hungary, perhaps 30-50 pairs in Bulgaria, c. 200 pairs in Estonia, 50-150 pairs in Latvia, 30 pairs in Lithuania, and 480-530 pairs in Poland; estimated 600-1100 pairs in Byelorussia, and 25,000 pairs in European

Russia; formerly very common in Ukraine, but on decline since 1930's, and now remains comparatively common only in NE & E. Additional small populations in other European countries; 10's of pairs in Morocco; perhaps 50-100 pairs in Turkey; very little information available on Asian populations. Important protection measures adopted in various European countries, particularly France, based mainly on rescue of nestlings from combine-harvesters; chicks moved to safety during harvesting, or small area round nest is left untouched by farmer (see page 103).

Genus *POLYBOROIDES* A. Smith, 1829

87. African Harrier-hawk

Polyboroides typus

French: Gymnogène d'Afrique **German:** Höhlenweihe **Spanish:** Aguilucho-caricervo Común
Other common names: Gymnogene, Banded Harrier-hawk

Taxonomy. *Polyboroides typus* A. Smith, 1829, South Africa.

Relationships of genus far from clear, and variously associated with *Dryotriorchis*, *Spilornis*, *Circus* and *Geranospiza*, but possibly closest to *Melierax*. Forms superspecies with *P. radiatus*, with which often considered conspecific. Birds from W Zaire sometimes awarded separate race, *prigoginei*. Two subspecies recognized.

Subspecies and Distribution.

P. t. pectoralis Sharpe, 1903 - Senegambia E to W Sudan, N to Air Mountains (NW Niger) and S to Zaire.

P. t. typus A. Smith, 1829 - E Sudan to Eritrea and S to Angola and South Africa.

Descriptive notes. 65 cm; 555-950 g. Small naked face, flushing from yellow to crimson, voluminous crest feathers and white band across tail notable. Long legs with tibio-tarsal joint flexible through 190°-205° and small feet distinctive, convergent with South American *Geranospiza caerulescens*. Underparts unbarred in some individuals. Juvenile plumage brown, but individually variable in tone and extent of paler markings; recalls juveniles of *Dryotriorchis* and some *Spilornis*, and also adult Crested Caracara (*Polyborus plancus*). Race *pectoralis* smaller and darker, with denser barring on underparts.

Habitat. All forms of forest, woodland and savanna, extending into arid steppe and onto Ethiopian highlands; in extensive tracts of forest is generally restricted to forest edge and rivers passing through.

Food and Feeding. Mainly small animals, such as birds, their eggs and nestlings, bats, squirrels, lizards, various arthropods and insect larvae; these are extracted from nests, holes and crevices in trees, rocks and banks using the slender bill and long, flexibly-jointed legs. Feeds extensively on *Elaeis* oil palm and other fruits in much of lowland tropical Africa; also rarely on carrion. Notable for clambering about and hanging from tree limbs or rock faces with wings dangling; also hunts by slow coursing flight low over vegetation, sometimes searching for nests where most vigorously mobbed by small birds. Takes most prey from trunks and foliage; less frequently from underneath objects on the ground.

Breeding. Laying Nov-Apr in W & NE Africa; Oct in E Kenya; Jun-Dec in S & C Africa. Builds a relatively large nest of sticks in a tree or on a rock ledge, well lined with sprays of green leaves. Usually 2 eggs (1-3); incubation 35 days; chick has first down rufous with long filaments on crown, second down grey; fledging 45-55 days; elder chick usually kills younger sibling soon after hatching, but two chicks may be fledged.

Movements. Resident and sedentary in most areas, but a regular wet season migrant into Sahel zone of W Africa; some vagrancy into marginal habitats, especially in S Africa.

Status and Conservation. Not globally threatened, CITES II. One of commonest birds of prey in forests and woodlands of W and C Africa, especially where oil and *Borassus* palms abundant. 500-1000 pairs in Transvaal, South Africa. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Brosset & Erard (1986), Brown, L.H. (1972a), Brown *et al.* (1982), Burton (1978), Cooper (1980), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Jensen & Kirkeby (1980), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Nikolaus (1987), Pickford *et al.* (1989), Pinto (1983), Smeenk & Smeenk-Enserink (1983), Snow (1978), Steyn (1982), Tarboton & Allan (1984), Thiollay (1975a, 1975b, 1975c, 1976a, 1976b, 1977c, 1978a), Thurow & Black (1981).

88. Madagascar Harrier-hawk

Polyboroides radiatus

French: Gymnogène de Madagascar **Spanish:** Aguilucho-caricervo Malgache
German: Madagaskarhöhlenweihe

Taxonomy. *Vultur radiatus* Scopoli, 1786, Madagascar.

Forms superspecies with *P. typus*, with which often considered conspecific. Monotypic.

Distribution. Madagascar.

Descriptive notes. 68 cm. Very similar to African congener *P. typus*, but generally paler, sometimes with brownish wash; black spotting on scapulars and upperwing-coverts much reduced. Slender build, long thin legs, long broad wings and white band across tail distinctive. Juvenile similar to that of *P. typus*, but much paler below.

Habitat. Forests and woodlands on E and W of Madagascar up to 2000 m. Not on deforested central plateau, although does enter secondary forest.

Food and Feeding. Mainly insects and their larvae or small vertebrates e.g. nestlings, birds' eggs, frogs and reptiles. Larger prey includes a flying-fox, and may also prey on smaller lemurs. Searches for food in a characteristic fashion, clambering over leaf bases of palms, streptitias or epiphytes, examining termite mounds, even peering under or levering over objects on the ground. Spends long periods perched within cover, but sometimes soars high above forest.

Breeding. Laying Jul-Aug. Build a stick nest in the fork of a tree. Usually 2 eggs; no further details recorded.

Movements. None recorded.

Status and Conservation. Not globally threatened. CITES II. One of the five commonest raptors on Madagascar, one bird every 8 km in palm savanna, and one every 105 km overall during road counts. Occurs throughout all wooded areas.

Bibliography. Dee (1986), Goodman & Pidgeon (1991), Langrand (1990), Langrand & Meyburg (1984), Milon *et al.* (1973), Salvan (1971).

Genus *KAUPIFALCO* Bonaparte, 1854

89. Lizard Buzzard

Kaupifalco monogrammicus

French: Buse unibande **German:** Sperberbussard **Spanish:** Busardo Gavilán

Taxonomy. *Falco monogrammicus* Temminck, 1824, Senegal.

Monotypic genus, probably allied to *Melierax* through plumage, behaviour and yolk colour; traditionally associated with sub-buteonine hawks (see page 55), although interestingly race *meridionalis* was originally described in genus *Micronisus*. Two subspecies recognized.

Subspecies and Distribution.

K. m. monogrammicus (Temminck, 1824) - Senegambia E to Ethiopia and S to Uganda and Kenya.
K. m. meridionalis (Hartlaub, 1860) - S Kenya S to N South Africa and W to Angola and N Namibia.

Descriptive notes. 35 cm; 249-410 g; wingspan 79 cm. Has underparts grey barred with white and white rump, like small, stocky *Melierax*, but with black line down white throat. Morphs with one or two broad white bars across tail. Similar to some South American *Buteo* (*Rupornis*) and *Leucopternis* species. Juvenile similar to adult, with brown wash and paler soft part colours; has brown edges to wing-coverts, and brown not red eye.

Habitat. Moist broad-leaved deciduous woodlands, extending along riverine forest and into adjacent savanna during the rainy season.

Food and Feeding. Mainly insects, especially grasshoppers, lizards and small snakes; also frogs, rodents, arachnids, rarely small birds, and possibly some carrion. Perches for long periods about 8 m up on a conspicuous perch, making fast hard strikes, often into long grass, at any prey detected on the ground below within a radius up to 45 m. Drops from perch to fly close to the ground before swooping up to a new vantage point.

Breeding. Laying Feb-Apr in W & NE Africa; Sept in Gabon; probably all months in Zaire; Jan-Feb and Aug-Oct in E Africa; May-Jan in S & C Africa. Calls or even "sings" regularly from open perch prior to nesting. Builds a small stick nest in an outer fork of a tree, often deeply lined with lichen and leaves. Usually 2 eggs (1-3); incubation 33-34 days; chicks have first down white, second down pale grey; fledging 40 days; 30-40 days post fledging dependence period.

Movements. Resident in many large tracts of woodland. Some irregular local expansion into drier areas of S Africa during the dry season, usually after breeding and while in moult, but also erratically to breed.

Status and Conservation. Not globally threatened. CITES II. Common and quite conspicuous in woodlands of W Africa at 1 pair/80 ha; less abundant in E, C & S Africa. Vulnerable to cutting of woodland and burning or grazing of grass cover, but has extended range into areas cleared of primary forest. Only rarely nests in exotic tree species, and does not adapt readily to open savanna or exotic plantations. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Brown *et al.* (1982), Chapin (1932), Chittenden (1979), Colebrook-Robjent (1986), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Kemp (1986), Mackworth-Praed & Grant (1957-1973), Maclean (1993), von Maltitz *et al.* (1984), Pickford *et al.* (1989), Pinto (1983), Snow (1978), Steyn (1982), Tarboton & Allan (1984), Thiollay (1975a, 1975b, 1975c, 1975d, 1976a, 1976b, 1977a, 1977c, 1978a, 1978c, 1985d), Thiollay & Clobert (1990).

Genus *MELIERAX* G. R. Gray, 1840

90. Dark Chanting-goshawk

Melierax metabates

French: Autour sombre **German:** Graubürzel-Singhabicht **Spanish:** Azor-lagartijero Oscuro
Other common names: Chanting Goshawk

Taxonomy. *Melierax metabates* Heuglin, 1861, White Nile between lat. 6° N and 7° N, Sudan. Probably forms superspecies with *M. canorus* and *M. poliopterus*. Five subspecies recognized.

Subspecies and Distribution.

M. m. theresae Meinertzhagen, 1939 - SW Morocco.
M. m. neumanni Harten, 1914 - Mali E to N Sudan.
M. m. ignoscens Friedmann, 1928 - SW Arabian Peninsula.
M. m. metabates Heuglin, 1861 - Senegambia E to Ethiopia and S to NE Zaire and N Tanzania.
M. m. meehowi Cabanis, 1882 - Angola E to S Tanzania and S to N Namibia and NE South Africa.

Descriptive notes. 45 cm; male 646-695 g, female 841-852 g; wingspan 101 cm. Generally darker grey on upperparts than *M. canorus* and *M. poliopterus*; plain grey upperwing-coverts; rump barred grey and white; redder cere. Similar at all ages to smaller *Micronisus gabar*, but only outer tail barred. Male usually has paler wing-coverts than female. Juvenile brown, with brown streaking on rump, and pale yellow eye. Races separated on size, intensity of grey and extent of white markings.

Habitat. Moist broad-leaved woodlands and well-wooded savanna, barely overlapping

with drier habitats of congeners.

Food and Feeding. Mainly small vertebrates, especially lizards, snakes and birds, up to size of guineafowl, together with rodents, frogs, some insects and carrion. Hunts mainly from a perch, gliding down to catch prey, even pursuing it on foot. Sometimes rapacious and makes fast sorties and chases through woodland, taking prey in flight. Occasionally follows honeybadgers (*Mellivora capensis*) or ground-hornbills (*Bucorvus*) for prey they disturb.

Breeding. Laying Mar-May in W and NE Africa; Jun-Jul in E Africa; Jul-Nov in S Africa. Vocal, chanting from tree top, before nesting. Builds a platform of sticks, often in a low fork in dense woodland, the nest lined with mud and dry debris, including small bird nests, and often covered in spiders' webs. 1-2 eggs; incubation at least 30 days; chick has white down with long filaments on head; fledging about 36-50 days; juvenile very noisy in nest area for up to 5 months.

Movements. Resident and sedentary in most areas; some movement S in dry season in W Africa, and into NE Zaire in Nov-Apr. Recorded as vagrant to Spain, but record now in doubt.

Status and Conservation. Not globally threatened. CITES II. Widespread and common, especially in C Africa. 400 pairs estimated in Transvaal, South Africa. Vulnerable to cutting of woodland, especially small isolated populations in Morocco and Arabian Peninsula. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Bergier (1987), Brown *et al.* (1982), Colebrook-Robjent (1986), Cramp & Simmons (1980), Etchécopar & Hùe (1964), Gallagher & Woodcock (1980), Génsbel (1986), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Hollom *et al.* (1988), Howland (1988), Jensen & Kirkeby (1980), Lewis & Pomeroy (1989), Lippens & Wille (1976), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Morel & Morel (1990), Nikolaus (1987), Pickford *et al.* (1989), Pinto (1983), Steyn (1982), Tarboton & Allan (1984), Thiollay (1978c).

91. Eastern Chanting-goshawk

Melierax poliopterus

French: Autour à ailes grises

Spanish: Azor-lagartijero Somali

German: Weißbürrzel-Singhabicht

Other common names: Eastern Pale/Somali Chanting-goshawk

Taxonomy. *Melierax poliopterus* Cabanis, 1869, Umba River, Kenya.

Probably forms superspecies with *M. canorus* and *M. metabates*; sometimes considered conspecific with the former, but well separated geographically. Monotypic.

Distribution. SE Ethiopia and Somalia S to E Uganda and N Tanzania.

Descriptive notes. 45-50 cm; male 514-581 g, female 673-802 g. Averages paler than *M. metabates*, with rump pure white. Generally browner than *M. canorus*, with cere and legs more orange. Juvenile brown with white rump; streaked on upper breast and barred below.

Habitat. Dry thorn woodland and savanna.

Food and Feeding. Mainly lizards, also snakes, birds up to size of small francolin, rodents and some large beetles; rarely carrion. Hunts mainly from a prominent tree perch, swooping down for prey on the ground. Rarely walks about or makes fast aerial chase after

small birds.

Breeding. Laying at end of dry season: Feb-Jun in NE Africa; Feb-Jun and Aug-Oct in NW Kenya, where double rainy season occurs, and species may breed biannually. Performs nocturnal communal aerial display with calling on moonlit nights. Builds small stick platform in canopy of densely foliated tree, lined with dry grass and other debris. 1-2 eggs; incubation 36-38 days; chick has grey down with long filaments on head and back; fledging 49-56 days; usually only single chick reared but no sibling aggression observed.

Movements. Generally sedentary but may move out of more arid areas during drought. Makes regular migration N through Taru Desert, Kenya, in Jan-Mar, overflying residents; also absent from other areas (Laikipia Plateau) after breeding.

Status and Conservation. Not globally threatened. CITES II. Widespread, conspicuous and often common in suitable habitat. Home range 1.2-2.1 km² in ideal habitat in Tsavo, Kenya, with densities of 50-60 pairs/100 km². Only vulnerable to cutting of trees, habitat destruction by elephants, and overgrazing of semi-arid habitat. Not known to be affected by pesticides.

Bibliography. Ash & Miskell (1983), Britton (1980), Brown & Amadon (1968), Brown & Britton (1980), Brown *et al.* (1982), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957), Rasa (1986, 1987), Short *et al.* (1990), Smeenk & Smeenk-Enserink (1976), Snow (1978).

92. Pale Chanting-goshawk

Melierax canorus

French: Autour chanteur

German: Großer Singhabicht

Spanish: Azor-lagartijero Claro

Other common names: Southern Pale Chanting-goshawk

Taxonomy. *Falco canorus* Rislachi, 1799, South Africa.

Probably forms superspecies with *M. poliopterus* and *M. metabates*; sometimes considered conspecific with the former. Two subspecies recognized.

Subspecies and Distribution.

M. c. argenteior Clancey, 1960 - S Angola S and E through Namibia, Botswana and Zimbabwe to NE South Africa in Transvaal and NW Orange Free State.

M. c. canorus (Rislachi, 1799) - S South Africa, in Cape Province, SE Orange Free State and (formerly) S Natal.

Descriptive notes. 46-54 cm; male 493-750 g, female 700-1250 g; wingspan 111 cm. White flecking on greater wing-coverts, pale secondaries and plain white rump notable. Female larger than male. Most similar to browner *M. poliopterus* but secondaries paler; paler and larger than *M. metabates*; much larger than *Micronisus gabar*, with only outer tail barred. Juvenile plumage brown, including upper breast, with pale yellow eye. Races *argenteior* paler.

Habitat. Dry thorn savanna, arid steppe and desert with a few trees or woody succulents.

Food and Feeding. Small vertebrates, especially lizards and rodents, but also birds up to the size of francolin or small bustard, small tortoises, insects and carrion. Hunts mainly from a low perch or while searching about on the ground. Can make swift dashes after prey, taking it in flight; also follows small carnivores for prey they disturb, especially honeybadger (*Mellivora capensis*), jackals and mongooses. Sometimes hunts in pairs, trios or family units.

Breeding. Laying Jun-Dec in S Africa. Chants from prominent perch with tail spread. Builds a stick platform, lined with dung, fur and other dry debris, in upper fork often of a thorny tree, or on a utility pole where trees lacking. Usually 2 eggs (1-2); incubation c. 35 days; chick has white down with long filaments on head; fledging 44 days; breeding trios with an extra male occur. May forgo breeding during drought years.

Movements. No regular movements recorded, but some long distance ringing recoveries of up to 770 km suggest extensive nomadism within arid areas, especially of young birds.

Status and Conservation. Not globally threatened. CITES II. Widespread and common in semi-arid areas, with 400-900 pairs at edge of range in W Transvaal, South Africa. Home range 5.4-6.7 km² in Namibia. Conspicuous, but not often persecuted and may benefit from presence of utility poles in desert areas for hunting from or nesting on. Not known to be affected by pesticides but may be poisoned locally during locust plagues.

Bibliography. Allan (1988b), Biggs *et al.* (1984), Brown *et al.* (1982), Ginn *et al.* (1989), Mackworth-Praed & Grant (1957-1973), Mackworth-Praed & Grant (1962), Maclean (1993), Malan (1992), Malan & Branch (1992), Penzhorn (1976), Pickford *et al.* (1989), Pinto (1983), Smeenk & Smeenk-Enserink (1976), Steyn (1982), Steyn & Meyburg (1992), Tarboton & Allan (1984).

Genus MICRONISUS G. R. Gray, 1840

93. Gabar Goshawk

Micronisus gabar

French: Autour gabar

German: Gabarhabicht

Spanish: Gavilán Gabar

Taxonomy. *Falco gabar* Daudin, 1800, Zwart River, Cape Province, South Africa.

Often included in genus *Melierax*, but may well be closer to *Accipiter*. Three subspecies recognized.

Subspecies and Distribution.

M. g. niger (Vieillot, 1823) - Senegambia E to N Ethiopia and SW Arabia, and S to N Cameroon, Chad and Sudan.

M. g. aequatorius Clancey, 1987 - Ethiopian highlands S to Zaire, Zambia and N Mozambique.

M. g. gabar (Daudin, 1800) - S Angola, Zambia and Mozambique S to South Africa.

Descriptive notes. 28-36 cm; male 110-173 g, female 180-221 g; wingspan 60 cm. Female larger than male. White rump prominent in adult and juvenile of normal phase. Melanistic morph (from hatching, 6-25% of population in different areas), with pale grey bars on flight-feathers and tail; lacks white rump. All phases and morphs similar to *Accipiter ovampensis*, but latter barred up to throat, with only slight white rump, and legs orange, not red. Juvenile brown, with streaks on upper breast and bars on lower breast. Races separated on size and greyiness of plumage.

Habitat. Mainly open thorn savanna, extending to semi-arid steppe along watercourses, and into deciduous broad-leaved woodland.

Food and Feeding. Mainly small birds of 10-80 g, up to 238 g francolin; also small reptiles, mammals and some insects. Hunts from within cover, often in pairs, sometimes in company of Red-necked Falcon (*Falco chicquera*), making fast dashes after prey and continuing into dense cover on foot. May also make low prospecting flights, and often raids or tears into birds' nests to devour contents.

Breeding. Laying usually at end of dry season: Mar-Jun in W & NE Africa; Mar-Nov, with two peaks, in E Africa; Aug-Mar in S Africa (peak Sept-Nov). One marked pair known to have bred twice in one year. Performs aerial and calling displays. Builds small stick nest in crown of an indigenous, often thorny tree, not lined with green leaves or bark like *Accipiter* species. Nest usually and characteristically occupied by and coated with web of colonial spider *Stegodyphus*, probably brought intentionally by hawk for concealment of nest. Usually 2 eggs (2-4); incubation 33-35 days; chicks have white down (grey in melanistic morph); fledging 30-35 days.

Movements. Resident in many areas, but fluctuations in numbers suggest some local movements S in dry season in W Africa. Regular migration N through Taru Desert, Kenya, in Jan-Mar, overflying residents.

Status and Conservation. Not globally threatened. CITES II. Common and widespread through a diverse range of savanna and woodland habitats, although rarely nests in plantations of exotic trees. Nests 4.3-5.8 km apart (Namibia). Bold, even colonizing urban areas, and too small to be serious threat to poultry. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Black & Ross (1970), Brown, C.J. (1986a), Brown, L.H. *et al.* (1982), Clancey (1987b), Colebrook-Robjent (1986), Ginn *et al.* (1989), Grimes (1987), Henschel *et al.* (1991), Herholdt

(1994). Kemp (1986, 1988), Kemp & Kemp (1976), Kemp & Snelling (1973), Lewis & Pomeroy (1989), Mack-worth-Pried & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Rasa (1987), Simmons (1986a), Smeenk & Smeenk-Enserik (1976), van Someren (1956), Steyn (1982, 1992), Tarboton & Allan (1984), Thiollay (1978c).

Genus *ACCIPITER* Brisson, 1760

94. Grey-bellied Goshawk

Accipiter poliogaster

French: Autour à ventre gris **German:** Graubauchhähne **Spanish:** Azor Ventrigrís
Other common names: Grey-bellied Hawk

Taxonomy. *Falco poliogaster* Temminck, 1824. São Paulo, Brazil. Birds in the very distinctive immature plumage formerly classified as separate species, *A. pectoralis*. Monotypic.

Distribution. E of Andes from Colombia and NE Ecuador (perhaps only migrants), S Venezuela and the Guianas S through Brazil (except NE), E Peru, Bolivia and Paraguay to N Argentina (Misiones); not recorded between R Negro and R Madeira in W Amazonia.

Descriptive notes. 43-50 cm. Crown and back black, sides of head black or grey; tail has three broad grey bars and white tip; below very pale whitish grey, underwings unbarred; throat and undertail white. Iris, legs and feet yellow. Very similar to Slaty-backed Forest-falcon (*Micrastur mirandollei*), but larger, with shorter square tail. Female larger than male. Immature quite different, and remarkably similar to adult *Spizaetus ornatus*: black crown, chestnut malar patches and nuchal collar continuing onto sides of breast; lower breast and belly white with broad, broken black barring.

Habitat. Rain forest, from lowlands up to 500 m; recorded at margins of riparian forest and in patches of dense woodland. Regularly soars over the forest.

Food and Feeding. No information available; large size suggests relatively large prey, especially birds.

Breeding. No information available.

Movements. Thought to be migratory, at least in extreme S of range. Colombian records may all refer to austral migrants, as all during period Mar-Jun. Transition between presumed migratory and resident populations unknown.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Very little information available. Generally seems to be rare, but wide distribution suggests no immediate overall threat. No recent records from NE Argentina. Estimated average density of at least 3 individuals/10,000 ha at one forest site in French Guiana.

Bibliography. 95. Crested Goshawk

Accipiter trivirgatus

French: Autour huppé **German:** Schopfhähne **Spanish:** Azor Moñudo

Taxonomy. *Falco trivirgatus* Temminck, 1824. Sumatra. Forms superspecies with *A. griseiceps*. Eleven subspecies recognized.

Subspecies and Distribution.

- A. t. luyardi* (Whistler, 1936) - Sri Lanka.
- A. t. peninsulæ* Koelz, 1949 - SW India.
- A. t. indicus* (Hodgson, 1836) - NC, NE & E India and Nepal to S China, including Hainan, and S to Indochina and Malay Peninsula.
- A. t. formosæ* Mayr, 1949 - Taiwan.
- A. t. trivirgatus* (Temminck, 1824) - Sumatra.
- A. t. niasensis* Mayr, 1949 - Nias I (off W Sumatra).
- A. t. javanicus* Mayr, 1949 - Java: recently recorded on Bali.
- A. t. microstictus* Mayr, 1949 - Borneo.
- A. t. palawanus* Mayr, 1949 - Palawan, Calamianes (SW Philippines); may also be race of *Natuna* Is (off W Borneo).
- A. t. extimus* Mayr, 1945 - SE Philippines.
- A. t. castroi* Manuel & Gilliard, 1952 - Polillo Is, off E Luzon (N Philippines).

Descriptive notes. 37-46 cm; 224-450 g; wing-span 65-85 cm. Medium-sized *Accipiter*, with short wings; short, pointed crest usually depressed and not visible; wide dark mesial throat stripe; tail with dark and pale bands of roughly equal width. Female larger and browner than male. Juvenile similar to adult but browner, especially on head, and paler. Racial differences rather slight: island forms generally smaller; some forms darker and more heavily marked, others paler and lightly marked.

Habitat. Moist deciduous and evergreen forest in lowlands and foothills up to 1800 m, and to 2289 m in SC Vietnam.

Food and Feeding. Feeds on small mammals, lizards, frogs, large insects and birds. Prey captured after short, rapid attack launched from concealed perch, usually inside forest. Also takes nestling birds and even bats.

Breeding. Season varies with locality: generally Dec-May, but earlier in S of range: Feb-Jul in Sri Lanka; Jan in Sumatra; Dec-Mar in Java. Large nest built by pair 9-13 m (occasionally higher) up large tree; lined with green leaves. Spectacular display flights include one bird, perhaps male, gliding over territory with white undertail-coverts widely spread and wings drooped. Usually 2 eggs, rarely 1 or 3; incubation c. 34 days. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Apparently uncommon to fairly common throughout extensive range; possibly commoner than thought and simply not detected because of unobtrusive habits and preference for forest interiors. Common in Tanjung Puting National Park, C Kalimantan (Borneo). Range reduced in Java due to loss of forest habitat; deforestation is clearly main threat throughout range.

Bibliography. Ali & Ripley (1978), Betts (1947, 1953), Cheng Tso-hin (1987), Deignan (1945, 1963), Dickinson *et al.* (1991), DuPont & Rabor (1973), Eichkopar & Hue (1978), Henry (1971), Inskapp & Inskapp (1985), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Phillips (1993), van Marle & Voous (1988), Mayr (1949), Medway & Wells (1976), Meyer de Schauensee (1984), Severinghaus & Blackshaw (1976), Smythies (1981, 1986), Thiollay & Meyburg (1988), Wattel (1973).

96. Sulawesi Goshawk

Accipiter griseiceps

French: Autour de Célèbes **German:** Graukopfhähne **Spanish:** Gavilán de Célebes
Other common names: Sulawesi/Celebes Crested Goshawk

Taxonomy. *Astur griseiceps* Schlegel, 1862. Atep and Gorontalo, northern Sulawesi.

Forms superspecies with *A. trivirgatus*. Monotypic.

Distribution. Sulawesi and off-lying Togian Is, Muna and Butung.

Descriptive notes. 33-38 cm; 212-299 g. Small goshawk with dark upperparts and very small crest; similar in structure to larger *A. trivirgatus*, but underparts streaked all over, and crest much smaller. Juvenile similar to that of *A. trivirgatus*. **Habitat.** Interior of primary and secondary forest; also mangroves and wooded savanna. Occurs from sea-level up to 2000 m.

Food and Feeding. Lizards, small birds, insects, small mammals and occasionally domestic fowl. Prey taken by surprise, often on ground, after short rapid flight from concealed hunting perch in forest.

Breeding. Very little information available.

Season includes May-Jul: laying probably in May, with nestlings heard in late Jun; another pair observed copulating in Jul. Goshawk-sized nest in main fork of not very tall tree in montane forest.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Generally reckoned to be uncommon, e.g. in Dumoga-Bone National Park (N Sulawesi); may actually be commoner than thought but infrequently observed due to unobtrusive behaviour.

Bibliography. Andrew (1992), van Bennekel & Voous (1951), Bishop *et al.* (1994), Brown & Amadon (1968), van Marle & Voous (1946), Mayr (1949), Siresmann (1940a), Wattel (1973), White & Bruce (1986).

97. Red-chested Goshawk

Accipiter toussenelii

French: Autour de Toussenel **German:** Rotbrusthähne **Spanish:** Azor de Toussenel
Other common names: West African Goshawk

Taxonomy. *Nisus Toussenelii* J. and E. Verreaux, 1855. Gahon.

Forms superspecies with *A. tachiro*, with which often considered conspecific, but differs in size, coloration and apparent lack of display flight. Races *macroselides* and *lopezi* have also been considered to form another full species. Four subspecies recognized.

Subspecies and Distribution.

- A. t. macroselides* (Hartlaub, 1855) - Senegambia to W Cameroon in rain forest.
- A. t. toussenelii* (J. & E. Verreaux, 1855) - S Cameroon to Gabon, in lower Zaire River basin.
- A. t. canescens* (Chapin, 1921) - upper Zaire River basin.
- A. t. lopezi* (Alexander, 1903) - Bioko I (Fernando Po).

Descriptive notes. 35 cm; male 150-235 g, female 270-365 g. Dark upperparts contrast with pale rufous underparts, with little or no barring, white underwing-coverts and white bands across tail; thighs range from white to greyish to reddish. Lowland forest equivalent of larger, well barred *A. tachiro*. Female larger, but similar shade of rufous below to that of male. Juvenile white or only sparsely spotted below, with white or only pale rufous thighs. Races differ in size, intensity of plumage colour and extent of barring on flanks; in equatorial forest belt. W to E cline in percentage of individuals with barred underparts: race *macroselides* small, and fairly well barred below; *canescens* typically lacks barring.

Habitat. Lowland tropical evergreen rain forest and adjacent secondary forest; also montane gallery forest.

Food and Feeding. Small mammals, including squirrels and mice, birds and some frogs, lizards, chameleons, crabs and insects. Attacks free-range poultry. Steals leus and feet suggest preference for larger birds, including hornbills, and mammalian prey (captives in takony regularly kill prey weighing 90-600 g). Hunts mainly from a perch, taking prey after a fast strike from within cover; rarely by surprise after a dashing flight in between vegetation. Active crepuscular.

Breeding. Season Dec-Feb in Ghana; laying Aug, Oct in Sierra Leone, with juveniles frequent in dry season, laying estimated Oct-Nov in Gabon; possibly in breeding condition in Jan and Feb in Zaire. Unlike *A. tachiro*, does not perform regular aerial flight display above territory with repeated single call note. Both sexes build stick platform in tall forest tree; 2 eggs at one nest; no further details recorded.

Movements. No movements recorded.

Status and Conservation. Not globally threatened. CITES II. Widespread and common, with large tracts of forest habitat remaining; in Sierra Leone and Ghana, common throughout lowland forest. Vulnerable to deforestation, but often hunts in secondary growth and along edge of forest. Not known to be affected by pesticides.

Bibliography. Brosset (1969, 1973), Brosset & Erard (1986), Brown *et al.* (1982), Gore (1990), Grimes (1987), Jensen & Kirkeby (1980), Lippens & Wille (1976), Louette (1992), Morel & Morel (1990), Nikolaus (1987), Pinto (1983), Sargeant (1993), Serle *et al.* (1977), Snow (1978), Thiollay (1978c, 1985d), Wattel (1973).

98. African Goshawk

Accipiter tachiro

French: Autour tachiro

German: Afrikahabicht

Spanish: Azor Tachiro

Taxonomy. *Falco tachiro* Daudin, 1800, Knysna district, Cape Province, South Africa.

Forms superspecies with *A. toussenelii*, with which often considered conspecific, but differs in size, coloration and characteristic display flight. Five subspecies recognized.

Subspecies and Distribution.

A. t. unduliventer (Rüppell, 1836) - Ethiopian highlands.

A. t. crociati Deshayes, 1974 - SW Ethiopia.

A. t. sparsimfasciatus (Reichenow, 1895) - Somalia, through E Africa, Zanzibar and SE Zaire to N Angola, N Zambia, N Malawi and N Mozambique.

A. t. pembuensis Benson & Elliott, 1975 - Pemba I (Tanzania).

A. t. tachiro (Daudin, 1800) - S Angola, S Zambia, S Malawi and S Mozambique S to South Africa.

Descriptive notes. 35-40 cm; male 160-230 g, female 230-510 g; wingspan 70 cm. Female larger than male, less rufous, with thicker bars below, similar to much smaller *A. minullus*. Juvenile brown with some barring and large spots on underparts, similar to juvenile *Aviceda cuculoides*; eye brown, as opposed to orange in adult; some populations have rufous thighs. Races differ in size, intensity of plumage colour and extent of barring: *sparsimfasciatus* polymorphic, with normal barred morph and dark morph.

Habitat. Dense vegetation, including evergreen, gallery and montane forest, deciduous forest, woodland and riverine forest, exotic plantations and adjacent savanna.

Food and Feeding. Mainly small birds and nestlings, bats and rodents; also squirrels, reptiles, amphibia, crabs and insects. Usually hunts from within cover, making a short dash to capture prey in flight, on the ground or from foliage. Sometimes stoops into canopy from regular high circling flights above forest, or makes fast sub-canopy pursuits. Often hunts at dawn and dusk in low light intensities, and generally inactive around midday.

Breeding. Laying at start of rains: about Jul in W Africa; Mar-Apr and Oct-Dec in E Africa, during both rainy seasons; Sept-Nov in C and S Africa. Regularly flies high over territory loudly repeating a single sharp note. Builds a small platform of sticks high in a forest tree, often concealed among creepers or foliage. Usually 2-3 eggs (1-4); incubation c. 30-35 days; chicks have white down; fledging 32-35 days.

Movements. Apparently resident and sedentary in all areas, but some wandering to more arid habitat during long rains in Kenya.

Status and Conservation. Not globally threatened. CITES II. The commonest and most conspicuous small hawk in most African forest habitats, either when calling above the forest or when perched over roads and paths. Vulnerable to forest clearance, but thrives in many secondary forest and woodland types. Not known to be affected by pesticides. Race *pembuensis* common in 1970's.

Bibliography. Benson & Benson (1975), Black & Ross (1970), Brown *et al.* (1982), Dewhurst (1986), Ginn *et al.* (1989), van Jaarsveld (1988), Kemp & Rautenbach (1987), Lewis & Pomeroy (1989), Lippens & Wille (1976), Louette (1992), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Piper (1989), Rautenbach *et al.* (1990), Simmons (1986a), Snow (1978), van Someren (1956), Steyn (1982), Tarboton & Allan (1984), Vernon (1986), Wattel (1973), Wood (1987).

99. Chestnut-flanked Sparrowhawk

Accipiter castanilius

French: Autour à flancs roux

German: Rotflankenhabicht

Spanish: Gavilán Flanquirojo

Other common names: Chestnut-flanked Goshawk, Chestnut-bellied Sparrowhawk

Taxonomy. *Accipiter castanilius* Bonaparte, 1853, South America; error, Gabon.

Apparently fairly close to *A. toussenelii* and *A. tachiro*, but distinguished by smaller size and long inner claw. Birds of W Zaire sometimes separated in race *beniensis*, on grounds of larger size. Monotypic.

Distribution. Nigeria E to Zaire River basin. Purported presence in Upper Guinea forests W of Nigeria requires confirmation.

Descriptive notes. c. 30-35 cm; male 135-150 g, female 152-200 g. Saturated colours and heavy grey and brown barring below distinctive: smaller, but longer-tailed and much darker than *A. toussenelii*, which is generally only lightly barred. Male has white bars, rather than spots, on tail. Juvenile has large spots on breast; generally similar to that of *A. toussenelii*, but thighs rusty.

Habitat. Lowland tropical evergreen forest, sometimes extending into dense adjacent secondary growth.

Food and Feeding. Little known, but probably mainly birds (captives in falconry take large insects; birds twice seen trying to catch a fruit bat. Attends parties of birds following driver-ant columns, to catch such birds and other small animals disturbed. Long slender legs and toes suggest mainly avian diet. Normally found perched only 1-3 m up in dense cover, attacking swiftly from such positions.

Breeding. Unrecorded. Laying probably Jan-Apr in Gabon. No aerial flight display reported.

Movements. None recorded; probably resident and sedentary.

Status and Conservation. Not globally threatened. CITES II. Secretive, but thought to be common in larger tracts of pristine forest, of which considerable areas remain. Vulnerable to deforestation, although will enter clearings to hunt; numbers may be much reduced in parts of range. Not known to be affected by pesticides.

Bibliography. Ash (1990), Bannerman (1953), Brosset (1973), Brosset & Erard (1986), Brown *et al.* (1982), Chapin (1932), Lippens & Wille (1976), Louette (1992), Mackworth-Præd & Grant (1970), Pinto (1983), Serle *et al.* (1977), Snow (1978), Thiollay (1978c), Wattel (1973).

100. Shikra

Accipiter badius

French: Épervier shikra

German: Schikrasperber

Spanish: Gavilán Chikra

Other common names: Little Banded Goshawk

Taxonomy. *Falco badius*, Gmelin, 1788, Sri Lanka.

Forms superspecies with *A. butleri* and *A. brevipes*, and perhaps also *A. soloensis* and *A. francescii*. Formerly considered conspecific with *A. brevipes*; sometimes considered to include *A. butleri*. Six subspecies recognized.

Subspecies and Distribution.

A. b. cenchroides (Severtsov, 1873) - Azerbaijan E to Kazakhstan and Iran E to NW India, migrating further S in winter.

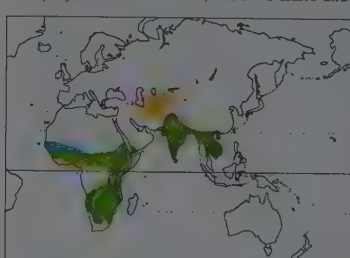

A. b. dumsumieri (Temminck, 1824) - C India and Bangladesh.

A. b. badius (Gmelin, 1788) - SW India and Sri Lanka.

A. b. polioptus (Hume, 1874) - NE India E to S China, S to Thailand and Vietnam.

A. b. sphenurus (Rüppell, 1836) - Senegambia E to SW Arabia, S to N Zaire and N Tanzania.

A. b. polyzonoides A. Smith, 1838 - S Zaire and S Tanzania to N South Africa.

Descriptive notes. 30 cm; 75-158 g; wingspan 58 cm. Pale yellow cere and red (male) or deep orange (female) eye notable. Female larger than male. Juvenile has brown spots on breast, bars on flanks, brown eye and black line down throat. Most similar to *A. brevipes*, but paler below, with fewer, less distinct bars on undertail. Races separated on size, and extent of brown in plumage and rufous below.

Habitat. Deciduous woodland and savanna, from arid steppe to mesic woodland with closed canopy; also small plantations of exotic trees, including suburban gardens.

Food and Feeding. Mainly lizards, geckos

and small birds (9-22 g); also nestlings, eggs, bats, rodents, frogs and insects, rarely carrion. Hunts mainly from a perch within vegetation, making a short dash to take prey on a trunk, in foliage or on ground. Rarely makes aerial pursuits, but generally forceful in attacks on prey. Changes perch with low flap-and-glide flight.

Breeding. Laying usually at end of dry season: Mar-Aug in Sri Lanka; Jan-June in India; Jan-May in W & NE Africa; probably all months in E Africa; Aug-Jan (peak Sept-Nov) in S Africa; late May (spring) in Azerbaijan. Vocal prior to nesting. Builds a small stick nest lined with bark flakes, in an outer fork or on a horizontal branch. Usually 2-3 eggs in Africa, 3-4 in India (1-5), and 3-4 in Azerbaijan (1-7); incubation 30 days in Africa, 33-35 days in Azerbaijan; chicks have pale buff down with white nape; fledging c. 32 days in Africa and India.

Movements. Regular winter migrant S from Palearctic edge of range: some birds move SW to Arabia; most to Pakistan, India and SE Asia. Resident in most other areas of India and in Africa, but in more deciduous habitats moves regularly between drier and wetter savannas. In W Africa moves S in dry season of Oct-Mar, to breed in Guinea woodlands, then N again in wet season; more precise study of movements in W Africa required, e.g. in Senegambia present all year round, but much more numerous in rains. Probably similar but more erratic movements in SW Africa. In Tanu Desert and arid Tsavo, Kenya, moves N in Jan-Mar. Vagrant to Malaysia and Sumatra.

Status and Conservation. Not globally threatened. CITES II. The commonest small hawk of most dry woodland and tree savanna in Africa and India; frequently common near human habitation. Attains densities of 1 pair/2.3 km² in W Africa, or 1 pair/50-117 km² in Transvaal, South Africa; apparently less common in E Africa. Extremely rare in Azerbaijan. One old record from Taiwan. Not known to be affected by pesticides.

Bibliography. Ali & Ripley (1978), Banks (1974), Benson & Benson (1975), Biddulph (1937), Black & Ross (1970), Brown *et al.* (1982), Clark & Parslow (1991), Cramp & Simmons (1980), Etchécopar & Hùe (1978), Flint *et al.* (1984), Gensbøl (1986), Ginn *et al.* (1989), Grimes (1987), Henry (1971), Lamba (1970), Lekagul & Round (1991), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1962), Maclean (1993), Naoraji (1991), Phillips (1933), Rasa (1987), Roberts (1991), Schmitt *et al.* (1982), Simmons (1986a), Smeenk & Smeenk-Enserik (1977), Smythies (1986), Steyn (1982), Steyn & Barbour (1973), Tarboton (1978b), Tarboton & Allan (1984), Thiollay (1975b, 1975c, 1976b, 1977c, 1977b, 1978a, 1978c), Wattel (1973).

101. Nicobar Sparrowhawk

Accipiter butleri

French: Épervier des Nicobar

German: Nikobarsperber

Spanish: Gavilán de Nicobar

Other common names: Nicobar Shikra, Car Nicobar Shikra.

Taxonomy. *Astur butleri* Gurney, 1898, Car Nicobar.

Sometimes considered a race of *A. badius*, but is quite different in plumage, especially that of juveniles: in structure, being short-winged; and in choice of habitat, a denizen of the upper storeys of forest. Most authorities now consider this a separate species. Forms superspecies with *A. badius* and *A. brevipes*. Two subspecies recognized.

Subspecies and Distribution.

A. b. butleri (Gurney, 1898) - Car Nicobar I (N Nicobar Is).

A. b. obsoletus Richmond, 1902 - Katchall I and possibly Camorta I (C Nicobar Is).

Descriptive notes. 28-34 cm. A small, shy, vocal sparrowhawk with short wings. Differs from larger, darker *A. badius* in single dark subterminal band in tail. Juvenile has rufous upperparts. Race *obsoletus* larger; lacks rufous on underparts.

Habitat. Upper storeys of forest.

Food and Feeding. Apparently mainly lizards; some insects also recorded. Hunting behaviour unreported.

Richmond (1903), Tikader (1988), Wattel (1973).

Breeding. Reproductive activity recorded in Feb and Sept; claim that species breeds twice annually (based on record of juveniles in Sept) seems unlikely. One nest found 12 m up in *Ficus* fig tree, at end of horizontal branch. No further information available.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened, CITES II. Various reported as not uncommon and fairly common, but not encountered during recent raptor surveys on Car Nicobar.

Bibliography. Ali & Ripley (1978), Brown & Amadon (1968), Butler (1899), Ferguson-Lees & Faull (1992).

size of bee-eaters; some mice and voles; in Africa, insects may predominate. Normally flies low (6-10 m above ground), often hunting in clearings and on edges of woods, sometimes on outskirts of human settlements. Sometimes hunts crepuscularly, and will even take bats. Normally solitary, but pairs may hunt together; during migration may hunt in flocks.

Breeding. Lays in May or early Jun. Nest built in tree, usually in deciduous trees and commonly in alders in some regions; placed on branch near trunk; nest is small platform of sticks lined with twigs and sometimes leaves;

may use other birds' old nests. Normally 3-5 eggs (mean 3.6); replacement laying possible; incubation perhaps 30-35 days per egg, by female; male brings food and female feeds chicks; chicks have white down; fledging c. 45 days; chicks dependent on adults for some weeks more. Sexual maturity at 1 year old.

Movements. Migratory. Most birds leave breeding areas in Sept and return in Apr or early May; believed to winter in sub-Saharan Africa, but winter quarters in Africa not well known. Migrants concentrate around Bosphorus, E Black Sea and especially Israel, where there are peaks during very short periods in second half of Apr and of Sept, and large groups can form; crossing point between Asia and Africa probably at Gulf of Suez. Some nocturnal migration recorded, with birds using flapping flight.

Status and Conservation. Not globally threatened, CITES II. Size and trends of populations insufficiently known, but species less rare than was thought before 1980's. Previously more abundant in SE Europe: e.g. in Bulgaria c. 50 pairs in early 1990's, whilst apparently more numerous than *A. nisus* in mid-20th century. Apparently stable in former USSR, where 2000 pairs estimated in early 1990's, with maximum concentration of 1000-1500 pairs in basin of R Don, but recent estimate of c. 3000 pairs in European Russia alone; c. 80 pairs in SW Ukraine rare in Azerbaijan. Over 40,000 birds pass through Israel each season on migration, with 49,800 in Elat in spring 1987. No reliable information regarding rest of range: very scarce in former Yugoslavia, Romania and Turkey; estimates of up to 1000 pairs in Greece.

Bibliography. Belik (1986a, 1992), Benson (1970), Brown *et al.* (1982), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Esilevskaya & Bryukhanov (1991), Gallagher & Woodcock (1980), Genshel (1986), Goodman *et al.* (1989), Handrinos & Demetropoulos (1983), Hollom *et al.* (1988), Hue & Etchécopar (1970), Jennings (1981), Lesnichy *et al.* (1986), Mackworth-Praed & Grant (1957), Patrikeev (1993), Paz (1987), Shirihai & Christie (1992), Shirihai & Yekutieli (1991), Simeonov *et al.* (1990), Stark & Loeche (1993), Thiollay (1989), Wattel (1973).

102. Levant Sparrowhawk

Accipiter brevipes

French: Épervier à pieds courts German: Kurzfangsperber Spanish: Gavilán Griego

Taxonomy. *Astur brevipes* Severtsov, 1850, Voronezh Province, Russia.

Formerly considered a race of *A. badius*. Forms superspecies with *A. badius* and *A. butleri*. Monotypic.

Distribution. SE Europe, SW Ukraine and S Russia E to W Kazakhstan; more locally in Turkey, Caucasus and Iran. Thought to winter mainly in E Sahel zone of sub-Saharan Africa.

Descriptive notes. 33-38 cm; wingspan 64-80 cm. In flight, contrast from below between almost white underwing and black wingtip; dull blue-grey above; breast and belly pale, lightly barred pinkish or reddish; dark red iris. Female somewhat larger, with browner upperparts; more heavily barred on underparts and underwing; dark streak on throat; lacks white supercilium of female *A. nisus*. Juvenile dark brown above, densely streaked on underparts, with pale spot on hindneck; dark streak on throat, as in female, but more distinct.

Habitat. Wooded plains, particularly in river basins; also foothills and mountain slopes. In Caucasus up to 1000 m, but observed exceptionally up to 2000 m in Armenia. Prefers deciduous trees; often in riparian woodland and copses; also orchards and scrub.

Food and Feeding. Mainly lizards and large insects, e.g. grasshoppers, locusts and other Orthoptera, beetles, cicadas; also variety of small birds, including sparrows, finches and swallows, up to

103. Chinese Goshawk

Accipiter soloensis

French: Épervier de Horsfield **German:** Froschsperber **Spanish:** Gavilán Ranero
Other common names: Horsfield's Sparrowhawk, Grey Frog Hawk, Grey Goshawk(!)

Taxonomy. *Falco Soloënsis* Horsfield, 1821, Solo, Java. Sometimes considered to form superspecies with *A. badius*, *A. brevipes*, *A. butleri* and *A. francesii*. Monotypic.
Distribution. S Ussuriland and Korea; C & E China and Taiwan. Winters from extreme SE China and Hainan, S through Indochina, Philippines and Indonesia to W New Guinea and occasionally W Micronesia.

Descriptive notes. 27-35 cm. Resembles *A. badius*, but more slate-coloured above and lacks dark tip to tail; throat white with dark shaft streaks, underparts and underwing-coverts tinged pale rufous, rather than barred; belly and undertail-coverts whitish; white patches on underwing. Also recalls *A. brevipes* and *A. trinitatus*, but differs in pattern and coloration of underparts and tail. Cere, legs and feet generally tinged orange. Female slightly larger, with somewhat more apparent barring below. Juvenile dark brown above, darker than juvenile *A. badius*; underparts densely marked, rufous barring on flanks.

Habitat. Forests and wooded areas, often near paddyfields or wetlands, where most of prey can be found.

Food and Feeding. Main prey probably frogs; also large insects, such as grasshoppers, as well as lizards and small birds. Hunts mainly in open country, scanning from perch; mainly catches prey on ground.

Breeding. Laying in Jun. Nests in tree, in fork or on branch, 8-12 m high; nest built of sticks and lined with green leaves which are added throughout breeding period. Normally 3-4 eggs, occasionally 5; incubation by both adults; both also hunt for chicks, although female normally hunts nearer nest; fledging from 22 days, with young birds beginning to hunt soon after. Adults actively defend nest against intruders, including man.

Movements. Almost completely migratory, although sedentary in Taiwan. Some birds winter in SE China, in Guangdong and on Hainan; most move farther S, reaching Indochina, peninsular Malaysia, Philippines, Greater and Lesser Sundaes, Sulawesi and W tip of New Guinea. Major migration route through Korea, W Kyushu (Japan) and Ryukyu Is towards Taiwan; migration detected in Sept and early Oct, but not well known in spring. Considerable movement recorded over Bali, where 924 birds seen from early Oct to early Nov 1990; movement over N Sulawesi in early Mar and early Oct. Birds arrive in Ussuriland in early May.

Status and Conservation. Not globally threatened. CITES II. Common at least in some areas, and total population probably sizeable. Large number of birds observed on migration in Japan, e.g. over 10,000 birds counted in autumn, coming from N part of range: these would therefore constitute just a small part of population. Common migrant and winter visitor in N Sulawesi, especially in lowlands.

Bibliography. 104. Frances's Sparrowhawk

Accipiter francesii

French: Épervier de Frances **German:** Echsenhabicht **Spanish:** Gavilán de Frances
Other common names: Madagascar/Malagasy Goshawk, Frances's/France's Goshawk, France's Sparrowhawk

Taxonomy. *Accipiter Francesii* A. Smith, 1834, Madagascar. Perhaps forms superspecies with *A. badius*, *A. brevipes*, *A. butleri* and *A. soloensis*. The three races of Comoros Is have been considered to constitute a separate species, on grounds mainly of much smaller size. Four subspecies recognized.

Subspecies and Distribution.

- A. f. francesii* A. Smith, 1834 - Madagascar.
- A. f. griveaudi* Benson, 1960 - Ngazidja (Grand Comoro), Comoro Is.
- A. f. pusillus* (Gurney, 1875) - Ndzuani (Anjouan), Comoro Is.
- A. f. brutus* (Schlegel, 1866) - Maore (Mayotte), Comoro Is.

Descriptive notes. 28-35 cm, male 102-116 g. Extent of rufous barring on underparts varies between individual males. Female larger and browner than male, with broader and much more profuse barring below. Juvenile resembles adult female. Races differ markedly in size, colour intensity and extent of barring on underparts; race *griveaudi* heavily barred below, *pusillus* almost unmarked whitish below, both similar in size to *brutus*.

Habitat. All types of primary and secondary forest up to 2000 m, including commercial plantations and suburban gardens. On Ngazidja occurs mainly on the edge of evergreen

forest up to 1800 m.

Food and Feeding. Mainly large insects, such as grasshoppers or beetles, and small vertebrates, such as frogs, chameleons, lizards, rodents and small birds. Usually hunts from a perch with a swift dash after quarry, sometimes in pairs.

Breeding. Laying Sept-Nov on Madagascar and Maore. Builds a substantial stick nest, lined with green leaves, 4.5-7 m up in a densely foliated forest tree, an exotic mango (*Mangifera indica*) near a village, or within an epiphyte on a plantation tree. Usually 3 eggs (3-5); no further details recorded.

Movements. None recorded. The distinct races on separate islands of the Comoro Is suggest a sedentary species.

Status and Conservation. Not globally threatened. CITES II. The commonest *Accipiter* on Madagascar, but uncommon in the arid S. In the Comoros: not common on Ngazidja; once common on Ndzuani, but later (1960) rare, and now probably close to extinction; on Maore was and still is common on moist W side, especially at low altitude. Not recorded from Mwali.

Bibliography. Benson (1960a), Benson *et al.* (1976), Dee (1986), King (1978/79), Langrand (1990), Langrand & Meyburg (1984), Louette (1988), Milon *et al.* (1973), Thibault & Guyot (1988), Wattel (1973)

105. Spot-tailed Goshawk

Accipiter trinitatus

French: Épervier à queue tachetée **German:** Fleckschwanzsperber **Spanish:** Gavilán Colipinto
Other common names: Spot-tailed Accipiter

Taxonomy. *Accipiter trinitatus* Bonaparte, 1850, Sulawesi. May represent old endemic element of Sulawesi. Purported race *haesitandus* of S Sulawesi probably not valid, as variation slight and apparently inconstant. Monotypic.

Distribution. Sulawesi and off-lying islands of Talisei, Muna and Butung.

Descriptive notes. 29-31 cm. Small, vocal *Accipiter*, almost identical in adult plumage to sympatric *A. rhodogaster* and *A. nanus*; leaden grey upperparts and whitish underparts with vinous red wash on breast and upper abdomen. Present species differs in having three (sometimes only two) white spots on uppertail; also longer tarsi and shorter toes, a reflection of its main prey of lizards. Juvenile dimorphic, and quite different from those of *A. rhodogaster* and *A. nanus*; one morph has spotted upperparts; other has unspotted chestnut upperparts.

Habitat. Primary forest in lowlands and hills up to 1600 m; also mangroves and tall secondary forest, occurring from canopy right down to forest floor.

Food and Feeding. Mainly small lizards and snakes, but also frogs, snails, grasshoppers, and occasionally bats and small birds. Moves regularly from one inconspicuous perch within the forest to another; attacks on prey launched from perch.

Breeding. No information available.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Common, especially in N Sulawesi; occurrence in secondary forest suggests species may be able to tolerate limited human pressure on habitat.

Bibliography. Andrew (1992), van Bemmelen & Voous (1951), Bishop *et al.* (1994), Brown & Amadon (1968), van Marle & Voous (1946), Stresemann (1940a), Wattel (1973), White & Bruce (1986).

106. Variable Goshawk

Accipiter novaehollandiae

French: Autour blanc **German:** Grauhabicht **Spanish:** Azor Variable
Other common names: Varied/Grey/White/Vinous-chested/Rufous-breasted/Goshawk; Grey-throated Goshawk (*griseogularis*)

Taxonomy. *Falco novae Hollandiae* Gmelin, 1788, New South Wales. Island races sometimes regarded as a distinct species, *A. hiogaster*, separate from Australian *novaehollandiae*. Moluccan *griseogularis*, *obiensis* and *mortyi* sometimes treated as a separate species, *A. griseogularis*. Race *natalis* of *A. fasciatus* may belong to present species. Polytypic; Australian and New Guinea mainland populations also polymorphic. Twenty-three subspecies normally recognized.

Subspecies and Distribution.

- A. n. sylvestris* Wallace, 1864 - Lesser Sundaes.
- A. n. polionotus* (Salvadori, 1890) - Banda I (Moluccas), Tanjibar Is.
- A. n. albiventris* (Salvadori, 1875) - Tayandu I (Moluccas), Kai Is.
- A. n. obiensis* (Hartert, 1903) - Obi (C Moluccas).
- A. n. griseogularis* (G. R. Gray, 1860) - N Moluccas.
- A. n. mortyi* Hartert, 1925 - Morotai (N Moluccas).
- A. n. hiogaster* (S. Müller, 1841) - S Moluccas.
- A. n. pallidiceps* (Salvadori, 1879) - Buru (S Moluccas).
- A. n. leucosomus* (Sharpe, 1874) - New Guinea.
- A. n. pallidimus* Mayr, 1940 - D'Entrecasteaux Is (New Guinea).
- A. n. manusi* Mayr, 1945 - Admiralty Is.
- A. n. bougainvillei* (Rothschild & Hartert, 1905) - Bougainville (N Solomons).
- A. n. rufoschistaceus* (Rothschild & Hartert, 1902) - Choiseul, Santa Isabel, Florida Is (C Solomon Is).
- A. n. rubianae* (Rothschild & Hartert, 1905) - C Solomon Is.
- A. n. pulchellus* (Ramsay, 1881) - Guadalcanal (SW Solomon Is).
- A. n. malaitae* Mayr, 1931 - Malaita (SE Solomon Is).
- A. n. misulae* Mayr, 1940 - Louisiade Is (New Guinea).
- A. n. misoriensis* (Salvadori, 1875) - Biak I.
- A. n. dampieri* (Gurney, 1882) - New Britain.
- A. n. lavongai* Mayr, 1945 - New Hanover and New Ireland (Bismarck Archipelago).
- A. n. lihirensis* Stresemann, 1933 - Lihir and Tanga Is.
- A. n. matthiae* Mayr, 1945 - St Matthias I (Bismarck Archipelago).
- A. n. novaehollandiae* (Gmelin, 1788) - N & E Australia and Tasmania.

Descriptive notes. Nominate race: 38-55 cm; male 238-470 g, much larger female 515-1050 g; wingspan 71-110 cm. Tropical races smaller: 33-50 cm; male 175-258 g, female 439 g. Australian birds either grey and white, or entirely white. Juvenile grey morph has slight brown collar, and is more coarsely barred with chevrons on breast. Regional variation in size and colour: tropical races darker and more brightly coloured, with rufous underparts; *leucosomus* also has white and sooty morphs; juveniles often resemble juvenile *A. fasciatus*. **Habitat.** Rain forest, open forest, forest edge and adjacent open country; riparian gallery

forest that traverses dry woodland; sea-level to 1450 m. Nests in forest, often near edge, also in woodland; in Queensland (NE Australia), nests in denser habitat than sympatric *A. fasciatus*.

Food and Feeding. Mammals, birds, reptiles, amphibians, arthropods and, rarely, carrion; takes prey up to size of rabbit and heron in Australia, but smaller prey in tropics. Forages mainly by still-hunting from concealed perch in tree canopy; also low, fast flight, quartering and soaring. Seizes prey on ground or perch by dive, stealthy glide or direct flying attack which may become short chase. Drags possums (*Pseudocheirus*) from their dreys.

Breeding. Season Sept-Dec in S Australia, May-Nov in N Australia; season longer in New Guinea; downy young in May on Sumbawa (Lesser Sundas). Solitary breeder. Platform of sticks lined with green leaves, 50-60 cm wide, 35 cm deep; placed up to 15 m above ground in canopy of live tree, often on fork near end of major branch; nest may be reused after successful attempt. Usually 2-3 eggs (2-4); incubation 31-34 days; chicks have white down; fledging c. 30-42 days; post-fledging dependence 38-43 days. Longevity 12 years in captivity. Success: 9 young fledged from 14 eggs; 94% of attempts successful, with failure usually related to tropical thunderstorms in Queensland. **Movements.** Resident; established pairs sedentary, juveniles dispersive.

Status and Conservation. Not globally threatened. CITES II. Uncommon in S and NW Australia, but generally common in tropics. Formerly abundant in Tasmania, but has declined due to clearing of forests, and large numbers still shot; current estimate of 70-110 pairs. Subject to habitat loss in SE Australia. Human disturbance can lead to nest desertion, but species sometimes occurs in urban areas. Eggshell thickness not significantly reduced by DDT use in Australia.

Bibliography. Aumann (1990c), Baker-Gabb (1985c), Beehler *et al.* (1986), Bowler (1989), Burton (1991), Burton *et al.* (1994), Coates (1985), Cupper (1976), Cupper & Cupper (1981), Fleay (1950), Hadden (1981), Hollands (1984), Marchant & Higgins (1993), Mooney & Holdsworth (1988), Olsen & Marples (1993), Olsen & Olsen (1985), Olsen, Crome & Olsen (1993), Olsen, Debus *et al.* (1990), Schodde (1977), Schodde & Tidemann (1988), White & Bruce (1986), Wilson & Whelan (1993)

107. Australasian Goshawk

Accipiter fasciatus

French: Autour australien **German:** Bänderhähcht **Spanish:** Azor Australiano
Other common names: Brown/Australian Goshawk

Taxonomy. *Astur fasciatus* Vigors and Horsfield, 1827, New South Wales.

Birds of Buru (S Moluccas) have traditionally been awarded a separate race, *buruensis*, but identical to Australian birds of race *didimus*; status remains uncertain, as these birds could refer to migrants of *didimus*, or a resident form. Race *natalis* may belong to *A. novaehollandiae* complex, or might even be separate species. Eleven subspecies normally recognized.

Subspecies and Distribution.

- A. f. natalis* (Lister, 1889) - Christmas I (Indian Ocean).
- A. f. tjendunae* Stresemann, 1925 - Sumba (Lesser Sundas).
- A. f. wallacii* (Sharpe, 1874) - Lesser Sundas, from Lombok E to Babar.
- A. f. stresemanni* Rensch, 1931 - islets between Sulawesi and Lesser Sundas.
- A. f. hellmayri* Stresemann, 1922 - Timor, Alor, Roti (Lesser Sundas).
- A. f. sawu* Mayr, 1941 - Sawu (Lesser Sundas).
- A. f. polycryptus* Rothschild & Hartert, 1915 - E New Guinea.
- A. f. dogwa* Rand, 1941 - S New Guinea.
- A. f. didimus* (Mathews, 1912) - N Australia; Buru (S Moluccas).
- A. f. fasciatus* (Vigors & Horsfield, 1827) - Timor (Lesser Sundas); Australia and Tasmania; Rennell and Bellona Is (Solomons).
- A. f. vigilax* Wetmore, 1926 - New Caledonia, Loyalty Is, Vanuatu.

Descriptive notes. Nominate race: 40-55 cm; male 250-415 g, much larger female 440-740 g; wingspan 74-96 cm. Tropical races smaller: *didimus* 37-46 cm; male 200-268 g, female 310-405 g. Medium to large *Accipiter*. Distinguished in all plumages from *A. cirrocephalus* by heavier brow ridges, rounded tail and powerful legs and feet, with shorter middle toe. Tropical races generally distinguished from sympatric races of *A. novaehollandiae* by chestnut collar on hindneck. Juvenile mottled brown, with underparts streaked and barred. Regional variation in size and colour, with tendency in tropical birds for ventral bars

to merge into solid rufous breast-shield.

Habitat. Forest, woodland and scrub, farmland with many trees and urban areas; from sea-level up to 1500 m. Avoids dense rain forest and treeless areas. Nests in forest and woodland; in Queensland (NE Australia), nests in smaller trees and in more open habitat than sympatric *A. novaehollandiae*.

Food and Feeding. Mammals, birds, reptiles, amphibians and arthropods; occasionally carrion. Mostly birds and young rabbits in S, lizards in tropics. Vertebrate prey usually weighs under 500 g, but sometimes over 1000 g. Forages mostly by still-hunting from concealed perch in foliage; also by soaring or low, fast flight. Seizes prey, usually on ground or perch, by stealthy glide or direct flying attack that sometimes becomes a short chase. Also flushes prey from cover, and stalks insects on ground.

Breeding. Sept-Dec; nestlings in late Apr on Sumbawa (Lesser Sundas). Solitary. Platform of sticks 38-70 cm wide, 18-30 cm deep, lined with green leaves; placed 2-36 m above ground in forks of living trees. Usually 3 eggs (2-4); incubation 29-33 days; chicks have white down; fledging 28-37 days; post-fledging dependence over 2 weeks. Sexual maturity at 1 year, though seldom breeds in

juvenile plumage. Mean annual survival 65-79%; oldest ringed bird 11 years. Success 1-6-175 young per attempt, 2-1-2-75 young per successful nest in SE Australia; 62% of attempts successful in Queensland, with failures mainly due to tropical thunderstorms.

Movements. Nominate race partly migratory over most of range; juveniles and some adults (particularly females) from high latitudes and altitudes winter in coastal, lowland and N parts of Australia, exceptionally reaching islands to N. Some adults defend regular winter territories separate from breeding territories. Tropical races largely sedentary, but some *didimus* from inland N Australia winter on N coast and occasionally reach islands to N, e.g. (possibly) Buru, in S Moluccas, whence few records could refer to this race.

Status and Conservation. Not globally threatened. CITES II. Common and widespread; local declines in S Australia where habitat clearance extensive, but species has benefited from introduction of rabbit; preys on introduced birds. Effects of DDT local and insignificant; often illegally shot (mainly juveniles) but effect also insignificant. Isolated Christmas I race vulnerable, owing to very small range, small population size of c. 50-150 pairs, and past habitat clearance and persecution, which has now largely ceased; its biology little known.

Bibliography. Aumann (1988a, 1988b, 1988c, 1988d, 1989a, 1989b, 1990b, 1990c, 1993), Baker-Gabb (1984a, 1984b), Beehler *et al.* (1986), Bregulla (1992), Burton (1991, 1993), Burton *et al.* (1994), Coates (1985), Cupper & Cupper (1981), Currie *et al.* (1993), Czechura *et al.* (1987), Garnett (1992), Hollands (1984), King (1978/79), Marchant & Higgins (1993), Morris (1976a), Newgrain *et al.* (1993a, 1993b), Olsen & Marples (1992, 1993), Olsen & Olsen (1981, 1985, 1987b), Olsen, Crome & Olsen (1993), Olsen, Debus *et al.* (1990), Olsen, Olsen & Mooney (1982), Schodde & Tidemann (1988), Stokes (1988), Thiollay (1993a), White & Bruce (1986).

108. Black-mantled Goshawk

Accipiter melanochlamys

French: Autour à manteau noir **German:** Schwarzmantelhähcht **Spanish:** Gavilán Rufinegro
Other common names: Black-mantled Sparrowhawk

Taxonomy. *Urospizias melanochlamys* Salvadori, 1875, Arfak Mountains, New Guinea.

Forms superspecies with *A. albogularis*, *A. haplochrous* and *A. rufitorques*. Two poorly defined races, doubtfully valid and not recognized by some authorities: eastern birds paler dorsally; differences possibly confounded by sexual characters or plumage wear of specimens. Two subspecies normally recognized.

Subspecies and Distribution.

- A. m. melanochlamys* (Salvadori, 1875) - Vogelkop (W New Guinea).
- A. m. schistacinus* (Rothschild & Hartert, 1903) - montane C & E New Guinea.

Descriptive notes. 30-43 cm; male 172-256 g, larger female 294 g. Medium-sized *Accipiter*. Adult unmistakable, with striking black and chestnut plumage, including broad chestnut collar. Juvenile mottled brown, similar to juveniles of some sympatric *Accipiter* species but head and underparts paler, less densely marked.

Habitat. Montane rain forest, forest edge, regrowth and adjacent native gardens, from 1200 m to 3000 m.

Food and Feeding. Mostly birds, including Papuan Mountain-pigeon (*Gymnophaps albertisii*); also small mammals, frogs and insects.

Flies through forest to seize pigeons among branches; also pursues flying flocks at forest edge and in the air. Has been seen hawking stealthily through gardens and secondary forest, and attacking small birds caught in mist-nets.

Breeding. Nests (presumably typical of genus) built in tall trees, including *Pandanus*, within forest; a male was in breeding condition in Oct. No further information available.

Movements. Unknown; no records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Widespread in all montane areas of mainland New Guinea but lives in remote, rugged and densely forested areas and is seldom encountered by ornithologists. Biology unknown; species possibly affected locally by deforestation.

Bibliography. Andrew (1992), Beehler (1978), Beehler *et al.* (1986), Coates (1985), Diamond (1972), Majnep & Bulmer (1977), Peckover & Filewood (1976), Rand & Gilliard (1967), Ripley (1964), Wattel (1973).

109. Pied Goshawk

Accipiter albogularis

French: Autour pie **German:** Elsterhähcht **Spanish:** Gavilán Pío
Other common names: Pied Sparrowhawk

Taxonomy. *Accipiter albogularis* G. R. Gray, 1870, San Cristobal, Solomon Is.

Forms superspecies with *A. melanochlamys*, *A. haplochrous* and *A. rufitorques*. Five subspecies recognized.

Subspecies and Distribution.

- A. a. eichhorni* Hartert, 1926 - Feni Is (Bismarcks).
- A. a. woodfordi* (Sharpe, 1888) - N, E & S Solomons.
- A. a. albogularis* (G. R. Gray, 1870) - San Cristobal, Santa Ana (Solomons).
- A. a. gilvus* Mayr, 1945 - C Solomons.
- A. a. sharpei* (Oustalet, 1875) - Santa Cruz Is.

Descriptive notes. 33-39 cm; male 170-250 g, larger female 365-440 g. Medium-sized *Accipiter*. Pied adults of most races (except nominate) have a variable rufous collar around hindneck, which distinguishes them from the larger *A. meyerianus* in pied plumage and the smaller *A. imitator*. Some adults melanistic, with plumage entirely slaty black. Juveniles mottled brown, with variable silver underparts; some birds are dark chestnut.

Habitat. Tropical rain forest, forest edge, secondary growth, clearings, native gardens and edge of towns; from sea-level to at least 1800 m. More confined to forest than *A. novaehollandiae*, except on those islands where latter species absent.

Food and Feeding. Poorly known: small birds (including starlings *Aplonis*) and nestlings, rarely up to size of domestic chicken; lizards and insects including phasmatids. Has been seen to flush a flock of Sharp-tailed Sandpipers (*Calidris acuminata*) from ground. Skulks on concealed perches in trees on edge of clearings or gardens; also perches on stumps and other low, exposed perches.

Breeding. Specimens in breeding condition in Sept and Dec; no further information available.

Movements. No information available, but species presumably sedentary as inferred from racial variation between island populations; no records outside normal range.

Status and Conservation. Not globally threatened, CITES II. Appears to be common, at any rate in parts of range, but biology and population trends virtually unknown. Habitat subject to deforestation in lowlands; species may also suffer reproductive failure through eggshell thinning in areas of heavy DDT use, but data lacking. Possibly being replaced by *A. novaeollandiae* in disturbed areas.

Bibliography. Brown & Amadon (1968), Coates (1985), Diamond (1975), Hadden (1981), Mayr (1945a, 1957), Schodde (1977), Watte! (1973), Webb (1992).

cm 20

110. New Caledonia Sparrowhawk

Accipiter haplochrous

French: Autour à ventre blanc

German: Weißbauchhähne

Spanish: Gavilán de Nueva Caledonia

Other common names: White-breasted Sparrowhawk, White-bellied/New Caledonia Goshawk

Taxonomy. *Accipiter haplochrous* P. L. Slater, 1859. Nu Island, off New Caledonia. Forms superspecies with *A. rufitorques*, *A. albugularis* and *A. melanochlamys*. Monotypic.
Distribution. New Caledonia.

Descriptive notes. 32–36 cm; male 152–218 g, larger female 227–281 g. Medium-sized *Accipiter*. Boldly pied adult unmistakable within range; dark cere separates from similar congeners. Juvenile mottled brown and cream, similar to juvenile of larger *A. fasciatus*.

Habitat. Tropical rain forest and forest edge, from sea-level up to 1300 m.

Food and Feeding. Poorly known. Mostly lizards, geckos, insects (grasshoppers, beetles) and small mammals (e.g. *Rattus exulans*). Said to take birds up to size of parrot, pigeon and domestic chicken, but avian prey apparently less important than traditionally held. Perch-

hunter (sit-and-wait method), normally taking prey on ground, but sometimes in trees; regularly hunts from lower perches than *A. fasciatus*, and apparently takes wider range of prey. A fierce predator of birds, sometimes pursuing them into buildings.

Breeding. Birds seen displaying in Sept; nest building and incubation at 2 sites in Oct; 3 eggs collected in Oct, but uncertain whether they were a single clutch of three. No further information.

Movements. Unknown; no records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Restricted distribution, but widespread throughout main island. Occurs at very high densities, with mean of 5.69 birds/km² in optimal habitat; in 1987 total population size estimated to be at least 2500 pairs, and likely to be over 5000 pairs; no evidence of decline. Possibly affected by deforestation, as dependent on forest, and larger congener (*A. fasciatus*) more adapted to open habitats. Likely to be affected by DDT where used, but data lacking.

Bibliography. Brown & Amadon (1968), Hannecart & Letocart (1980), Stokes (1980), Thiollay (1993a), Vuilleumier & Gochfeld (1976), Warner (1947), Wattel (1973).

111. Fiji Goshawk

Accipiter rufitorques

French: Autour des Fidji

German: Fidschihähne

Spanish: Gavilán de las Fiji

Other common names: Grey Goshawk(!)

Taxonomy. *Accipiter rufitorques* Peale, 1848, Fiji.

Forms superspecies with *A. haplochrous*, *A. albugularis* and *A. melanochlamys*. Formerly considered race of *A. fasciatus*; separated by plumage. Monotypic.

Distribution. Fiji Is.

Descriptive notes. 30–40 cm, female larger; male 209 g. Medium-sized *Accipiter*. Adult unmistakable within distribution, where is the only *Accipiter*; smaller and more brightly coloured than *A. fasciatus*, and lacks barring. Juvenile mottled brown; underparts streaked and barred.

Habitat. All wooded habitats, from forest to urban parks; sea-level to 900 m. Nests in forest, forest edge, coconut plantations, and trees in clearings.

Food and Feeding. Small birds up to size of pigeon, occasionally chickens. Also rodents, lizards, crustaceans and large insects; rarely takes small fish and prawns from shallow water. Juveniles occasionally eat carrion. Forages by still-hunting on concealed or un concealed perch in tree, or by low fast flight. Also flies slowly, inspecting tree crowns. Seizes prey by stealthy glide or direct flying attack, which may become short chase. Pursues prey into cover; harries and flushes sheltering prey.

Breeding. Season Jul/Aug–Nov/Dec, with most laying in Sept/Oct; exceptional records in Feb–May may represent late re-nesting, after cyclones disrupt normal season. Solitary. Nest is platform of sticks lined with leaves, commonly 6–16 m (up to 24 m) up in lightly foliated tree, e.g. *Samanea*. Usually 2–3 eggs (2–4); broods of 2 fledglings common.

Movements. Breeding adults presumably sedentary. Juveniles disperse to urban non-breeding territories in Feb; leave in Aug at start of next breeding season.

Status and Conservation. Not globally threatened. CITES II. Small range and total population, but density high, with neighbouring active nests as little as 400 m apart; species common but little studied. Often shot; presumably susceptible to DDT-induced eggshell thinning and consequent breeding depression.

Bibliography. Belcher & Sibson (1972), Blackburn (1971), Clunie (1972a, 1972b, 1981), Clunie & Morse (1984), DuPont (1976), Holyoak (1979), Pratt *et al.* (1987), Watling (1982), Wattel (1973).

112. Moluccan Goshawk

Accipiter henicogrammus

French: Autour des Moluques

German: Halmaherahähne

Spanish: Ázor Moluqueo

Other common names: Gray's Goshawk

Taxonomy. *Accipiter henicogrammus* G. R. Gray, 1860. Halmahera.

Thought by some to be race of *A. fasciatus* or *A. novaehollandiae*, but best retained as full species due to differences in plumage and structure. May represent old endemic element of Moluccas. Monotypic.

Distribution. N Moluccas, on Morotai, Halmahera, Bacan and perhaps Ternate.

Descriptive notes. 38–48 cm. Medium-sized *Accipiter*. Similar in plumage to some forms of *A. novaehollandiae*, but different structure, with particularly rounded wings and longtail, and rather weak feet. Juvenile barred above and below, unusual in *Accipiter*.

Habitat. Forest interior, occasionally forest edge, from sea-level up to 1300 m.

Food and Feeding. Preys on reptiles, small birds, small mammals and insects. Hunting method involves sitting on inconspicuous perch and surprising prey with a quick dash.

Breeding. No information available. May not use display flight; has not been reported to soar.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Apparently uncommon, but unobtrusive; possibly commoner than thought.

Bibliography. Andrew (1992), Bishop *et al.* (1994), Brown & Amadon (1968), Wattel (1973), White & Bruce (1986)

113. Slaty-backed Goshawk

Accipiter luteoschistaceus

French: Autour bleu et gris

German: Rabauhähne

Spanish: Gavilán de Nueva Bretaña

Other common names: Slaty-mantled/Blue and Grey Sparrowhawk

Taxonomy. *Accipiter luteoschistaceus* Rothschild and Hartert, 1926. Talasea, New Britain. Monotypic.

Distribution. New Britain.

Descriptive notes. 30–38 cm, female larger; male 205–222 g. Medium-sized *Accipiter*, coloration of underparts ranges from whitish to pale cinnamon. Distinguished from sympatric *A. brachyurus* by orange-red, rather than yellow, facial skin and legs; also by shorter middle toe, and lack of rufous collar. Juvenile has strongly barred rufous upperparts, coarsely barred pale underparts, recalling juvenile of larger *A. henicogrammus*.

Habitat. Forest, forest edge and partly cleared areas of lowlands and hills; from sea-level to at least 700 m.

Food and Feeding. Lizard in stomach of specimen; one bird seen on ground. Morphology suggests that it preys on reptiles and insects. No further information.

Breeding. No information available.

Movements. Unknown; no records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Restricted distribution and presumably low total population size. Apparently scarce, and seldom seen by ornithologists; biology unknown. Habitat subject to deforestation in lowlands.

Bibliography. Brown & Amadon (1968), Coates (1985), Finch & McKean (1987), Gilliard & LeCroy (1967b), Wattel (1973).

114. Imitator Sparrowhawk

Accipiter imitator

French: Autour imitateur

German: Trughähne

Spanish: Gavilán Imitador

Other common names: Little Pied Goshawk/Sparrowhawk, Imitator Goshawk

Taxonomy. *Accipiter eichhornii imitator* Hartert, 1926. Choiseul, Solomon Islands. Monotypic.

Distribution. Bougainville, Choiseul and Santa Isabel, in N & C Solomon Is.

Descriptive notes. 28–33 cm, female larger; female 200–250 g. Medium-sized *Accipiter*. Pied adults in black-breasted plumage readily distinguished from *A. albugularis*; white-breasted adults distinguished by jet black rather than slaty upperparts, and slate black rather than grey underwings. A melanistic (all black) morph may exist; calls said to differ from those of *A. albugularis*, but confirmation of voice and plumages required. Juvenile has brown upperparts with pale mottling on crown, and underparts finely barred rufous.

Habitat. Tropical rain forest and tall secondary forest, from lowlands to 1000 m.

Food and Feeding. Unknown; one bird perched in understorey of forest. Morphology suggests that it lives within dense forest, and may prey on reptiles and insects.

Breeding. No information available.

Movements. Unknown; no records outside normal range.

Status and Conservation. RARE. CITES II. Restricted distribution, and presumably low total population size; habitat subject to deforestation in lowlands. Seldom encountered by ornithologists, and biology unknown.

Bibliography. Brown & Amadon (1968), Coates (1985), Collar & Andrew (1988), Hadden (1981), Mayr (1957), Schodde (1977), Wattel (1973), Webb (1992)

On following pages: 115. Grey-headed Goshawk (*Accipiter poliocephalus*); 116. New Britain Goshawk (*Accipiter princeps*); 117. Tiny Hawk (*Accipiter superciliosus*); 118. 115. Grey-headed Goshawk

Accipiter poliocephalus

French: Autour à tête grise

German: Aschkopfhäbicht

Spanish: Gavilán Cabecigrís

Other common names: New Guinea (Grey-headed) Goshawk

Taxonomy. *Accipiter poliocephalus* G. R. Gray, 1858, Aru Islands.Forms superspecies with *A. princeps*, with which has been considered conspecific. Monotypic.**Distribution.** W Papuan Is and Aru Is through New Guinea to Fergusson I (D'Entrecasteaux Is) and Misima I and Tagula I (Louisiade Archipelago).**Descriptive notes.** 30-38 cm; male 180-283 g, larger female 225-380 g. Medium-sized *Accipiter*. Adult unmistakable within range; head and nape noticeably paler than rest of upperparts. Juvenile also distinctive, with coarse breast streaking on otherwise white underparts. A possible dark morph has been claimed, but details lacking.**Habitat.** Tropical rain forest, gallery forest, secondary growth and forest edge; from sea-level to 1500 m. Nests in forest and in tall residual trees among regrowth near native gardens.**Food and Feeding.** Poorly known. Mostly lizards; also snakes and insects. Attacks small birds caught in mist-nets. Forages by still-hunting; attacks prey from perch.**Breeding.** Incubation observed at one nest late Aug/early Sept; egg near hatching collected from another nest in Dec. Solitary. Nest is platform of sticks lined with leaves, placed high in tree (one 27 m above ground). One nest in active colony of Metallic Starlings (*Aplonis metallica*). One apparently complete clutch of 1 egg with developing chick inside. No further information.**Movements.** Unknown; no records outside normal range.**Status and Conservation.** Not globally threatened. CITES II. Fairly common and widespread throughout lowlands and hills of mainland New Guinea, including vicinity of native cultivation, but biology poorly known.**Bibliography.** Andrew (1992), Beehler *et al.* (1986), Bell (1984), Coates (1985), Diamond (1972), Harrison & Frith (1970), Mayr & Rand (1937), Peckover & Filewood (1976), Rand & Gilliard (1967), Wattel (1973).

116. New Britain Goshawk

Accipiter princeps

French: Autour de Mayr

German: Prinzenhäbicht

Spanish: Azor de Nueva Bretaña

Taxonomy. *Accipiter princeps* Mayr, 1934, Balayang, Baining Mountains, New Britain.Forms superspecies with *A. poliocephalus*, of which formerly considered a race, but larger and more robust with some differences in adult plumage. Monotypic.**Distribution.** New Britain.**Descriptive notes.** 38-43 cm, female larger. Medium-large *Accipiter*. Adult unmistakable within distribution; darker on head than *A. poliocephalus*, with underwing unbarred. Juvenile not satisfactorily described; possibly similar to juvenile of sympatric *A. meyerianus*. **Habitat.** Hill and montane primary rain forest, 760-1430 m.**Food and Feeding.** Stomach of one specimen contained insects; another killed and ate a Melanesian Ground-thrush (*Zoothera talasea*) caught in a mist-net. No further information.**Breeding.** No information available.**Movements.** Unknown; no records outside

normal range.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Scarce, and seldom encountered by ornithologists; biology unknown.**Bibliography.** Bishop (1983), Brown & Amadon (1968), Coates (1985), Diamond (1971), Mayr (1934), Wattel (1973).

117. Tiny Hawk

Accipiter superciliosus

French: Épervier nain

German: Däumlingsperber

Spanish: Gavilancito Americano

Other common names: Tiny Sparrowhawk

Taxonomy. *Falco superciliosus* Linnaeus, 1766, Surinam.Forms superspecies with *A. collaris*. Two subspecies recognized.**Subspecies and Distribution.***A. s. fontanieri* Bonaparte, 1853 - Nicaragua S to W Colombia and W Ecuador.*A. s. superciliosus* (Linnaeus, 1766) - E of Andes, from Colombia E through Venezuela (except NW) to the Guianas, and S through Ecuador, E Peru, Bolivia (Beni, Santa Cruz) and Brazil to Paraguay and N Argentina (Misiones).**Descriptive notes.** 24-27.5 cm; male 75 g, female 115-134 g. Tiny *Accipiter*; differs from closely related *A. collaris* by thinner barring on underparts and lack of pale nuchal collar. Crown darker than bluish slate back; tail dark, with three grey bands and narrow white tip which quickly wears off; throat white; underparts, including wing linings, white finely barred with dark greyish brown. Yellow cere and legs, bright red iris. Female browner above; below buff barred with brownish grey; significantly larger than male. Immature has two morphs: greyish brown above with paler feather edgings and dark crown, buff below

with fine cinnamon-rufous barring; or bright rufous above, with dusky barring on back and wings,

reddish buff below barred with reddish brown (adult too said to have rufous morph). Race *fontanieri* has broader, blacker, more distinct barring on underparts.**Habitat.** Lowland rain forest up to 1500 m; perhaps not normally in primary forest, preferring edges of large clearings with isolated forest fragments and patches of secondary forest. Soars over the forest.**Food and Feeding.** Very few data available; these, together with very long toes, suggest a highly specialized predator of birds; one stomach contained rodents. Feeds heavily on hummingbirds, using apparently specialized behaviour: either by still-hunting, or by actively checking perches used for territorial display by the hummingbirds.**Breeding.** Very incompletely known. In Colombia seen carrying sticks in Apr, specimens in breeding condition in Oct and Feb; nest in Feb in Panama; well grown chicks in Aug (mid-dry season), in Manaus, NC Brazil. Stick nest in tall tree; 1 pair usurped abandoned nest of *Busarellus nigricollis*. Clutch size: 1 egg in Panama; 3 in SW Brazil.**Movements.** No evidence of movements.**Status and Conservation.** Not globally threatened. CITES II. Status very poorly known, but large range and tendency to use second growth forest suggest species in no immediate danger.**Bibliography.** Blake (1977), Haverschmidt (1968), Hilty & Brown (1986), Marín *et al.* (1992), Meyer de Schauensee & Phelps (1978), Oniki & Willis (1982), de la Peña (1992), Pinto (1964), Rensen & Ridgely (1980), Rensen & Taylor (1983), Ridgely & Gwynne (1989), Sick (1985a, 1993), Slud (1964), Siles (1978), Thiollay (1985b, 1989a, 1989b, 1991a), Tostain *et al.* (1992), Wetmore (1965).

118. Semi-collared Hawk

Accipiter collaris

French: Épervier à collier interrompu

German: Halsbandsperber

Spanish: Gavilancito Torcaz

Other common names: Collared Sparrowhawk

Taxonomy. *Accipiter collaris* P. L. Sclater, 1860, New Granada = Bogotá, Colombia.Subtropical counterpart of *A. superciliosus*, with which forms superspecies. Monotypic.**Distribution.** SW Venezuela (Mérida, Táchira) S, on W & E slopes of Andes, through Colombia to Ecuador; recent range extension of 1500 km to S Peru.**Descriptive notes.** 25-29 cm. Blackish crown and nape, with broken white nuchal collar, separating from *A. superciliosus*; rest of back blackish brown; throat white, rest of underparts white barred with brownish black; tail grey with five black bands. Iris orange-yellow, cere and legs yellow. Female similar, but larger. Immature has brownish and rufous morphs as in *A. superciliosus*, but brownish morph has incomplete rufous nuchal collar, while rufous morph has conspicuous chestnut collar.**Habitat.** Forest and forest edge, mostly sub-tropical and moist or wet, at 1700 m in Peru, at 600-1800 m in Colombia; occurs at higheraltitude than *A. superciliosus*, but lower than *A. ventralis*.**Food and Feeding.** No information available; presumably takes mostly birds, although heavier feet suggest it may have broader diet than *A. superciliosus*.**Breeding.** No information available.**Movements.** No information available.**Status and Conservation.** Not globally threatened. CITES II. Currently considered near-threatened.

Very little known; thorough surveys needed. Can be relatively abundant within its altitudinal range.

Bibliography. Amadon (1964), Blake (1977), Brown & Amadon (1968), Collar (1986a), Collar & Andrew (1988), Hilty & Brown (1986), Meyburg (1986), Meyer de Schauensee & Phelps (1978), Parker & O'Neill (1980), Thiollay (1991a).

119. Red-thighed Sparrowhawk

Accipiter erythropus

French: Épervier de Hartlaub

German: Waldsperber

Spanish: Gavilancito Muslirrojo

Other common names: Red-thighed/Western Little Sparrowhawk

Taxonomy. *Nisus erythropus* Hartlaub, 1855, Rio Bontry, Ghana.Forms superspecies with *A. minullus*, and sometimes considered conspecific. Two subspecies recognized.**Subspecies and Distribution.***A. e. erythropus* (Hartlaub, 1855) - Senegambia to Nigeria.*A. e. zenkeri* Reichenow, 1894 - Cameroon E to W Uganda and S to N Angola and C Zaire.**Descriptive notes.** 25 cm; male 78-94 g, female 132-170 g. Very small size. Dark upperparts grey, underparts with variable rufous wash or barring, and broken white bars across spread tail distinctive, separating from *A. minullus* of drier forests. Female much larger than male. Juvenile only lightly spotted below with some barring on flanks. Race *zenkeri* very similar, but larger, darker above and sometimes more clearly barred below.**Habitat.** Lowland tropical evergreen rain forest and adjacent secondary forest. In Sierra Leone also occurs in savanna, in areas with thick clumps of trees.**Food and Feeding.** Small birds, such as waxbills or weavers, and large insects, such as caterpillars, butterflies and dragonflies; captives trained for falconry take birds and mice of 8-40 g. Unobtrusive, remaining well below canopy in primary forest, but often hunting along forest border and adjacent secondary growth. Most active at dawn and dusk.**Breeding.** Laying Dec-Mar in Gabon; Mar-May in Sierra Leone; Jul in Zaire. Small stick nest built in tall forest tree, usually in rather open situations, e.g. by edge of swamp or grassland. 2 eggs, further details unrecorded.**Movements.** None recorded. Apparently sedentary.**Status and Conservation.** Not globally threatened. CITES II. Small size suggests may occur at high density in primary forest, large areas of which remain in C Africa. Vulnerable to deforestation, but extends along gallery forest into savanna and will use adjacent dense secondary habitats, so range probably not much reduced in W Africa; widespread but uncommon in Sierra Leone; rare in Gambia. Not known to be affected by pesticides.

Bibliography. Brosset (1973), Brosset & Erard (1986), Brown *et al.* (1982), Chapin (1932), Gatter (1988), Gore (1990), Grimes (1987), Jensen & Kirkeby (1980), Lippens & Wille (1976), Mackworth-Praed & Grant (1957-1973), Morel & Morel (1990), Pinto (1983), Sargeant (1993), Serle *et al.* (1977), Snow (1978), Thiollay (1985d), Wattel (1973).

120. African Little Sparrowhawk

Accipiter minullus

French: Épervier minule **German:** Zwergsperber **Spanish:** Gavilancito Chico
Other common names: Little Sparrowhawk

Taxonomy. *Falco minullus* Daudin, 1800, Gamtoos River, South Africa.
Forms superspecies with *A. erythropus*, and sometimes considered conspecific. Monotypic.
Distribution. S Sudan and Ethiopia S to South Africa and W to Angola and Namibia.

Descriptive notes. 23-27 cm; male 74-85 g, female 68-105 g; wingspan 39 cm. A tiny woodland hawk. Less rufous than *A. erythropus*, but notable for two pale spots on central tail feathers, like much larger male *A. tachiro*. Female larger and browner than male. Juvenile brown with large spots on white underparts.

Habitat. Patches of woodland and forest, typically along rivers or in valleys; also small plantations of exotic trees in drier savanna.

Food and Feeding. Mainly small birds of 10-40 g, together with some bats, lizards and insects. Hunts from a perch, passing with speed and agility through foliage and taking most

prey on the wing. Pursues some prey to the ground; a bold predator despite its diminutive size.
Breeding. Laying Mar-Apr in NE Africa; Oct-Nov in W Kenya; Aug-Dec in S Africa (peak Oct). Builds a small platform of sticks lined with fine twigs and green leaves, in a high fork of a tree. Usually 2 white eggs (1-3); incubation 31-32 days; chicks have first down white, second down pale brown; fledging 25-27 days.

Movements. Resident where studied but easily overlooked, except for frequent mimicry of calls by local drongos (*Dicrurus*). Some wandering into drier areas in Kenya.

Status and Conservation. Not globally threatened. CITES II. Widespread and common even in small patches of habitat, quickly colonizing new exotic habitats and small plantations. Approximate density of 1 pair/58-88 km² in Transvaal savanna, where estimated 1000 pairs. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Black & Ross (1970), Brown *et al.* (1982), Colebrook-Robjent & Steyn (1975), Craib (1983), Ginn *et al.* (1989), Lewis & Pomeroy (1989), Liversidge (1962), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Simmons (1986a), Snow (1978), Steyn (1972c, 1982), Tarboton & Allan (1984), Thiollay (1978c), Wattel (1973).

121. Japanese Sparrowhawk

Accipiter gularis

French: Épervier du Japon **German:** Trillersperber **Spanish:** Gavilancito Japonés
Other common names: Japanese Lesser/Asiatic Sparrowhawk

Taxonomy. *Astur (Nisus) gularis* Temminck and Schlegel, 1844, Japan.
Sometimes included in *A. virgatus*, but full species status now generally agreed upon; these two probably form superspecies, possibly along with *A. nanus*. Races sometimes rejected, and species considered monotypic. Three subspecies normally accepted.

Subspecies and Distribution.

A. g. sibiricus Stepanian, 1959 - upper R. Ob and Mongolia E to middle R. Lena, E China and Taiwan; presumably winters from Andaman and Nicobar Is E to S China and Greater Sundas.

A. g. gularis (Temminck & Schlegel, 1844) - Sakhalin, S Kuril Is and Japan; winters S to Philippines, Greater Sundas, N Sulawesi and Timor.

A. g. iwasakii Mishima, 1962 - S Ryukyu Is (Iriomote, Ishigaki).

Descriptive notes. 29-34 cm. Throat with mesial streak narrower than in *A. virgatus* or indistinct; underparts lightly barred. Female slightly larger; dark or greyish brown above, rather than slate grey; more heavily barred on underbody and underwing; iris yellow (red in male). Juvenile dark brown above, with rufous edged feathers; breast streaked brown; belly barred; black mesial streak on throat more marked.

Habitat. Different types of forest, including coniferous (e.g. of firs and spruces in S taiga), deciduous and mixed; also riparian woodland; race *iwasakii* inhabits evergreen subtropical

forest. Normally at low altitudes, although also in hills and mountains; in summer rises to mixed subalpine forests in Japan, and has been reported at 1800 m in Siberia. In Japan has colonized residential areas, even in parts of Tokyo. Hunts in clearings; less restricted to forests in winter.

Food and Feeding. Mostly small forest passerines and occasionally medium-sized birds, e.g. Azure-winged Magpie (*Cyanopica cyanea*) and feral pigeons. In suburban areas of Japan, main prey is Tree Sparrow (*Passer montanus*); fledgling Great Tits (*Parus major*) briefly predominate, when available in mid-May. Occasionally takes small mammals, e.g. rodents, shrews and bats; also some reptiles and insects. Apparently hunts in style similar to that of *A. virgatus* and *A. nisus*.

Breeding. Laying fairly late; mainly Jun in S Siberia, though somewhat earlier in China and Japan. Nests in tree, normally neat trunk, small nest built from twigs and foliage. Normally 2-5 eggs; incubation 25-28 days; chicks fledge in Jun in Japan, in Aug in S Siberia. Nest is defended vigorously against intruders.

Movements. Mainly migratory, although sedentary in Taiwan and S Ryukyu Is; small numbers winter in breeding range, in C & S Japan and S China. Winter visitor from S China to Indochina, Malay Peninsula, Philippines, Greater and Lesser Sundas and N Sulawesi; limited numbers in Burma, considerable movement recorded over Bali, where 78-85 birds seen from early Oct to early Nov. 1989. In Japan birds mostly present from Apr to Sept, in S Siberia possibly from May to Sept or early Oct.

Status and Conservation. Not globally threatened. CITES II. Status and trends of populations very poorly known, with virtually no figures available. Very shy species which seems to be uncommon both in S Siberia and Japan; in Japan, however, has bred in suburban areas since 1981, and currently on increase in such areas. Status uncertain in Andaman and Nicobar Is; said to breed.

Bibliography. Ash (1993), Austin & Kurud (1953), Brazil (1991), Brazil & Hanawa (1991), Bucknill & Chasen (1990), Deignan (1945), Dementiev & Gladkov (1951), Dickinson *et al.* (1991), Endo *et al.* (1991), Etchécopar & Hue (1978), Hirano *et al.* (1988), King *et al.* (1975), Knyshaus (1993), Lekagul & Round (1991), Madoc (1976), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Pratt *et al.* (1987), Rogacheva (1992), Smythies (1981, 1986), Takada (1956), Ueta (1992a, 1992b, 1993, 1994).

122. Besra

Accipiter virgatus

French: Épervier besra **German:** Besrasperber **Spanish:** Gavilán Besra
Other common names: Besra Sparrowhawk

Taxonomy. *Falco virgatus* Temminck, 1822, Java.

Has been considered to include *A. gularis*, with which probably forms superspecies, perhaps also including *A. nanus*. Eleven subspecies recognized.

Subspecies and Distribution.

A. v. affinis (Hodgson, 1836) - N India and Nepal E to C & S China, and Indochina.

A. v. fuscipectus Mees, 1970 - mountains of Taiwan

A. v. hesra Jerdon, 1839 - SW India and Sri Lanka; probably also SE India.

A. v. abdulali Mees, 1980 - Andaman Is. and possibly Nicobar Is.

A. v. nisoides Blyth, 1847 - Burma and Thailand; possibly also Malay Peninsula.

A. v. confusus Hartert, 1910 - Luzon, Mindoro, Negros and Catanduanes (N & E Philippines).

A. v. quagga Parkes, 1973 - Cebu, Bohol, Leyte, Samar, Siquijor and Mindanao (SE Philippines).

A. v. rufotibialis Sharpe, 1887 - N Borneo.

A. v. vanbemmeli Voous, 1950 - Sumatra.

A. v. virgatus Temminck, 1822 - Java and Bali.

A. v. quinquefasciatus Mees, 1984 - Flores (Lesser Sundas).

Descriptive notes. 23-36 cm; 83-140 g; wingspan 50-65 cm. Small sparrowhawk with rounded wings; broad dark mesial throat stripe; dark and light tail bands of equal width. Female larger than male and generally browner. Juvenile brown above, pale below with streaked breast and barred flanks and belly. Races differ primarily in size and colour intensity; *affinis* largest and relatively longest-winged; *rufotibialis* and especially *vanbemmeli* much redder on underparts.

Habitat. Wide variety of forests, including moist deciduous and evergreen; secondary forest, mangroves and pine forest, from sea-

level up to 2400 m. Does not occur in lowlands in some regions (e.g. plains of India and lowland Java) most likely because of removal of forests.

Food and Feeding. Mostly birds, but also insects and lizards. Feeds like typical sparrowhawk, with quick agile chase of birds launched from inconspicuous perch. Prey taken either in air (birds) or, to lesser extent, on ground and trees (lizards, small mammals, insects). Often seen perched on tall dead tree in forest. Regularly soars.

Breeding. Season varies extensively with wide range: Jan-Apr in S India; Mar-Jun in N India; May-Sept in Borneo; Apr, Jul in Philippines; Apr in Sumatra. Small nest built by pair 15-25 m up large tree in forest; lined with green leaves; nest tree often situated on precipice overlooking ravine. Usually 2-4 eggs (up to 5). No further information available.

Movements. Mainly sedentary, but some birds from N India and Nepal may move down onto plains in winter.

Status and Conservation. Not globally threatened. CITES II. Uncommon to common throughout extensive range. May be even commoner, as unobtrusive when not soaring or perched on high snag. Main threat is deforestation, e.g. in much of lowland India, Philippines and Java.

Bibliography. Ali & Ripley (1978), Andrew (1985), Betts (1953), Bishop *et al.* (1994), Cheng Tso-hin (1987), Deignan (1945, 1963), Dickinson *et al.* (1991), Etchécopar & Hue (1978), Henry (1971), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Phillips (1993), van Marle & Voous (1988), Mees (1980, 1984), Meyer de Schauensee (1984), Parkes (1973), Riley (1938), Roberts (1991), Smythies (1981, 1986), Thiollay & Meyburg (1988), Tikader (1988), Wattel (1973).

123. Sulawesi Dwarf Sparrowhawk

Accipiter nanus

French: Épervier des Célèbes **German:** Archboldsperber **Spanish:** Gavilancito de Célebes
Other common names: Small/Celebes Sparrowhawk, Celebes Little Sparrowhawk

Taxonomy. *Erythrospizias trinitatus nanus* W. Blasius, 1897, Rurukan, Sulawesi.
May belong in *A. virgatus* superspecies. Monotypic.

Distribution. Mountains of Sulawesi, except SW.

Descriptive notes. 23-28 cm. Small, vocal *Accipiter*, almost identical in adult plumage to sympatric *A. rhodogaster* and *A. trinitatus*, and long confused with former: leaden grey upperparts and vinous red underparts. Present species differs in having white thighs, long toes and little size dimorphism between sexes; lacks white spots on upperpart. Juvenile rufous chestnut above, whitish below with scattered dark streaks.

Habitat. Mountain and hill forest between 900 and 2000 m.

Food and Feeding. Preys on grasshoppers, crickets and other large insects; also small birds

and snails. Takes prey on or near ground after a steep rapid stoop.

Breeding. Only one nest known: discovered in Jun; egg found beneath same nest in Aug. Smallest nest on branch next to trunk of not very tall tree in montane forest. No further information available.

Movements. Apparently sedentary.

Status and Conservation. RARE. CITES II. Apparently uncommon to rare, but status difficult to ascertain because of unobtrusive behaviour. Not known to be directly threatened at present, but loss of forest habitat likely to have negative impact.

124. Rufous-necked Sparrowhawk

Accipiter erythrauchen

French: Épervier à gorge grise **German:** Rotnackensperber **Spanish:** Gavilancito Moluqueño
Other common names: Moluccan/Grey-throated Sparrowhawk, Rufous-necked Collared Sparrowhawk

Taxonomy. *Accipiter erythrauchen* G. R. Gray, 1861, Halmahera.

Closely related to *A. cirrocephalus*; most authorities consider these two to form superspecies with *A. brachyurus* and possibly *A. rhodogaster*. Two subspecies recognized.

Subspecies and Distribution.

A. e. erythrauchen G. R. Gray, 1861 - Motrotai, Halmahera, Bacan and Obi (N Moluccas).
A. e. ceramensis (Schlegel, 1862) - Buru, Ambon and Seram (S Moluccas).

Descriptive notes. 28-35 cm; 156 g (1 bird). Small, slender sparrowhawk distinguished by bright rufous collar; underparts unmarked. Juvenile has typical streaked underparts of genus. Race *ceramensis* slightly larger and blacker above, with some pale grey on underparts.

Habitat. Primary forest in lowlands and hills, from sea-level up to 1400 m. Also in tree plantations and selectively logged lowland forest.

Food and Feeding. Small birds. Prey captured in typical sparrowhawk fashion, after quick dash from hidden perch in forest or at forest edge. One seen chasing Red Lory (*Eos bornea*).

Breeding. No information available.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Uncommon, but unobtrusive and easily overlooked. Status very poorly known; most likely threat is loss of forest habitat.

Bibliography. Andrew (1992), Bishop *et al.* (1994), Bowler & Taylor (1989), Brown & Amadon (1968), Deignan (1963), Thiollay & Meyburg (1988), Wattel (1973), White & Bruce (1986).

125. Collared Sparrowhawk

Accipiter cirrocephalus

French: Épervier à collier roux **German:** Sydneysperber **Spanish:** Gavilán Acolarado
Other common names: Australian Sparrowhawk

Taxonomy. *Spurivus cirrocephalus* Vieillot, 1817, New Holland = New South Wales.

Forms superspecies with *A. brachyurus*, *A. erythrauchen* and perhaps *A. rhodogaster*. Birds of N Australia sometimes recognized as race *quiescendus*, but doubtfully valid. Emendation of original spelling to *cirrocephalus* is not justified. Three subspecies normally recognized.

Subspecies and Distribution.

A. c. papuanus (Rothschild & Hartert, 1913) - New Guinea, W Papuan Is, Aru Is.
A. c. rossellianus Mayr, 1940 - Rossel I (Louisiade Archipelago).
A. c. cirrocephalus (Vieillot, 1817) - Australia, Tasmania.

Descriptive notes. 29-38 cm; male 98-160 g, much larger female 162-300 g; wingspan 55-78 cm. Small *Accipiter*. Distinguished from sympatric *A. fasciatus* by square or notched rather than rounded tail tip, slender legs, long middle toe. Juvenile mottled brown with streaked and barred underparts. Slight regional variation in size and colour: tropical races less distinctly barred ventrally.

Habitat. Forest, woodland and scrub, including well wooded farmland and urban areas; from sea-level to at least 1500 m in Australia, to 2500 m in New Guinea. Avoids treeless areas and dense, unbroken rain forest. Nests

in forest and woodland, including dense woodlots in large urban parks.

Food and Feeding. Mainly small birds, particularly passerines, including exotic sparrows (*Passer*) and starlings (*Sturnus*); also lizards, insects and rarely small mammals. Most prey under 100 g, rarely over 200 g. Forages by short-stay perch-hunting from concealed position in foliage, punctuated by short flights from tree to tree, often in undulating mode; also by quartering flight or low fast flight, sometimes hedge-hopping. Prey often seized in flight by direct flying attack or stealthy glide that becomes short chase.

Breeding. Jul-Dec. Solitary. Platform of sticks 27-32 cm wide, 12-15 cm deep, lined with green leaves; placed 4-39 m above ground in fork of living tree. Usually 3-4 eggs (2-5); incubation 35 days; chicks have white down; fledging c. 28-33 days; post-fledging dependence of up to 6 weeks. Sexual maturity at 1 year; sometimes breeds in juvenile plumage. Success 1-6 young fledged per clutch laid, 1-7 per successful nest; nestlings sometimes taken by monitor lizards (*Varanus*).

Movements. Poorly understood; apparently some resident and other partly migratory populations, with some birds from S wintering in coastal and N areas; also certain amount of apparently short range post-breeding dispersal, particularly by females, to winter territories, including towns.

Status and Conservation. Not globally threatened. CITES II. Uncommon, but widespread; secretive and probably under-recorded. Local declines in extensively cleared areas, particularly in SW Australia where few exotic passerines; eggshell thickness significantly reduced by DDT use (now ceased) in S Australia, suggesting some local breeding depression. Possibly affected in SE Australia by population explosion of Pied Currawong (*Strepera graculina*), a predator and competitor capable of robbing and injuring adults, or killing nestlings. Sometimes collides with windows; occasionally shot or trapped.

Beehler *et al.* (1986), Coates (1985), Cupper & Cupper (1981), Czechura *et al.* (1987), Debus, Ley *et al.* (1993), Hollands (1984, 1992), Marchant & Higgins (1993), Metcalf *et al.* (1989), Newgrain *et al.* (1993a), Olsen & Marples (1993), Olsen & Olsen (1987a), Olsen, Crome & Olsen (1993), Olsen, Fuller & Marples (1993), Ross *et al.* (1989), Schodde & Tidemann (1988).

126. New Britain Sparrowhawk

Accipiter brachyurus

French: Épervier de Nouvelle-Bretagne **Spanish:** Gavilancito de Nueva Bretaña
German: Dreifarbensperber

Taxonomy. *Astur brachyurus* Ramsay, 1879, New Britain.

Forms superspecies with *A. cirrocephalus*, *A. erythrauchen* and perhaps *A. rhodogaster*. Monotypic.

Distribution. New Britain.

Descriptive notes. 27-34 cm, female larger. Small *Accipiter*. Distinguished from adult of sympatric *A. luteoschistaceus* by yellow (not orange-red) facial skin and legs, long middle toe and rufous collar. Juvenile has strongly barred rufous upperparts, pale underparts coarsely streaked brown.

Habitat. Tropical rain forest, forest edge and partly cleared areas; from sea-level to at least 900 m.

Food and Feeding. Unknown. Morphology suggests that it probably hunts small birds of densely wooded areas.

Breeding. No information available.

Movements. Unknown; no records outside normal range.

Status and Conservation. RARE. CITES II. Scarce, and seldom encountered by ornithologists; population trend and biology unknown. Possibly affected by deforestation in lowlands, and subject to breeding failure through eggshell thinning in areas of DDT use, but data lacking.

Bibliography. Brown & Amadon (1968), Coates (1985), Collar & Andrew (1988), Diamond (1971), Schodde (1978), Wattel (1973).

127. Vinous-breasted Sparrowhawk

Accipiter rhodogaster

French: Épervier à poitrine rousse **German:** Schlegelsperber **Spanish:** Gavilán Pechirrojo

Taxonomy. *Nisus virgatus rhodogaster* Schlegel, 1862, Gorontalo, Sulawesi.

May belong in *A. cirrocephalus* superspecies. Validity of race *butonensis* has been questioned. Three subspecies recognized.

Subspecies and Distribution.

A. r. rhodogaster (Schlegel, 1862) - Sulawesi.
A. r. butonensis Voous, 1951 - Muna and Butung (off SE Sulawesi).
A. r. sulawensis (Schlegel, 1866) - Banggai and Sula Is.

Descriptive notes. 28-33 cm; male 113 g, female 264 g (both juveniles). Small, vocal *Accipiter*, almost identical in adult plumage to sympatric *A. nanus* and *A. trinitatus*; leaden grey upperparts and vinous red underparts, but thighs grey. Present species largest and differs in having grey thighs, long toes and marked sexual dimorphism in size; lacks white spots on uppertail. Juvenile deep rufous above, whitish below with heavy dark streaking. Racial variation slight, mainly in coloration of head, and possibly also in size.

Habitat. Primary and old secondary forest, from sea-level up to 2000 m; also mangroves

and cultivated areas with some woodlands.

Food and Feeding. Stomach contents were insects, lizards, squirrels, mice and small birds. Hunting behaviour unreported.

Breeding. No information available.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Widespread and apparently uncommon; perhaps commoner than thought, but overlooked because of unobtrusive habits.

Bibliography. Andrew (1992), van Bemmelen & Voous (1951), Bishop *et al.* (1994), Brown & Amadon (1968), van Marle & Voous (1946), Stresemann (1940a), Wattel (1973), White & Bruce (1986).

128. Madagascar Sparrowhawk

Accipiter madagascariensis

French: Épervier de Madagascar **German:** Madagaskarsperber **Spanish:** Gavilán Malgache

Taxonomy. *Accipiter Madagascariensis* A. Smith, 1834, Madagascar.

Forms superspecies with *A. nisus*, *A. rufiventris* and perhaps the *A. striatus* complex. Monotypic.

Distribution. Madagascar.

Descriptive notes. 29-40 cm. Dark greyish brown upperparts and brown underparts barred white are darker than sympatric congeners. Recalls *A. nisus*, but generally much darker, lacking any rufous tones. Female much larger, browner and more heavily barred than male. Juvenile brown with dark streaks on underparts.

Habitat. Primary rain forest and dry thorn forest or scrub. Rarely in secondary habitats.

Food and Feeding. Small birds, insects taken in flight and some frogs and crickets. Long slender legs and toes suggest mainly avian prey.

Breeding. Laying Nov. Builds a stick nest high in a forest tree. One clutch of 3 eggs; no further details recorded.

Movements. None recorded.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Status poorly known. Uncommon in all areas and rare on deforested central plateau. Not commonly sighted and confined to primary habitats, many of which in Madagascar have already been seriously damaged, or are currently in process of being degraded.

Bibliography. Brown & Amadon (1968), Dee (1986), Langrand (1990), Langrand & Meyburg (1984), Milon *et al.* (1973), Watel (1973).

129. Ovambo Sparrowhawk

Accipiter ovampensis

French: Épervier de l'Ovampo **German:** Ovambosperber **Spanish:** Gavilán del Ovampo
Other common names: Ovampo Sparrowhawk

Taxonomy. *Accipiter ovampensis* Gurney, 1875, Okavango River, Ovamboland, Namibia. May belong in the *A. nisus* superspecies, but relationships uncertain. Monotypic.

Distribution. Senegambia, Sierra Leone and Ghana E to Ethiopia and S to Angola, N Namibia, N Botswana and N South Africa.

Descriptive notes. 30-40 cm; 119-305 g; wingspan 67 cm. Underparts barred up to throat, small snaky head, dark red eye and orange-red legs and cere notable. A rare melanistic morph also occurs, with birds all black at all ages. Most like smaller *Micronisus gabar* in all morphs, but lacks white rump (some white in uppart-coverts) and latter has red legs. Female much larger than male. Juvenile has two colour morphs, one brown, one rufous, but both with pale stripe above eye; rufous juvenile similar to *A. rufiventris*, but with dark eye.

Habitat. Edges of forest, woodland and exotic

plantations, moving into surrounding savanna and grassland when hunting.

Food and Feeding. Small birds of 10-60 g, although female takes doves of up to 250 g. Hunts mainly on the wing with fast coursing over the canopy or by stooping from high soaring flight. Also makes fast persistent chases from a high perch. Rather falcon-like in most aspects of hunting behaviour, with relatively long wings and shortish legs for a sparrowhawk.

Breeding. Laying May, Sept in Kenya; Aug-Nov in S Africa. Builds a nest of fine sticks lined with twigs, bark and leaves, high in a fork of a tall tree. Often sited on edge of forest, woodland or exotic plantation. Usually 3 eggs (1-5); incubation 33-35 days; chicks have white down; fledging c. 33 days.

Movements. Resident in S Africa but generally a secretive species. Thought to enter some marginal areas in E Africa only temporarily, probably from C African woodlands; to some extent nomadic in E Africa. Possibly only a non-breeding migrant during the wet season (Jun-Oct) to W Africa, where has been recorded W to Sierra Leone and Senegambia.

Status and Conservation. Not globally threatened. CITES II. Widespread and locally common in S and C African woodlands and plantations. Apparently uncommon in E and W Africa, but status uncertain, as species is easily overlooked. Vulnerable to cutting of woodland, but has extended range using small exotic plantations on savanna-grassland ecotone in South Africa, where densities of 1 pair/30-350 km² recorded. Not known to be affected by pesticides.

Bibliography. Allan & Hustler (1984), Benson & Benson (1975), Black & Ross (1970), Brown, L.H. (1970b), Brown *et al.* (1982), Craib (1983), Ginn *et al.* (1989), Grimes (1987), Irwin *et al.* (1982), Kemp & Crowe (1994a), Kemp & Kemp (1975c), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Simmons (1986a), Steyn (1982), Tarboton & Allan (1984), Thiollay (1978c, 1985d), Watel (1973).

130. Eurasian Sparrowhawk

Accipiter nisus

French: Épervier d'Europe **German:** Sperber **Spanish:** Gavilán Común

Taxonomy. *Falco Nisus* Linnaeus, 1758, Sweden.

Sometimes considered to include *A. rufiventris*. Forms superspecies with *A. madagascariensis*, *A. rufiventris* and perhaps the *A. striatus* complex. Birds from mountains of C Asia (Tien Shan) sometimes separated in race *dementjevi*; many other dubious races described. Six subspecies currently recognized.

Subspecies and Distribution.

A. n. nisus (Linnaeus, 1758) - Europe and Asia Minor E to W Siberia; winters S to NE Africa and Middle East.

A. n. nisusimilis (Tickell, 1833) - C & E Asia; winters S to India, Sri Lanka and Indochina.

A. n. melaschistos Hume, 1869 - Himalayas and mountains of C Asia.

A. n. wolterstorffi Kleinschmidt, 1901 - Corsica and Sardinia.

A. n. granti Sharpe, 1890 - Madeira and Canary Is.

A. n. puniceus Erlanger, 1897 - NW Africa, from Morocco to Tunisia.

Descriptive notes. 28-38 cm; male 110-196 g, female 185-342 g; wingspan 60-75 cm. Cheeks and flanks have reddish tinge; conspicuous pale supercilium; pale underparts barred rufous and brown. Female considerably larger; underparts white with grey bars. Juvenile similar to female, but browner above with rusty feather margins; broader barring on underparts. Geographical variation largely clinal: races separated on size, coloration and density of barring.

Habitat. Forests, including coniferous, deciduous and mixed; also more open woodland; not unusual in urban parks. From sea-level to

mountains, in summer up to tree-line, foraging above it. Particularly favours mosaic of woodland or groves with more open areas. More catholic in winter, sometimes occurring in areas with very few trees.

Food and Feeding. Almost exclusively small and medium-sized birds, with predominance of former; prey rarely over 120 g. Enormous variety of species taken; more conspicuous prey types predominate, e.g. those that forage on ground. Commonest prey in Europe includes finches, especially Chaffinch (*Fringilla coelebs*), sparrows, buntings, tits, Tree Pipit (*Anthus trivialis*) and larks; larger birds commonly taken include thrushes and starlings; much more occasionally pigeons, jays and gamebirds. Takes many fledglings and nestlings; breeding season timed to coincide with period of maximum availability of young of prey species. Small mammals, particularly voles and other rodents, of very limited importance, as are young hares and rabbits, shrews and bats; also some insects. Tends to hunt in clearings, on edges of woods or in sparsely wooded areas; males hunt in more densely wooded areas than females, and catch smaller prey on average. Hunts stealthily, trying to surprise prey; often flies using vegetation for cover, or makes short flights between concealed perches.

Breeding. Laying Apr-Jun, varying with latitude. Nests in woods, preferably coniferous or mixed; often near clearing to ease access to nest. Nest built in tree, in lower crown, in fork or on branch; new nest built each year by both adults; platform of sticks with little or no greenery. Normally 3-6 eggs (1-7); replacement laying can occur twice in same season; incubation c. 32-34 days per egg, by female; chicks fed by female, but prey caught exclusively by male at least until mid-nesting period; chicks have first and second down white; fledging c. 26 days for males, c. 30 days for females; young fed for 3-4 weeks more. Breeding success variable, with marked decline historically following pollution by pesticides; in W Germany before 1950's c. 80% of nests produced chicks, in 1960's and 1970's only 54%; in Scotland in 1971-1984, average 2.3 chicks fledged per breeding pair, 3.4 per successful pair; up to 5 chicks fledge. Sexual maturity at 1-3 years. Rarely lives beyond 7 years; oldest recorded bird over 15 years old.

Movements. Migratory in northernmost parts of Europe and in most of Asia; partially migratory in C Europe; sedentary in S of range. Various C European countries receive N migrants, some of their breeding birds possibly migrating further S, reaching Mediterranean countries; most migration actually from NE to SW. Few migrants reach Africa, although some birds winter in N Africa and sub-Saharan Africa, occasionally S to Kenya and Tanzania. Siberian population winters in S & SE Asia.

Status and Conservation. Not globally threatened. CITES II. Declined drastically in Europe during 1950's and 1960's, due to generalized use of organochlorine pesticides, which killed adults and lowered breeding success. Gradual recovery since these pesticides banned in 1960's or 1970's (varying with country); recovery apparent in increased density and recolonizations, and also in numbers of migrants counted. No figures available for total population, only partial and approximate estimates. In 1980's probably over 100,000 pairs in Europe, excluding former USSR, including c. 25,000 pairs in Britain, 10,000-20,000 pairs in France, c. 14,000 pairs in Sweden, c. 10,000 pairs in Finland, 3500-5000 pairs in Denmark and c. 2500 pairs in Czechoslovakia; in early 1990's, c. 4500 pairs in Austria, 8500-10,000 pairs in Byelorussia, and possibly 160,000 pairs in European Russia. In 1980's, 200-500 pairs of race *wolterstorffi* in Corsica, 500-1000 pairs of *puniceus* in Morocco, and at least 175 pairs of *granti* in Canary Is. Heavily persecuted in 20th century by gamekeepers and hunters, with bounties regularly paid in several parts of Europe (see page 92); huge numbers killed. In Turkey, thousands captured by falconers each year and used for hunting migrating quails. Direct persecution now fairly limited in much of range and populations generally stable or increasing; more affected by reduction in prey availability and habitat alteration.

131. Rufous-breasted Sparrowhawk

Accipiter rufiventris

French: Épervier menu **German:** Rotbauchspërber **Spanish:** Gavilán Papirufu
Other common names: Red-breasted/Rufous-chested/Rufous Sparrowhawk

Taxonomy. *Accipiter rufiventris* A. Smith, 1830, South Africa.

Forms superspecies with *A. nisus* (with which often considered conspecific), *A. madagascariensis* and perhaps the *A. striatus* complex. Two subspecies recognized.

Subspecies and Distribution.

A. r. perspicillaris (Rüppell, 1836) - Ethiopian highlands.

A. r. rufiventris A. Smith, 1830 - Kenya and E Zaire S to South Africa.

Descriptive notes. 33-40 cm; 180-210 g; wingspan 72 cm. Yellow eye distinctive at all ages. Female much larger than male. Juvenile with fine white bars on rufous underparts, similar to rufous morph of juvenile *A. ovampensis*. Race *perspicillaris* considerably larger and also darker.

Habitat. Patches of montane forest and exotic pine, eucalypt and poplar plantations; hunts over adjacent savanna, grassland and fynbos. Occurs down to sea-level and in suburbia in S South Africa, extending into arid karoid steppe by use of exotic plantations.

Food and Feeding. Mainly birds of 10-90 g, up to size of pigeons, together with some bats, rodents, lizards and a few insects. Hunts from a perch within cover, or more often from low coursing flight, making a fast dash in pursuit of prey, which is taken in flight or forced to the ground or into cover. Sometimes hunts by stooping from soaring flight, and regularly hunts over open ground near woodland.

Breeding. Laying Jul in Uganda; Sept-Dec in S Africa. Builds a platform of small sticks lined with leaves, bark and moss, in the upper fork of a tree. Usually 3 eggs (2-4); incubation 34 days; chicks have white down; fledging 31-36 days; post-fledging dependence 22-41 days.

Movements. May make some altitudinal movements down from montane forest during winter, as in some high-lying areas of S Africa, but apparently resident in most forest patches.

Status and Conservation. Not globally threatened. CITES II. Locally common, as at density of 1 pair/23-33 km² in Transvaal, South Africa. Vulnerable to degradation of small indigenous forest patches and cutting of montane timber, but readily adopts exotic plantations and is common in suburban Cape Town. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Black & Ross (1970), Brown *et al.* (1982), Butynski & Kalina (1988), Ginn *et al.* (1989), Grobler (1981), Irwin *et al.* (1982), Macdonald (1986), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Simmons (1984, 1986a, 1986b, 1986c), Steyn (1982, 1988), Tarboton & Allan (1984), Thiollay (1978c), Wattel (1973), van Zyl & Cooke (1987).

132. Sharp-shinned Hawk

Accipiter striatus

French: Épervier brun **German:** Eekschwanzspërber **Spanish:** Gavilán Americano
Other common names: Sharpshin, Sharpie, Little Blue Darter

Taxonomy. *Accipiter striatus* Vieillot, 1807. Santo Domingo, Hispaniola.

Forms superspecies with *A. chionogaster*, *A. ventralis* and *A. erythronemius*, all of which have traditionally been included within present species, but differ on morphology, ecology and probably behaviour. Also close to *A. nisus* and associated species. Seven subspecies recognized.

Subspecies and Distribution.

A. s. perobscurus Snyder, 1938 - Queen Charlotte Is; possibly also mainland coast of British Columbia.

A. s. velox (Wilson, 1812) - Alaska and Canada S to California, Arizona, New Mexico and Alabama (USA); winters S to Panama.

A. s. suttoni van Rossem, 1939 - extreme S New Mexico (USA) S locally to Veracruz (Mexico).

A. s. madrensis Storer, 1952 - Guerrero and perhaps W Oaxaca (S Mexico).

A. s. striatus Vieillot, 1807 - Hispaniola, in both Haiti and Dominican Republic.

A. s. fringilloides Vigors, 1827 - Cuba.

A. s. venator Wetmore, 1914 - Puerto Rico.

Descriptive notes. 25-34 cm; male 82-125 g, female 144-208 g; wingspan 51-69 cm. A typical small short-winged, long-tailed forest hawk. Bluish upperparts; underparts rufous to tawny buff, with extent of barring variable; broad grey bars in tail; eye red. Female much larger than male. Juvenile dark brown above with pale streaked underparts; eye yellow. Races vary in coloration, extent of barring on underparts, especially thighs, and size.

Habitat. Wide variety of habitats, depending on region. Boreal coniferous forests, brushy areas or mixed open deciduous woodlands in N; pine forests on mountain slopes, tropical

and subtropical cloud forest, savanna woodland and gallery forest in S of range. Seldom seen above canopy. Shows some preference to be close to water. Almost any terrain in non-breeding season; frequent in treed urban areas of North America.

Food and Feeding. Highly specialized catcher of birds, which constitute c. 90% of prey. Most prey of 15-27 g. Other food includes small mammals, frogs, lizards and insects. Hunts by fast bursts of speed along woodland routes, or by still-hunting attacks. Prey typically plucked at "butcher-blocks", or plucking posts, not too distant from nest.

Breeding. Apr-Jul in North America, Jan-Jul in Caribbean. Solitary. Nests typically in small stand of conifers with dense foliage; also uses oaks, maples, aspens; nest is bulky platform c. 50 cm wide, 20 cm deep, placed c. 4-11 m from ground; lined with bark or greenery. 4-5 eggs in North America, 2-3 in Caribbean; incubation 30-32 days (N America); chicks have white down; move out of nest at 21-27 days, but feathering fully developed at 38-40 days. May breed (especially females) in 1st full year, in juvenile plumage; occasionally pairs of juveniles occur. Oldest ringed bird c. 7 years. Nest success of c. 60-100% (North America) and 29% (Caribbean) per attempt; hatching success c. 63-85% of eggs laid; c. 2-7-3-5 (North America) and 0-8 (Caribbean) young fledged per attempt.

Movements. Race *velox* migratory, especially from taiga, moving S to Panama; most other races seemingly resident; dark individuals, similar to *perobscurus*, found outside breeding range suggesting that this race may wander. Juvenile females of *velox* start autumn migration in late Aug. before young males or adults; migration ends by late Oct. Spring migration Mar-Jun, depending on latitude. Winter movement occurs from high to lower altitudes.

Status and Conservation. Not globally threatened. CITES II. Race *velox* affected by organochlorine chemicals in 1960's and 1970's; some general declines. Habitat alteration, especially removal of forest, continues to affect populations, although species capable of adapting to urban areas. Migration data suggest *velox* increasing (1980's-1990's). No reliable data on numbers of any population, but races *venator* and *fringilloides* reportedly rare; total population of former estimated at 155 individuals remaining in five forests, and this race currently proposed for listing as endangered.

Bibliography. Buxley (1930), Clark, W.S. (1984), Cruz & Dickinson (1983), Delannay (1982), Delannay & Cruz (1988), Duncan (1980), Evans & Rosenfield (1985), Fischer, D.L. (1984, 1986), Friedmann (1950), Garrido (1985), Harwood (1975), Hennessey (1978), Holthuijzen *et al.* (1985), Johnsgard (1990), King (1978/79), Moore & Henny (1983), Mueller & Berger (1967a), Mueller *et al.* (1979a, 1981), Murray (1964), Noble & Elliott (1990), Palmer (1988), Platt (1976c), Reynolds & Meslow (1984), Reynolds *et al.* (1982), Ridgely & Gwynne (1989), Slud (1964), Snyder & Wiley (1976), Snyder *et al.* (1973), Smith *et al.* (1990), Storer (1952, 1966), Swann (1922), Wattel (1973), Wetmore (1965).

133. White-breasted Hawk

Accipiter chionogaster

French: Épervier à poitrine blanche **German:** Weißbrustspërber **Spanish:** Gavilán Ventri blanco

Taxonomy. *Nisus* (*Accipiter*) *chionogaster* Kaup, 1852. Cobán, Guatemala.

Often considered race of *A. striatus*, or alternatively of *A. erythronemius*, forming superspecies with these two and *A. ventralis*; group split on grounds of differences in morphology, ecology and probably also behaviour. Monotypic.

Distribution. Highlands of Central America, from S Mexico (Chiapas, Oaxaca) through Guatemala, Honduras and El Salvador to NC Nicaragua.

Descriptive notes. c. 30 cm. Uniform dark grey above, white below with fine blackish streaks on feather shafts of crown, throat and upper breast; thighs show hint of pale rufous; tail dark with broad

grey bands. Smaller and generally paler below than *A. bicolor*. Iris red or orange. Female similar, but larger. Immature has more extensive, browner and broader vertical streaking below.

Habitat. Pine forests or mixed pine and oak forests up to temperate zone; also in cloud forest, montane rain forest and semi-open areas. Usually above 600 m, and up to at least 1080 m; rarely down to sea-level.

Food and Feeding. No information available; presumably feeds extensively on birds, as do close relatives.

Breeding. No information available; presumably uses stick nests in tall trees.

Movements. No information available.

Status and Conservation. Not globally threatened. CITES II. Status uncertain; relatively restricted range and extensive deforestation within this range suggest that careful monitoring is merited.

Bibliography. Blake (1977), Brown & Amadon (1968), Land (1970), Monroe (1968), Ridgely & Gwynne (1989), Siles & Skutch (1989), Wattel (1973), Wetmore (1941).

134. Plain-breasted Hawk

Accipiter ventralis

French: Autour à gorge rayée **German:** Andenspërber **Spanish:** Gavilán Andino

Taxonomy. *Accipiter ventralis* P. L. Selater 1866. Bogotá, Colombia.

Often considered race of *A. striatus*, or alternatively of *A. erythronemius*, forming superspecies with these two and *A. chionogaster*; group split on grounds of differences in morphology, ecology and probably also behaviour. Monotypic.

Distribution. Hills and mountains from N & SE Venezuela and Colombia through Ecuador and Peru to W Bolivia (Cochabamba).

Descriptive notes. 28-33 cm. Dark grey above; tail with 3-4 thin grey bands; thighs deep rufous to reddish chestnut brown. Polymorphic: underparts usually cinnamon rufous, barred and spotted white, throat whitish with very fine dark streaking; pale forms have underparts almost completely white, with some faint dark streaking or barring and red thighs; melanistic morph slate grey with rufous belly and thighs. Female similar, but larger. Immature streaky dark brown above, white with dark brown streaks below, and characteristic rufous thighs.

Habitat. Forested mountain slopes from upper tropical to temperate zone, often at forest edge, in woodlots, and in brushy second growth. Normally at 900-2700 m, but regularly down to 300 m in Venezuela and also sighted at 3540 m in Peru.

Food and Feeding. Little known, but reported to chase birds from a concealed perch, as do closely related species.

Breeding. One female in breeding condition collected in Colombia in Jun. Nest undescribed, but presumably stick nest in tall trees.

Movements. No information available.

Status and Conservation. Not globally threatened. CITES II. Currently fairly common in parts of range; propensity to use second growth suggests no grounds for immediate concern.

Bibliography. Blake (1977), Brown & Amadon (1968), Cabot & Serrano (1986), Fjeldsa & Krabbe (1990), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Parker *et al.* (1982), Reimsen & T aylor (1989).

135. Rufous-thighed Hawk

Accipiter erythronemius

French: Épervier à cuisses rousses **German:** Rotschenkelspërber **Spanish:** Gavilán Muslirrufo

Taxonomy. *Nisus* vel *Accipiter erythronemius* Kaup (ex G. R. Gray MS), 1850. Bolivia.

Often considered race of *A. striatus*, with which forms superspecies, along with *A. chionogaster* and *A. ventralis*; group split on grounds of differences in morphology, ecology and probably also behaviour. Monotypic.

Distribution. S Brazil (S from Mato Grosso and Bahia) to Uruguay, and SE Bolivia (Santa Cruz to Tarija) through Chaco of Paraguay to N Argentina (La Rioja & Córdoba).

Descriptive notes. 30 cm. Similar to normal morph of closely related *A. ventralis*; above uniform slate black to fuscous brown, below barring (when present) more conspicuous; thighs and middle of flanks uniformly rusty; grey and black tail bars of equal width. Female similar, but noticeably larger than male. Immature has wings and back brown, below white with brownish streaking.

Habitat. Generally rather arid forests, woodland and semi-open areas such as wooded savannas.

Food and Feeding. Little known but probably mostly birds.

Breeding. Nest undescribed, but presumably stick nest in tall trees, as with closely related species.

Movements. No information available.

Status and Conservation. Not globally threatened. CITES II. In general fairly common, but locally threatened where extensive monocultural agriculture removes all stands of woodland; otherwise probably fairly adaptable and no apparent grounds for concern.

Bibliography. Benson (1984), Blake (1977), Courcier *et al.* (1990), Ginn & Ginn (1978), Janssens & Kruze (1990), Kinnaird & Moschione (1987), Navas & Bo (1991), de la Peña (1992), Pino (1964), Reimsen & T aylor (1989), Ruschi (1979), Sick (1985a, 1993).

136. Cooper's Hawk

Accipiter cooperii

French: Épervier de Cooper **German:** Rundschwanzspërber **Spanish:** Gavilán de Cooper
Other common names: Big Blue Darter, Chicken Hawk

Taxonomy. *Falco cooperii* Bonaparte, 1828, Bordentown, New Jersey.

Forms superspecies with *A. gundlachi*, *A. bicolor* and *A. chilensis*. Monotypic.

Distribution. USA and S Canada. Winters from N USA to C America, regularly as far S as Honduras, occasionally to Colombia.

Descriptive notes. 37-49 cm; male 235-300 g, female 413-598 g; wingspan 90-99 cm. Smallish long-tailed forest hawk, with rounded wings; eye red. Bluish upperparts and rufous barred underparts; essentially a larger version of *A. striatus*. Female much larger than male. Juvenile brown with streaked underparts; eye yellow.

Habitat. Forests with dense canopy cover; fairly equal use of coniferous and deciduous forests, with preference apparently depending on dominant species. Riparian communities heavily used in arid regions. Tends to use forest edge and clearings. In winter, all habi-

tats, even urban. Has also bred in urban areas.

Food and Feeding. Proportion of mammals to birds varies regionally; birds appear favoured overall (60-80%), but shares can be c. 50:50; also takes some reptiles. Prey normally 36-51 g, c. 12% of adult weight. Hunting by extended flights along forest edge or naturally cleared routes, and by still-hunting from perch. Hunting success may be 50% for mammals, 20% for birds.

Breeding. Mar-Jul; probably slightly earlier at S limits, e.g. Texas and N Mexico. Solitary. Nest is compact platform of sticks, broad and flat; tends to be smaller (c. 64-76 cm wide, 15-20 cm deep) in conifer than in deciduous tree (c. 43 cm deep); lined with bark, leaves or other greenery. Nest tree often near stream, other water or forest opening; c. 8-16 m above ground; usually in main crotch or horizontal limb against trunk; nest tree varies regionally from c. 90% conifer use to c. 90% deciduous (e.g. aspen) use. Usually 3-6, commonly 4-5 eggs; incubation 30-34 days; chicks have white down; fledging 27-30 days. Will breed in immature plumage at 1 year (usually females), but normally at 2 years. Longevity record 8 years, but believed to live longer; annual mortality rate c. 60-70%. Nest success c. 70-81% of attempts; fledging success c. 53-69% of eggs laid; 1.9-3.2 young fledged per attempt, depending somewhat on age of female, or region.

Movements. Generally migratory from N half of range, but some birds remain even at N part of range. Sedentary elsewhere, though birds at high altitudes may move to lowlands. In autumn, yearlings migrate first, and females precede males in each age category; migration late Aug-early Nov, with peak from mid-Sept to mid-Oct. In spring, males precede females. Mar-May. Migrates commonly to Mexico, but as far as Costa Rica and rarely Colombia.

Status and Conservation. Not globally threatened. CITES II. Widespread and common; perhaps one of commonest hawks in W USA. Seriously affected by organochlorines in 1940's and 1950's, with calculated annual rate of population decline of 25% in E, after 1948. Less severely affected in W, but pre-1945 fledging rate of 3-53 declined to 2-67 during period of pesticide usage (1949-1967). Significant correlation between percentage of birds in diet and DDE content found in eggs. Greatest decrease in eggshell thickness was 19%; 15-17% eggshell decrease produced serious reproductive difficulty. Migration counts in 1993 indicate species on increase.

Bibliography. Bielefeldt & Cary (1991), Bielefeldt *et al.* (1992), Blake (1977), Evans (1982), Hennessey (1978), Henry & Wight (1972), Hoffman, S.W. *et al.* (1992), Johnsgard (1990), Jones, S. (1979), Kennedy & Johnson (1986), Kratz (1989), Meng (1959), Millsap (1981a), Moore & Henry (1983), Mosher (1989), Mueller *et al.* (1979b), Murphy *et al.* (1988), Palmer (1988), Reynolds (1989), Rosenfield (1990), Rosenfield & Bielefeldt (1993), Rosenfield *et al.* (1991), Slud (1964), Smith *et al.* (1990), Snyder & Snyder (1979), Snyder & Wiley (1976), Snyder *et al.* (1973), Stahlacker & Beach (1979), Titus & Mosher (1981), Toland (1985a), Wattel (1973), Whaley & White (1994), Wiggers & Kratz (1991).

137. Gundlach's Hawk

Accipiter gundlachi

French: Épervier de Cuba **German:** Gundlachsperber **Spanish:** Gavilán Cubano

Taxonomy. *Accipiter Gundlachi* Lawrence, 1860, Hanábara, Cuba.

Closely related to *A. cooperii*, *A. bicolor* and *A. chilensis*, forming superspecies with all three; at present no indications as to which of first two species is ancestral to present species. Two subspecies recognized.

Subspecies and Distribution.

A. g. gundlachi Lawrence, 1860 - W & C Cuba.

A. g. wileyi Wotzkow, 1991 - E Cuba.

Descriptive notes. 42-50 cm. Intermediate in plumage between *A. cooperii* and *A. bicolor*, differing from former in grey breast, from latter in grey and rufous barring on belly and thighs. Dark grey above; tail broadly banded light and dark grey; blackish grey cap contrasts with largely pale bill; greyish white flanks and undertail-coverts conspicuous against darker fine grey barring on rufous brown thighs and belly. Female averages slightly larger, with longer tail. Immature brown above, with brown streaking below, and spotting on underwing. Recently described race *wileyi* differs principally in

underpart coloration of immature.

Habitat. Not specialized; populations of W and C nest in low sub-montane (under 800 m) evergreen forest, and also in semi-deciduous marshy forest, at forest edge, and along forested coastline;

E race nests in better developed forests, and also pine forest, cloud, riverine, and dry evergreen microphyllous forests, as well as tropical rain forest. An upland nest was found at 780 m in a dense stand of pines.

Food and Feeding. Little information available; items recorded include parrots, pigeons and doves, crows, nighthawks, Northern Bobwhite (*Colinus virginianus*), Red-legged Thrush (*Turdus plumbeus*) and domestic fowl; these, together with large feet and long toes, suggest that species specializes on avian prey. Females appear to take larger and more conspicuous prey in or above the canopy, while males capture smaller prey in the understorey.

Breeding. Poorly known, but data is accumulating: several nests reported at or around swamp of Ciénaga de Zapata in W Cuba. Nest building Jan-Apr, with young fledged by Jun. Stick nest built 7-20 m up tree; birds will reuse same nest for at least 3 years, and presumably more. Normally 3-4 eggs, once 2. No further information available.

Movements. Sedentary.

Status and Conservation. VULNERABLE/RARE. CITES II. Total numbers estimated at c. 150-200 pairs, mostly in E Cuba, but with three additional populations in W, in provinces of Las Villas, Matanzas (Zapata Swamp) and Pinar. Some populations occur within protected areas, but recent recognition of subspecifically distinct E population argues for further inventories. Although apparently never common, formerly much more widely distributed on the island. Human persecution aggravated by the fact that species is known to take poultry; this and loss and disturbance of wooded habitats seem to be principal threats. Recently more woodland being cut as consequence of fuel shortage in Cuba. There are records of young birds taken for captivity, or for international raptor trade.

Bibliography. Abreu *et al.* (1989), Balat & González (1982), Bond (1979), Collar (1986a), Collar & Andrew (1988), Collar *et al.* (1992), Garrido (1985), Garrido & Montaña (1975), Gundlach (1871-1875), Meyburg (1986), Rams & Pena (1988), Reynard *et al.* (1987), Torres *et al.* (1988), Wattel (1973), Wiley (1985, 1986), Wotzkow (1985, 1986b, 1991).

138. Bicoloured Hawk

Accipiter bicolor

French: Épervier bicoloré **German:** Zweifarbensperber **Spanish:** Gavilán Bicolor
Other common names: Spotted Hawk (*guttifer*)

Taxonomy. *Sparvius bicolor* Vieillot, 1817, Cayenne.

Normally considered to include *A. chilensis* as a race, but differs in ecology, especially in habitat preferences; also closely related to *A. cooperii* and *A. gundlachi*, and these four form a superspecies. Race *guttifer* has been considered full species; alternatively a race of *A. chilensis*, but isolated range of *A. chilensis* and intergradation of *guttifer* with *A. b. pileatus* suggest *guttifer* closer to *A. bicolor*. Race *schistochlamys* of W Ecuador incorporated in nominate. Four subspecies currently recognized.

Subspecies and Distribution.

A. b. fidens Bangs & Noble, 1918 - S Mexico, N of Yucatán, in Oaxaca and Veracruz.

A. b. bicolor (Vieillot, 1817) - S Mexico (Yucatán) to Amazonia and the Guianas, S to E Bolivia, and W of Andes S to NW Peru (Lambayeque).

A. b. pileatus (Temminck, 1823) - Brazil S of Amazonia (E Mato Grosso to S Maranhão and Ceará) and S to NE Argentina (Misiones).

A. b. guttifer Hellmayr, 1917 - Brazil (W Mato Grosso) and Bolivia through Chaco of Paraguay to N Argentina.

Descriptive notes. 30-42 cm; wingspan 65-80 cm. Considerable variation in plumage. Dark slate grey above, with or without pearl grey collar; below pale to dark grey to rufous, with conspicuous bright rufous thighs; tail with 2-4 narrow whitish to greyish bars. Cere and legs yellow, iris orange. Resembles *Harpagus diodon* in both adult and immature plumages, especially of race *pileatus*, but quite different structure; likeness may be result of protective mimicry by *H. diodon*. Female noticeably larger. Immature blackish to blackish brown above, with paler scalloping; more or less conspicuous whitish or buffy collar; below white

to buff, occasionally deep rufous; thighs darker, sometimes mottled. Races separated on coloration of underparts, and also on size; race *guttifer* grey on upper throat and rich rufous below, mottled with white or grey.

Habitat. Not specialized: rain forest in the Guianas; elsewhere more common in drier, open or thinned forest; also palm savanna with gallery forest and scattered forest patches, and second growth; cerrado in SW Brazil. Up to 2000 m in Colombia. Soars over the forest.

Food and Feeding. A specialist on avian prey. Of 91 prey items recorded in Petén, Guatemala, 68% were birds; 6% mammals and reptiles; the rest unidentified, most of these probably small birds. Elsewhere predilection for avian prey maintained, with doves and thrush recorded. Still-hunts from perches in forest, or pursues birds through forest; sometimes hunts in pairs. Seen attacking troops of squirrel monkeys (*Saimiri*) and tamarins (*Saguinus*); but also following troop of capuchins (*Cebus*), feeding on insects flushed by the monkeys.

Breeding. Laying in Apr-May (mid to late dry season) in Petén; in rainy season in Venezuela. Stick nest in tall tree, often near forest edge; nest c. 30-40 cm wide. 1-3 eggs in Petén; possibly 4 in S of range; incubation 33-37 days; fledging 30-36 days; young remain near nest being fed by parents for at least 60 days after fledging. At one site in Petén, 67% hatch rate, with 92% of hatched young fledging. Male and female defend area of 30 m around nest from other birds, both raptors and large passerines; one adult male had home range of 440 ha during nesting period.

Movements. No evidence of movements.

Status and Conservation. Not globally threatened. CITES II. Widespread, but generally rare. Estimated average density of at least 4 individuals/10,000 ha at one French Guiana forest site. In Petén, average distance between nests was 3.1 km.

Bibliography. Amadón (1961b, 1964), Belton (1984), Blake (1977), Contreras *et al.* (1990), Feltus & Krabbe (1990), Hilty & Brown (1986), Jakse & Juarez (1985), Mader (1985), Meyer de Schauensee & Capen (1958), Monks (1968), Ojeda (1985), de la Peña (1992), Pimentel (1994), Quisenberry *et al.* (1991), Rams & A. Drake (1989), Rusch (1979), Sick (1985a, 1993), Slud (1964), Tello (1983), Thallus (1989a, 1989b, 1991a), Thorstrom, Castillo & Castillo (1991), Trail (1987), Wattel (1973), Wetmore (1965).

139. Chilean Hawk

Accipiter chilensis

French: Épervier du Chili

German: Chilesperber

Spanish: Gavilán Chileno

Taxonomy. *Accipiter chilensis* Philippi and Landbeck, 1864, Chile.

Forms superspecies with *A. bicolor*, *A. cooperii* and *A. gundlachi*. Often considered (mega)subspecies of *A. bicolor*, but isolated range with no geographical variation, and use of temperate forests, unlike *A. bicolor*, suggest treatment as full species is merited. Sometimes held to include *A. bicolor guttifer*. Monotypic.

Distribution. Andes of C Chile (O'Higgins) and adjacent Argentina S to Tierra del Fuego and Staten I. Winters N to NW Argentina (Catamarca).

Descriptive notes. c. 30–42 cm. Dark slate above; throat white, rest of underparts grey, brownish grey or salmon rufous, barred and flecked with white; thighs and underwing rufous. Generally darker above and paler below than *A. bicolor guttifer*. Female similar to male, but markedly larger. Immature creamy white below, with heavy dark brown streaking.

Habitat. Temperate wet forests, especially of Chilean oak (*Nothofagus obliqua*), but also *Araucaria*, usually intermixed with open areas; recorded in open scrub. From sea-level up to 1000 m.

Food and Feeding. Primarily birds; a bold and rapacious predator.

Breeding. Laying in Oct (austral spring). Nest of dead and green sticks and other material in tall tree, often near forest edge. 4 eggs. No further information available.

Movements. Part of population migrates to NW Argentina, perhaps following northbound migratory passerines. Limits of transition between migratory and resident populations not known.

Status and Conservation. Not globally threatened. CITES II. Status very poorly known. Reportedly declining in much of Chile, but said to be little influenced by moderate levels of forest clearing.

Bibliography. Blake (1977), Fjeldså & Krabbe (1990), Hellmayr (1932), Humphrey *et al.* (1970), Johnson (1965), Olrog (1949, 1985), de la Peña (1992), Vuilleumier (1985), Wattel (1973).

140. Black Sparrowhawk

Accipiter melanoleucus

French: Autour noir

German: Mohrenhabicht

Spanish: Azor Blanquinegro

Other common names: Great Sparrowhawk, Black/Pied Goshawk, Black-and-white Sparrowhawk/Goshawk

Taxonomy. *Accipiter melanoleucus* [sic] A. Smith, 1830, South Africa.

May form superspecies with *A. gentilis*, *A. henstii* and even *A. meyerianus*. Two subspecies recognized.

Subspecies and Distribution.

A. m. temminckii (Hartlaub, 1855) - Senegambia E to Gabon, Congo and Central African Republic.
A. m. melanoleucus A. Smith, 1830 - E Sudan and N & W Ethiopia; Gabon and Zaire E to Kenya and S to Angola and South Africa; Pemba and Zanzibar.

Descriptive notes. 46–58 cm; male 430–490 g, female 650–980 g; wingspan 102 cm. Pied plumage of adult notable, with white breast in normal morph, or only white throat in melanistic morph (nominative race only). Similar to *Hieraaetus* and *Spizaeus* hawk-eagles, differing notably in unfeathered yellow legs and dark eye. Female much larger than male. Juvenile also with two morphs, underparts rufous or cream and streaked with dark brown; large (female) juveniles of *A. tachiro* are similar, but speckled or barred on underparts.

Habitat. All types of forest, dense woodland and exotic plantations, from tropical lowlands to high montane patches. Even occurs in and around cities, e.g. Yaoundé, Cameroon.

Food and Feeding. Mainly birds of 80–300 g, up to size of guineafowl, but especially doves, pigeons and francolins. Takes some small mammals and snakes, and also poultry if available. Hunts by fast dash from perch within cover, less often after fast coursing flight under cover of vegetation or low over ground, sometimes by fast stoop from high soaring flight. A bold predator, capable of prolonged tail chases after quarry that extend into secondary forest, savanna and grassland. May carry prey 12 km to nest, flying high above the canopy.

Breeding. Laying Aug–Nov in W Africa; Mar–Jun and Oct–Dec in Zaire and Kenya; May–Oct in S and C Africa (peak Sept–Oct). Builds large stick nest high in tall forest tree, especially attracted to eucalypt plantations; lines nest with sprays of green leaves; same site may be used repeatedly over successive seasons; rarely nests on ground at base of tree. 2–4 eggs; incubation 34–38 days; chicks have white down; fledging 37–47 days.

Movements. Resident and territorial in most areas. However, rapidly colonizes new plantations in grassland or savanna and may undertake long excursions across sea, lake or desert. Possibly even locally migratory in W and NE Africa.

Status and Conservation. Not globally threatened. CITES II. Widespread and common, but apparently at low density in extensive lowland rain forest tracts despite nest territory of only 250 ha. Among forest patches and savanna, occurs at densities of 1 pair/13 km² in Kenya, or 1 pair/38–150 km² in Transvaal, South Africa, where total of 800 pairs. Adapts well to various secondary forests and readily colonizes exotic plantations and subsistence farmland. Vulnerable to cutting of forest and deciduous woodlands; known to have high pesticide levels in some areas of N Africa, and to have suffered local extinctions in some unmanaged forests.

Bibliography. Benson & Benson (1975), Black & Ross (1970), Britton (1980), Brosset (1973, 1977), Brosset & Enard (1980), Brown & Brown (1979), Brown *et al.* (1982), Crabb (1983), Ginn *et al.* (1989), Grimes (1987), Hart (1977), Hartley (1976), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957–1973), Maclean (1993), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Simmons (1986a), Snelling *et al.* (1984), Steyn (1982), Tarboton & Allan (1984), Tarboton *et al.* (1978), Thiollay (1978c), Thomson (1991a)

141. Henst's Goshawk

Accipiter henstii

French: Autour de Henst

German: Madagaskarhabicht

Spanish: Azor Malgache

Other common names: Madagascar Goshawk

Taxonomy. *Astur henstii* Schlegel, 1873, Madagascar.

May form superspecies with *A. gentilis*, *A. melanoleucus* and even *A. meyerianus*. Monotypic.

Distribution. Madagascar.

Descriptive notes. 52–62 cm. Both sexes have upperparts brownish grey with underparts finely barred greyish brown and white; pale stripe above the eye distinctive. Remarkably similar to Eurasian *A. gentilis*, but eye yellow; also shows fairly similar colours and markings to rare sympatric *Eutriorchis astur*, but has white supercilium and rather different structure. Female larger than male. Juvenile with large brown spots on tan underparts.

Habitat. Primary rain forest of E and dry forest of W up to 1800 m; sometimes in secondary woodland.

Food and Feeding. Larger forest birds, some poultry and small mammals; suspected to take some lemur species. Spends long periods perched within cover; probably mainly perch-hunts, but also flies swiftly through forest. Rarely soars above canopy.

Breeding. Laying Oct–Nov. Large nest of sticks placed in main fork of large tree, even in an exotic eucalypt plantation. Adults noisy around nest. Chicks have white down; no further details recorded.

Movements. None recorded.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Known from forests of E and W coasts but not from drier S. Generally rare; only seen twice during 18 months of recent field work. Vulnerable to deforestation, and may deserve increased conservation attention.

Bibliography. Benson *et al.* (1976), Dee (1986), Langrand (1990), Langrand & Meyburg (1984), Milon *et al.* (1973), Wattel (1973).

142. Northern Goshawk

Accipiter gentilis

French: Autour des palombes

German: Habicht

Spanish: Azor Común

Taxonomy. *Falco gentilis* Linnaeus, 1758, (Swedish) Alps.

May form superspecies with *A. melanoleucus*, *A. henstii* and even *A. meyerianus*. Internal taxonomy somewhat confused. American races may merit treatment as distinct species. Separate races have been awarded to birds from W & C Europe (*gallinarum*), Spain and N Africa (*kleinschmidtii*), SE Europe (*marginatus*), and SW USA and NW Mexico (*apache*), but of doubtful validity, as at least some of variation clinal; many other dubious races described. Eight subspecies currently recognized.

Subspecies and Distribution.

A. g. gentilis (Linnaeus, 1758) - Europe and extreme NW Africa.
A. g. arrigonii (Kleinschmidt, 1903) - Corsica and Sardinia.
A. g. buteoides (Menzies, 1882) - extreme NE Eurasia, from N Sweden E to R Lena; winters S to C Europe and C Asia.
A. g. albidus (Menzies, 1882) - NE Siberia to Kamchatka.
A. g. schvedowi (Menzies, 1882) - Asia, from Urals to Amurland, Sakhalin and Kuril Is, S to C China; winters S to Himalayas and N Indochina.
A. g. fujiyamae (Swann & Hartert, 1923) - Japan.
A. g. atricapillus (Wilson, 1812) - North America, S to Tennessee and S Arizona (USA) and Jalisco (W Mexico).
A. g. laingi (Taverner, 1940) - Queen Charlotte Is and Vancouver I, British Columbia (W Canada).

Descriptive notes. 48–68.5 cm; male 517–1170 g, female 820–1509 g; wingspan 96–127 cm. Conspicuous white supercilium. Differs from *A. henstii* in reddish orange iris, and generally weaker barring on underparts. Male larger and stockier than female of *A. nisus*; less heavily barred below; tail proportionally shorter, not square-ended. Female considerably larger than male; browner grey above; iris yellowish orange. Juvenile brown above, pale buff to whitish and streaked below; supercilium less distinct; iris yellow until c. 4th year. Considerable geographical variation, with races separated on size, coloration and

plumage pattern, but much variation clinal; palest forms from boreal zone of Palearctic; race *albidus* polymorphic.

Habitat. Mature woods, particularly coniferous, but also deciduous or mixed; mostly near edges of wood. Both lowlands and mountainous areas, from sea-level up to mountainous subalpine woods; widespread across taiga N to tree line. Greatly favours clearings, due to greater variety and availability of prey; maximum densities in areas where cultivation interspersed with patches of forest, with as little as 15% tree cover overall. Sometimes in town parks or in small woods in essentially treeless areas.

Food and Feeding. Small and medium-sized birds and mammals, up to size of grouse, even capercaillies and hares; other vertebrates normally of minor importance, although lizards important in C Spain. Not specialized, and relative importance of birds or mammals varies from one region to another and even between seasons: in boreal regions, Tetraonidae (grouse, etc.) are fundamental, accounting for up to 80% of prey, particularly for chicks and juveniles; in North America, ground squirrels and sometimes hares very important; in parts of Europe with fairly extensive agriculture, partridges, pheasants and rabbits predominate. Wide range of small and medium-sized birds of varying importance in diet: pigeons (up to 30% or more in C Europe), corvids, thrushes and starlings, many nesting and fledgling birds during breeding season. Hunts from hidden perch or with inconspicuous surveying flight; prey mainly caught on ground, typically in clearings and around edges of woods.

Breeding. Laying in Apr and early May. Solitary; neighbouring pairs normally several kilometres apart, rarely less than 1 km. Nests in large trees; nest built in fork, or on branch near trunk or touching it; up to 20+ m above ground; built by both adults with sticks, lined with twigs and fresh leaves. Normally various nests (up to 6) per nesting territory, but often same nest used at least 2 years running. 1-5 eggs, normally 3-4; replacement laying occurs; incubation 35-38 days per egg, almost exclusively by female; most food brought by male; female feeds chicks and also hunts, near nest, during second half of breeding period; chicks have greyish white first and second down; fledging 34-37 days (males) or 37-41 days (females); independent at 70-90 days, females c. 1 week later than males. In North America, nest vigorously defended against intruders, including man. Sexual maturity at 2-3 years, sometimes at 1 year old (especially females). Heavy failure rate, and loss of 40% of clutches not uncommon, partly due to destruction or robbing of nests by man; average 1.4-3.1 chicks fledge per successful pair. Oldest recorded bird 19 years.

Movements. Mainly sedentary; partially migratory in northernmost populations of North America. Fenno-Scandia and Russia. Scale and extent of movements dictated by cycles of prey abundance in Arctic regions. Irruptions occur roughly every decade in North America, with birds reaching S USA and N Mexico. In Fenno-Scandia, movements far less extensive, not normally involving more than a few hundred kilometres. Migrants leave N areas mainly in Oct-Nov, returning to breeding zones in Mar-Apr.

Status and Conservation. Not globally threatened. CITES II. Significant decline in Europe during 19th century and part of 20th, mainly due to persecution and deforestation; subsequent trends generally less regular, but sharp drop in 1950's and 1960's, particularly in W Europe, linked with pollution by pesticides and heavy metals. Despite continued persecution and nest robbing for falconry, in 1980's and 1990's species tending towards stabilization or recovery; numerous and increasing in much of former USSR; population of North America apparently stable overall. Regional recolonization, notably in Britain, where species extinct from 19th century; re-established in late 1960's, apparently from escaped or released falconers' birds; also favoured by reforestation, both natural and managed, e.g. in Ukraine, expanding towards S in plantations. Only rough figures available, including, in early 1990's: 70,000 pairs in European Russia; 4500-5000 pairs in Byelorussia; no more than 100 pairs in Azerbaijan; 1000-1500 pairs in Bulgaria; c. 2300 pairs in Austria. Figures from 1980's for other sizeable European populations: 2300-3000 pairs in Spain; 3000-4500 pairs in France; 1500-1800 pairs in Netherlands; 4200-4700 pairs in Germany; c. 8000 pairs in Poland; c. 2000 pairs in Czechoslovakia; c. 1500 pairs in Hungary; 2000-3000 pairs in Norway; 5000 pairs in Sweden; 6000 pairs in Finland. Only a few dozen pairs in Morocco; 100-250 pairs in Turkey; estimated breeding population of at least 300-480 birds in Japan.

143. Meyer's Goshawk

Accipiter meyerianus

French: Autour de Meyer **German:** Meyerhabicht **Spanish:** Azor de Meyer
Other common names: Papuan Goshawk

Taxonomy. *Accipiter meyerianus* Sharpe, 1878, Anson, Yapen Island.

Possibly forms superspecies with *A. gentilis*, *A. melanoleucus* and *A. henstii*. Geographical variation may exist. Monotypic.

Distribution. Halmahera and Seram (Moluccas) through N & E New Guinea to New Britain and Solomon Is (on Kolombangara and Guadalcanal).

Descriptive notes. 48-56 cm; male 530 g, female 1100 g. Large *Accipiter*, similar to *A. gentilis*, but with black and white much more contrasted. Melanistic plumage in some adults, similar to rare melanistic morph of *Erythrotriorchis buergeri*, but with fewer and more obscure tail bars; present species also has red, as opposed to yellow, eyes. Female larger, more distinctly barred on flight-feathers and underparts. Juvenile mottled brown, with streaked underparts.

Habitat. Hill and montane rain forest, forest edge and adjacent native gardens; near sea-level to at least 2700 m. Nests in forest.

Food and Feeding. Little known. Birds of many species, commonly including Papuan Mountain-pigeon (*Gymnophaps albertisii*); also free-ranging domestic fowl in native villages. Hunts on favoured perches with a wide view; also flies over forest ridges and terraces in early morning when pigeons are feeding and takes them as they fly up, or soars high and stoops on flying pigeon flocks, seizing prey in the air.

Breeding. Season apparently long, from austral winter to early summer: copulation observed late May/early Jun; specimen in breeding condition in Sept; one clutch hatching early Dec; one brood of dependent flying young mid-Aug. Solitary. Nests in very tall trees, including beech (*Nothofagus*). One complete clutch of 3 eggs; both sexes incubate; one fledged brood of 2 young. No further information.

Movements. Unknown; no records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Scarce, and seldom encountered by ornithologists; biology poorly known. Possibly subject locally to effects of deforestation, and to breeding failure through eggshell thinning where DDT used, but data lacking.

Bibliography. Ammann (1964), Beahler *et al.* (1986), Bowler & Taylor (1980), Cates (1985), Danks *et al.* (1994), Diamond (1985), Diamond & LeCroy (1979), Majnep & Bulmer (1977), Mayr (1934), Rand & Gilliard (1967), Watell (1973), White & Bruce (1986).

Genus *ERYTHROTRIORCHIS* Sharpe, 1875

144. Chestnut-shouldered Goshawk

Erythrotriorchis buergeri

French: Autour de Bùrgers **German:** Prachthabicht **Spanish:** Azor de Bùrgers
Other common names: Bùrgers'/Buergers' Goshawk/Sparrowhawk, Chestnut-shouldered Hawk

Taxonomy. *Astur buergeri* Reichenow, 1914, Augusta River, Mäanderberg, New Guinea.

Formerly placed in superficially similar genus *Accipiter*, but now considered closely related to *E. radiatus* and to form part of old endemic Australasian clade (see page 55). Monotypic.

Distribution. N & E New Guinea.

Descriptive notes. 43-53 cm, female larger; male 575 g. Shorter wings, and more pied than congener, lacking rufous on underparts. Rare melanistic morph occurs in some adults, similar to melanistic *Accipiter neovernatus*, but with more and narrower tail bars and yellow eyes. Juvenile rich rufous, marked black, with sooty flight-feathers and tail.

Habitat. Hill and lower montane rain forest from 450 m to 1580 m.

Food and Feeding. Poorly known, but apparently takes mostly birds. Seen pursuing Hooded Butcherbird (*Circus caesus*), and feeding on unidentified bird. Seen perching in tree on ridge before making direct flying attack at distant prey in forest; also hunts by soaring.

Breeding. A fully grown but dependent juvenile, emitting begging calls, observed in Oct. No further information.

Movements. Unknown; no records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Scarce, and seldom encountered by ornithologists; biology unknown. Likely to be affected by deforestation, and by breeding failure through eggshell thinning where DDT used, but data lacking.

Bibliography. Andrew (1992), Beahler (1978), Beahler *et al.* (1986), Coates (1985), Debus & Edelman (1994), Debus *et al.* (1994), Diamond (1972, 1985), Rand & Gilliard (1967), Schodde (1993), Watell (1973).

145. Red Goshawk

Erythrotriorchis radiatus

French: Autour rouge **German:** Fuchshabicht **Spanish:** Azor Rojo

Taxonomy. *Falco radiatus* Latham 1801, Sydney, New South Wales.

Has been merged in *Accipiter*, but recent studies show it to be unrelated to that genus; now regarded as part of old endemic Australasian clade (see page 55). Proposed race *rufifrons* invalid. Monotypic.

Distribution. N & E Australia, from Kimberley's round to N New South Wales.

Descriptive notes. 46-61 cm; male 630-640 g, female 1110-1370 g; wingspan 111-136 cm. Longer wings, and adult plumage generally more rufous than in *E. buergeri*. Superficially like *Accipiter*, but has loose, streaky plumage, occipital crest, longer wings, and very powerful legs and feet. Female much larger, with whiter underparts. Juvenile more rufous, particularly on head and breast.

Habitat. Coastal and sub-coastal open forest and woodland, often riparian, in tropics and subtropics; from sea-level to c. 1000 m. Nests in forest and tall woodland, near water.

Food and Feeding. Mostly birds, particularly

parrots and pigeons; sometimes herons, ducks, cockatoos (*Calyptorhynchus*), large kingfishers (*Dacelo*); occasionally megapodes (*Alectura*) of up to 2000 g. Rarely mammals, including fruit-bat (*Pteropus*) and young hare; also reptiles (snakes, lizards) and large insects. Forages by short-stay perch-hunting from concealed position in trees, early and late in day; long gliding or flapping transects and low quartering through, or just above, tree canopy; also high soaring flight, in middle of day. Often seizes prey in flight after stealthy glide or direct flying attack that becomes vigorous chase; also stoops on prey from a height.

Breeding. May-Oct in N, Aug-Oct in E Australia. Solitary. Usually monogamous; one male possibly bigamous with females in neighbouring territories. Platform of sticks 60-120 cm wide and 30-50 cm deep, lined with green leaves; placed 15-29 m above ground in exposed fork of tallest emergent living or partly dead tree. Usually 2 eggs (1-2); incubation 39-43 days; chicks have white down; fledging 51-53 days for males (probably slightly longer for females); post-fledging dependence of at least 10-11 weeks. Sexual maturity probably at 2 years or older, no breeding in juvenile plumage. Success 0.9 young fledged per attended nest, 1.3 per successful nest; nests and young sometimes destroyed by bush fires.

Movements. Poorly known. Breeding adults sedentary, though may expand home range in non-breeding season; regularly ranges 8-10 km from nest. Juveniles apparently dispersive, as inferred from sightings up to 500 km from known breeding sites.

Status and Conservation. VULNERABLE. CITES II. Scarce, with specialized requirements, and locally restricted within continental range declining, with contraction of breeding range in E Australia through habitat loss. Total population estimated at c. 350 breeding pairs, most of which occur in N. Has low breeding density and recruitment rate. Breeding success is threatened through egg-collecting, and locally by disturbance from birdwatchers and photographers at nests. Probably affected locally by DDT use (now ceased), but insufficient data to assess changes in eggshell thickness. Conservation measures required include monitoring of known breeding territories in N Australia; also survey in E Australia to locate breeding territories, which should subsequently be secured and monitored.

Bibliography. Andrew (1991), Ammann & Baker-Gibb (1991), Blakers *et al.* (1984), Brickhill (1991), Cullar & Andrew (1988), Debus (1991c, 1993b), Debus & Czechura (1988a, 1988b), Debus, McAllan & Mead (1993a, 1993b).

Garnett (1992), Marchant & Higgins (1993), Olsen (1991), Olsen & Marples (1993), Olsen, Crome & Olsen (1993), Schodde (1993), Schodde & Tidemann (1988), Smith, L.E. (1991).

Genus *MEGATRIORCHIS*

Salvadori & D'Albertis, 1875

146. Doria's Hawk

Megatriorchis doriae

French: Autour de Doria **German:** Salvadorihabicht **Spanish:** Azor de Doria
Other common names: Doria's Goshawk

Taxonomy. *Megatriorchis doriae* Salvadori and D'Albertis, 1875, Yule Island, New Guinea. Has frequently been merged into superficially similar genus *Accipiter*, but now considered part of old endemic Australasian clade, related instead to *Erythrotriorchis* and others (see page 55). Monotypic.

Distribution. New Guinea; also recorded on Batanta I, off NW New Guinea.

Descriptive notes. 51-69 cm, female larger; female 1000 g. Distinctively barred and streaked; has powerful legs and feet like *Accipiter*, but shorter wings. Juvenile slightly paler and more rufous, lacks mask; may have pale head.

Habitat. Lowland and hill rain forest, monsoon forest and mangroves; also seen at interface between disturbed forest and secondary scrub; occurs from sea-level to 1650 m.

Food and Feeding. Little known. Birds, including Lesser Bird-of-paradise (*Paradisaea*

minor); also seen repeatedly snatching small (invertebrate?) prey from outer foliage. Spends much time inside forest canopy, where perches for long periods; waits in ambush at sites attractive to prey, e.g. flowering trees, or bird-of-paradise leks. Occasionally flies by forest edge or low over canopy.

Breeding. No information available.

Movements. Unknown, but presumably sedentary, as inferred from short wings and infrequent, slow flight; no records outside normal range.

Status and Conservation. Not globally threatened. CITES II. Scarce, and seldom encountered by ornithologists; biology unknown. Possibly affected by deforestation and DDT use in lowlands.

Bibliography. Andrew (1992), Beehler *et al.* (1986), Bishop (1986), Coates (1985), Diamond (1972), Finch (1981), Rand & Gilliard (1967), Schodde (1993).

Genus *UROTRIORCHIS* Sharpe, 1874

147. Long-tailed Hawk

Urotriorchis macrourus

French: Autour à longue queue **German:** Langschwanzhabicht **Spanish:** Azor Rabilargo

Taxonomy. *Astur macrourus* Hartlaub, 1855, Dabocrom, Ghana.

Monotypic genus, apparently very close to *Accipiter*, with which has been merged; has also been linked with other endemic African genera, *Melierax* and *Kaupifalco*. Invalid race *batesi* proposed for populations from Cameroon eastwards. Monotypic.

Distribution. Liberia E to W Uganda and S to SW & C Zaire.

Descriptive notes. 65-70 cm; male 492 g. Long, graduated tail with large white spots and white rump. Superficially similar in structure to Australasian *Megatriorchis*, but aspects of colour and behaviour recall chanting-goshawks (*Melierax*). A melanistic morph has been claimed to exist and even depicted, but is apparently unsubstantiated. Female larger than male. Juvenile variably marked below, sometimes with large spots typical of several African *Accipiter* and *Aviceda* species; others almost unmarked, possibly in an intermediate plumage, with fine white bars on underparts.

Habitat. Lowland tropical evergreen forest; ventures into adjacent gallery forest and also secondary forest.

Food and Feeding. Known to take squirrels, bats and rodents; stout legs and feet suggest preference for mammalian prey, but also takes some birds. Long tail permits agile pursuit around and among branches. Hunts more often at low levels in understorey than in forest canopy, sometimes near ground level along logging tracks. Difficult to observe, but will cross clearings and descend to ground; accused of taking some free-range poultry.

Breeding. Nesting habits undescribed. Adult seen feeding newly fledged juvenile in Sept, in Sierra Leone; probably Jul-Aug in Cameroon, based on condition of gonads in collected specimen. Calling within forest may reveal presence.

Movements. Resident and sedentary.

Status and Conservation. Not globally threatened. CITES II. Secretive but widely recorded from primary forest; restricted to large tracts of dense forest, although readily occurs at edge of clearings. Much affected by deforestation, due to intolerance of secondary habitats, and has probably decreased considerably throughout much of W Africa. Not uncommon in Sierra Leone; widespread and common in Ghana. Not known to be affected by pesticides.

Bibliography. Bannerman (1953), Brosset & Erard (1986), Brown *et al.* (1982), Cockburn (1946), Ferguson-Lees & Faull (1992), Gatter (1988), Grimes (1987), Kemp (1986), Lippens & Wille (1976), Mackworth-Præd & Grant (1957, 1970), Pinto (1983), Serle *et al.* (1977), Snow (1978).

Genus *BUTASTUR* Hodgson, 1843

148. Grasshopper Buzzard

Butastur rufipennis

French: Busatour des sauterelles **German:** Heuschreckenteesa **Spanish:** Busardo Langostero

Taxonomy. *Poliornis rufipennis* Sundevall, 1851, Khartoum, Sudan.

Only African member of genus, forming superspecies with Asian *B. teesa*, *B. liventer* and *B. indicus*. Monotypic.

Distribution. Senegambia E to Ethiopia, migrating S to Sierra Leone, Cameroon, NE Zaire, Kenya and N Tanzania.

Descriptive notes. 35 cm; male 310-342 g, female 300-383 g. Rufous wing-coverts and underparts distinctive at all ages. Sexes indistinguishable. Juvenile with head and neck also rufous and darkly streaked below.

Habitat. Ranges from woodland and forest edge to arid thorn savanna; sometimes on edges of swamps and over burnt ground.

Food and Feeding. Mainly insects, especially grasshoppers, together with mantids, termite and ant alates, beetles, stick insects and spiders. Will take some other arthropods and a few small birds, reptiles and rodents. Breeding diet unstudied. Often gregarious in flocks

of 50-100 birds. Hunts from a low perch (on average 6 m up), taking 95% of prey from the ground, and hawking the remainder on the wing with buoyant flight; recorded catching some 0.2-1.6 items/hour. Attracted in flocks to fires, newly burnt areas and insect emergences; also follows flocks of egrets or herds of game for the insects they flush.

Breeding. Laying during rainy season: Mar-Apr across Sahel zone. Probably disperses to breed in territorial pairs. Builds substantial stick nest in fork of tree, often rather low down and lined with green leaves. 1-3 eggs; further details unrecorded.

Movements. A widespread and common intra-African sub-Saharan migrant, moving across 22° of latitude, S to the border of Guinea woodland and forest during the Oct-Mar dry season, when fires and grazing reduce cover, then departing N with first heavy rains to breed in semi-arid steppe during Mar-Sept. Also non-breeding migrant to E Africa, moving N through Taru Desert of lowland Kenya in Jan-Mar, and through NW Somalia in Sept-Oct. Well studied only on non-breeding range of W Africa.

Status and Conservation. Not globally threatened. CITES II. Locally abundant in several areas of W Africa during dry season, outnumbering all other raptors but *Milvus migrans*. Vulnerable to overgrazing and drought in Sahel zone, but nomadic to take advantage of local situations of plentiful prey. Recent decline in non-breeding visitors to Kenya. Not known to be affected by pesticides, but may be vulnerable to spraying for locusts.

Bibliography. Brown *et al.* (1982), Chapin (1932), Gore (1990), Grimes (1987), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957-1973), Rasa (1987), Thiollay (1975a, 1975b, 1975c, 1976a, 1976b, 1977b, 1977c, 1978a, 1978c, 1985d), Thiollay & Clobert (1990).

149. White-eyed Buzzard

Butastur teesa

French: Busatour aux yeux blancs **German:** Weißaugenteesa **Spanish:** Busardo Tisa
Other common names: White-eyed Buzzard-Eagle

Taxonomy. *Circus Tessa* Franklin, 1831. Further India = Ganges and Narmada Rivers.

Forms superspecies with *B. rufipennis*, *B. liventer* and *B. indicus*. Monotypic.

Distribution. SE Iran, Afghanistan and Pakistan through India and Nepal to Burma (S to Tenasserim).

Descriptive notes. 36-43 cm; 325 g; wingspan 86-96 cm. Small greyish brown buteo-like raptor; striking white eye and rufous brown upper side of tail; white throat with wide dark central stripe; small to large white patch on nape; very variable pale patches on upwing-coverts can be extensive, and frequently conspicuous when bird is perched. Juvenile similar to adult, but paler on head and less heavily marked below.

Habitat. Dry, open country and cultivated areas in lowlands up to 300 m in Himalayas; occasionally higher.

Food and Feeding. Small mammals, lizards, frogs, snakes, crabs and large insects; occasionally birds. Hunts from perch, making short flights to ground to capture prey.

Breeding. Season Feb-May throughout range. Loose, unlined, crow-sized nest built by pair 8-12 m up tall tree, often in grove or village. Display flights as such unreported, but accounts of pair soaring over territory constantly calling may constitute display. Usually 3 eggs (2-4); incubation by female only, reported to last 19 days, but probably much longer; chicks have white down, buff-coloured on back; both parents feed young; fledging and dependency periods unrecorded.

Movements. Mainly sedentary. Some local movements in N Pakistan, in region of border with Afghanistan. Vagrant to Tibet.

Status and Conservation. Not globally threatened. CITES II. Common to fairly common locally; abundant in Pakistan. Over 100 birds seen at Sariska Tiger Reserve, Rajasthan (NW India), in 1989, during period of rodent abundance, but few recorded at same site in 1990. No threats known at present.

Bibliography. Ali & Ripley (1978), Cheng Tso-hin (1987), Clark & Schmitt (1992), Inskipp & Inskipp (1985), King *et al.* (1975), Meyer de Schauensee (1984), Roberts (1991), Smythies (1986)

150. Rufous-winged Buzzard

Butastur liventer

French: Busatour pâle **German:** Malaienteesa **Spanish:** Busardo Alirrufo
Other common names: Rufous-winged Buzzard-Eagle

Taxonomy. *Falco liventer* Temminck, 1827, Java.

Forms superspecies with *B. rufipennis*, *B. teesa* and *B. indicus*. Monotypic.

Distribution. Burma and SC China (SW Yunnan) S to Indochina and N Malay Peninsula: Java; Sulawesi. Reported occurrence in SE Borneo doubtful; old record of questionable validity from Timor.

Descriptive notes. 35-40 cm; 336-340 g; wingspan 83-91 cm. Small, buteo-like raptor with rufous wings and tail. Juvenile has rufous buff head, neck and underparts.

Habitat. Open country, savanna and scrub; also near rivers and swamps in lowland plains, up to at least 800 m. Sometimes found in towns and villages.

Food and Feeding. Small mammals, lizards, frogs, crabs and insects. Hunts from exposed perch, making short flights to ground to capture prey. Regularly soars.

Breeding. Laying Feb-Mar/Apr in Java; probably Jun-Jul in Sulawesi. Large, solid nest built by pair in crown of large, solitary tree; lined with leaves. Usually 2-3 eggs. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Throughout most of range fairly common to uncommon, but local: rare in Yunnan (SC China) and Java. Not encountered in Java during recent raptor surveys.

Bibliography. Bishop *et al.* (1994), Cheng Tso-hin (1987), Coomans de Ruiter (1947), Deignan (1945), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), Meyer de Schauensee (1984), Smythies (1986), Stresemann (1940a), White & Bruce (1986).

151. Grey-faced Buzzard

Butastur indicus

French: Busatour à joues grises **German:** Kiefernteesa **Spanish:** Busardo Carigrís
Other common names: Frog Hawk

Taxonomy. *Falco indicus* Gmelin, 1788, Java.

Forms superspecies with *B. rufipennis*, *B. teesa* and *B. liventer*. Monotypic.

Distribution. NE China to Amurland and Ussuriland, Japan and Izu Is. Winters from S & SE China and Taiwan through Indochina and Malay Peninsula to Greater Sundas, Philippines, Sulawesi and islands off NW New Guinea.

Descriptive notes. 46 cm. White throat with dark mesial streak; head greyish brown; brown above and on upper breast; rest of underparts, including thighs, whitish, broadly barred brown; eyes, cere, legs and feet yellow. Juvenile generally paler, especially on head and breast; breast streaked brown.

Habitat. Wooded areas in proximity of open country, e.g. pastures, peat bogs; often near water, e.g. marshes, paddyfields, etc., in which finds considerable proportion of prey. Prefers low mountains, hills and foothills to absolutely flat land, and mixed woods to unvaried deciduous woods; generally favours

evergreen forest for nesting; perches in: nests in woods.

Food and Feeding. Mainly frogs, reptiles (snakes, lizards), rodents and possibly birds. Often hunts from perch, typically at top of dead tree, waiting to spot prey and dive down on it; forages mainly in morning and evening.

Breeding. Laying May. Fairly small nest of twigs and sometimes sedges, built in tree, normally conifer, 4-14 m above ground; lined with bits of bark, grass and green leaves, which continue to be added throughout breeding. 2-4 eggs; incubation 28-30 days; fledging 34-36 days; in Ussuriland chicks start to hunt for themselves in second half of Aug.

Movements. Migratory; flocks of thousands of birds sometimes gather. Sets off for winter quarters mainly in Sept. or up to mid-Oct from Japan. Major migration route along Pacific coast of Japan, through Ryukyu Is to Taiwan and S to Philippines (where migration more concentrated in autumn); of 101 ringed birds recovered in Philippines, 99 had been ringed in Ryukyu Is. Also passes through parts of continental E Asia in some numbers, e.g. not uncommon in Korea during both spring and autumn migrations. Returns to breeding grounds in Ussuriland during first half of Apr. and to those in C Honshu (Japan) in late Apr or early May.

Status and Conservation. Not globally threatened. CITES II. Size and trends of populations very poorly known. Not uncommon in Japan, nor perhaps in Ussuriland, where distances of 4-5 km between pairs are normal in large river valleys; however, Russian population apparently undergoing major decline; up to 1000 migrants shot annually on Taiwan. Abundant on migration in various parts of Japan; one of commonest migrant raptors in Thailand

Bibliography. Anon. Genus *GERANOSPIZA* Kaup, 1847

152. Crane Hawk

Geranospiza caerulescens

French: Buse échasse **German:** Sperberweihe **Spanish:** Azor Zancón
Other common names: Blackish Crane-hawk (*nigra*); Grey Crane-hawk (*caerulescens*); Banded Crane-hawk (*gracilis*)

Taxonomy. *Sparvius caerulescens* Vieillot, 1817, Cayenne.

Genus *Ischnosceles* is best regarded as forgotten name. Relation of genus unclear; probably allied to Neotropical sub-buteonines, rather than Afrotropical *Polyboroides*. Substantial geographical variation, with three well defined groups, perhaps approaching separate species status: *nigra* group, including races *livens* and *balzarensis*; *caerulescens* group; and *gracilis* group, including race *flexipes*. However, extensive intergradation between *nigra* group and *caerulescens*. At other extreme, some authorities recognize only two or three races. Six subspecies normally recognized.

Subspecies and Distribution.

G. c. livens Bangs & Penard, 1921 - NW Mexico.

G. c. nigra (Du Bus de Gisignies, 1847) - N Mexico (Sinaloa and Tamaulipas) S to zone of Panama Canal.

G. c. balzarensis W. L. Sclater, 1918 - Panama E of canal zone on Pacific slope to W Colombia, W Ecuador and NW Peru (Lambayeque).

G. c. caerulescens (Vieillot, 1817) - E slope of Colombia and Ecuador to the Guianas and Amazonian Peru and Brazil.

G. c. gracilis (Temminck, 1821) - NE Brazil, from Maranhão, Ceará and Piauí to C Goiás and Bahia.

G. c. flexipes Peters, 1935 - S Brazil (Minas Gerais, S Goiás and Mato Grosso) and Bolivia through Chaco of Paraguay, to NC Argentina (S to La Rioja, Córdoba and Buenos Aires) and Uruguay.

Descriptive notes. 43-51 cm; male 225-358 g, female 273-353 g, maximum 430 g. Very long legs, particularly the tarsometatarsus. Plumage generally bluish grey, slate or blackish; some forms have varied extents of fine white barring below, and sometimes also on upperwing; long, slender tail black with two conspicuous white or buff bands and narrow white tip; prominent white crescent in primaries visible in flight. Superficially recalls Afrotropical *Polyboroides*, but smaller and more lightly built, with relatively longer legs. Tarsi orange red, iris crimson, cere leaden. Female similar, but larger. Immature dark

above, lightly tinged with brown; head streaked with white; below barred with buff on belly and legs. Races separated primarily by overall body colour and amount of vermiculation on wings and underparts: race *livens* similar to *nigra*, but paler; race *balzarensis* similar to *livens*, but smaller; race *flexipes* like *gracilis*, but even more intensively barred.

Habitat. Very adaptable; in lowlands, from dry forest to rain forest, mangroves, wooded savanna or grassland with gallery forest, or tall second growth, often near ponds and marshes. Up to 500 m in Colombia, 730 m in Mexico.

Food and Feeding. Very versatile, feeding on lizards, snakes, frogs, nestling birds and large arthropods (Orthoptera and spiders); one record of a bat. Clings to tree trunk somewhat like a woodcreeper (Dendrocolaptidae); double-jointed leg used for reaching into hollows in trees, and probably also into long, narrow gaps between tight-packed leaves of bromeliads, whither tree frogs retreat; observed hanging upside down plundering bird's nest in palm tree. Sometimes drops from trees to prey on the ground; also feeds on the wing, in forest as well as open country, coursing low in manner of harrier. Sometimes hunts near fires, where prey may be flushed.

Breeding. Laying rather prolonged (Apr-Jun) in Mexico; Jan in Panama; Jul in NE Colombia; mostly rainy season (Jul-Sept) in Venezuela; Apr in Surinam. Nest of sticks and vines, lined with grass, weeds and fine twigs and trimmed with fresh leaves; built in tall trees. Courtship is quite vocal and includes more or less elaborate aerial displays and courtship feeding. 2 eggs. No further information available.

Movements. Unknown, presumably mostly sedentary.

Status and Conservation. Not globally threatened. CITES II. Generally not common, but extensive geographical range and broad habitat tolerance suggest little grounds for immediate concern. In Colombia, widespread but local and rarely common.

Bibliography. Belton (1984), Blake (1977), Bokermann (1978), Burton (1978), Contreras *et al.* (1990), Haverschmidt (1962), Hilty & Brown (1986), Jehl (1968), Lowery & Dalquest (1951), Mader (1981), Meyer de Schauensee & Phelps (1978), Monroe (1968), Olmos (1990a), Ouellet (1991), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), van Rossem (1945), Sick (1985a, 1993), Stud (1964), Smeenk & Smeenk-Enserink (1983), Stiles & Skutch (1989), Sutton (1954), Sutton & Burleigh (1939), Tostain *et al.* (1992), Voous (1969), Wetmore (1965).

Genus *LEUCOPTERNIS* Kaup, 1847

153. Plumbeous Hawk

Leucopternis plumbea

French: Buse plombée **German:** Bleibussard **Spanish:** Busardo Plomizo

Taxonomy. *Leucopternis plumbea* Salvin, 1872, Ecuador.

Forms superspecies with *L. schistacea*, of which it was formerly considered a subspecies. Monotypic.

Distribution. E Panama through W Colombia and W Ecuador to extreme NW Peru.

Descriptive notes. 35-37 cm. Leaden grey overall; wings black, single conspicuous white or greyish band through black tail; underwing-coverts white; thighs finely barred with white. Iris brownish

orange, cere and legs yellowish orange. Rather smaller than closely related *L. schistacea*, differing also in colour of bare parts and underwing-coverts. Female similar to male, but averages very slightly larger. Immature has more conspicuous barring on thighs and faint grey mottling on belly.

Habitat. Tropical rain forest in lowlands and foothills, up to 800 m. Not known to soar.

Food and Feeding. Little known: frogs, crabs, fish and water snakes. Hunts along banks of rivers and lakes; probably captures prey mainly by perch-hunting.

Breeding. No information available.

Movements. No information available; presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Status very poorly known, but in general rare to uncommon. May have been extirpated from W Panama; apparently rare in Colombia. Low density and relatively restricted range in a region where deforestation is on the increase are grounds for concern; surveys and research required.

Bibliography. Amadon (1982b), Blake (1977), Brown & Amadon (1968), Collar & Andrew (1988), Davis (1972), Hilty & Brown (1986), Ridgely & Gwynne (1989), Ruschi (1979), Sick (1985a, 1993), Wetmore (1965).

154. Slate-coloured Hawk

Leucopternis schistacea

French: Buse ardoisée **German:** Schieferbussard **Spanish:** Busardo Pizarroso

Taxonomy. *Asturina schistacea* Sundevall, 1851, Brazil.

Previously placed in *Buteogallus*. Forms superspecies with *L. plumbea*, with which it has been considered conspecific. Monotypic.

Distribution. Amazonia, from SE Colombia and SW Venezuela S through E Ecuador and E Peru to N & E Bolivia, and E to E French Guiana and CN Brazil.

Descriptive notes. 39-43 cm; female 455 g. Dark leaden grey; blackish on head and wings; tail black, narrowly tipped white, with a bold white bar; underwing-coverts blackish. Iris, cere and feet yellowish red. Larger than closely related *L. plumbea*, differing also in colour of bare parts and underwing-coverts. Female similar to male, but averages very slightly larger. Immature has belly, thighs and underwing finely barred with white.

Habitat. Tropical lowland forest, up to 500 m in Colombia; usually near swamps or streams in várzea forest; frequents mangroves, occurring in more advanced successional stages than *Buteogallus*; also lagoons, rivers and gallery forest in S llanos of Venezuela. Rarely, if ever, soars.

Food and Feeding. Snakes and frogs recorded. Observed attacking troops of squirrel monkeys, and also Cock-of-the-rock (*Rupicola*) leks. Usually perches at medium or low levels alongside forest streams, dropping down to catch prey beside water, without entering water.

Breeding. No information available.

Movements. Presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Generally fairly common. Status uncertain, but extensive range suggests there is no need for immediate concern; surveys required to assess situation more definitely. Biology very poorly known.

Bibliography. Amadon (1982b), Blake (1977), Brown & Amadon (1968), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Pinto (1964), Remsen & T aylor (1989), Sick (1985a, 1993), Terborgh (1983), Tostain (1986b), Trail (1987).

155. Barred Hawk

Leucopternis princeps

French: Buse barrée **German:** Prinzenbussard **Spanish:** Busardo Azoreño

Taxonomy. *Leucopternis princeps* P. L. Sclater, 1865, Costa Rica.

Populations of Ecuador and Colombia have been assigned to separate race, *zimmeri*, on grounds of differences in size, but this is unsubstantiated. Monotypic.

Distribution. Costa Rica and Panama, and locally into W Colombia and N Ecuador on both sides of the Andes.

Descriptive notes. 55-59 cm; c. 1000 g. Black above and below on throat and upper breast; feathers of crown, nape and mantle edged bluish slate; belly and underwing-coverts white, finely barred with black. Cere and legs bright yellow. Much smaller than *Geranoaetus melanoleucus* and quite different shape; occurs in totally different habitat. Female similar, but marginally larger than male. Immature has white edging to upperwing-coverts.

Habitat. Mountain forests, from foothills up to subtropical zone; rare in coastal plains of Colombia. Conflicting reports on altitudinal

preferences: in SE Ecuador and NW Colombia, primarily 1200-2225 m, and rarely below 1000 m; but elsewhere reported mainly from 300-1800 m in Colombia. Associated more with natural or man-made clearings and forest edge than with extensive tracts of undisturbed forest. Often soars over forest, sometimes in groups of 3-4.

Food and Feeding. Assumed to feed on reptiles, but this is apparently based on only 1 prey record, a snake. Perch-hunts within forest, sometimes at low level.

Breeding. No information available.

Movements. Presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Too little known to permit accurate assessment of status, but propensity to use forest edge suggests it is not a species of imminent concern. Conspicuous, due to habit of soaring, and relatively frequently seen within its altitudinal range at one site in NW Colombia.

Bibliography. Amadon (1982b), Blake (1977), Brown & Amadon (1968), Davis (1972), Hilty & Brown (1986), Ridgely & Gwynne (1989), Robbins *et al.* (1987), Slud (1964), Stiles & Skutch (1989), Thiollay (1991a), Wetmore (1965).

156. Black-faced Hawk

Leucopternis melanops

French: Buse à face noire **German:** Zügelbussard **Spanish:** Busardo Carinegro

Taxonomy. *Falco melanops* Latham, 1790, Cayenne.

Forms superspecies with *L. kuhli*. Monotypic.

Distribution. The Guianas and Amazonia N of Amazon R to E Colombia and E Ecuador. Specimens from R Tapajós (S of Amazon) may refer to *L. kuhli*.

Descriptive notes. 38-41.5 cm; 297-317 g. Head, upper back and neck white, streaked black; wings and tail black, with wing-coverts and scapulars boldly marked white; single narrow white band across middle of tail; underparts entirely white. Eye grey or tan, legs and cere yellow or orange-yellow. Separated from similar congeners by tail pattern: from *L. kuhli* by head pattern. Female similar to male, but larger. Immature has only very faint dark streaking on head and neck; brownish margins to feathers of back and upperwing.

Habitat. Lowland rain forest; may favour dense vegetation along rivers and mangroves.

Never soars over forest.

Food and Feeding. Very few data available, but probably reptiles to a greater or lesser extent. One bird observed eating snake on ground, having first removed head; another record of a lizard as prey; also seen preying on nestling dove.

Breeding. No information available.

Movements. No information available; presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Status very poorly known. Apparently rare throughout, but very secretive and often overlooked; most of forest in extensive range persists, so probably not a species of immediate concern.

Bibliography. Amadon (1964, 1982b), Blake (1977), Brown & Amadon (1968), Hilty & Brown (1986), Meyburg (1986), Meyer de Schauensee & Phelps (1978), Pinto (1964), Sick (1985a, 1993), Snyder (1966), Thiollay (1989a).

157. White-browed Hawk

Leucopternis kuhli

French: Buse à sourcils blancs **German:** Weißbrauenbussard **Spanish:** Busardo Cejiblanco

Taxonomy. *Leucopternis Kuhli* Bonaparte, 1850, no locality = Pará, Brazil.

Forms superspecies with *L. melanops*, with which has been considered conspecific, but the two may be sympatric on lower R Tapajós, Brazil (validity of *melanops* specimens from Tapajós have been questioned). Monotypic.

Distribution. E Peru (C Loreto S to Madre de Dios), N Bolivia (Pando) and Amazonian Brazil S of R Amazon (from R Madeira E to E Pará).

Descriptive notes. 37-40 cm. Dark head with narrow white eyestripe. Black above with some white streaks or splotches on nape and mantle, and single narrow white band through tail; all white below, except grey wingtips boldly barred black. Iris brown or reddish brown, cere, legs and feet orange. Female similar to male, but larger.

Habitat. Tropical rain forest in lowlands.

Food and Feeding. Very little known: a snake and a lizard reported. Hunts near the forest floor.

Breeding. No information available.

Movements. No evidence of any movements.

Status and Conservation. Not globally threatened. CITES II. Very poorly known, but so much forest in its extensive range remains intact that species can not be considered of immediate concern. Surveys and research required.

Bibliography. Amadon (1982b), Blake (1977), Brown & Amadon (1968), Dunning (1982), Remsen & T aylor (1989), Robbins *et al.* (1991), Sick (1985a, 1993).

158. White-necked Hawk

Leucopternis lacernulata

French: Buse lacernulé **German:** Weißhalsbussard **Spanish:** Busardo Cuelliblanco

Taxonomy. *Falco lacernulatus* Temminck, 1827, Rio de Janeiro, Brazil.

Probably most closely allied to *L. kuhli* and *L. melanops* of Amazonia. Monotypic.

Distribution. E Brazil, from Alagoas and S Bahia to São Paulo and Santa Catarina.

Descriptive notes. 43-48 cm; wingspan 96 cm. Head and underparts white; upperparts dark; tail black, with thick white bar. Iris brown or pale yellow, legs and feet yellow. Tail pattern separates from congeners. Female similar, but larger. Immature like adult, but with dark streaks on crown and nape; rufous brown tips to wing-coverts and scapulars; irregular white barring on basal half of tail.

Habitat. Dense primary Atlantic forest, occurring at lower altitudes in valleys. Will perch in the canopy, but most often seen in the middle storeys of the forest.

Food and Feeding. Very few data available; apparently a broad generalist, as prey recorded includes reptiles (e.g. snakes), mammals, birds, snails, insects (ants, beetles, Orthoptera) and large spiders;

arthropods may predominate. Prey taken on the ground. Follows army ants, preying on flushed insects.

Breeding. No information available.

Movements. Sedentary.

Status and Conservation. VULNERABLE/RARE. CITES II. Although reported in a number of protected reserves, species should be considered vulnerable owing to low population densities, significant distances between protected areas, and massive deforestation of its habitat outside protected areas. Shooting is also a threat. Surveys and research required.

Bibliography. Albuquerque (1986), Amadon (1964,

159. Semiplumbeous Hawk

Leucopternis semiplumbea

French: Buse semiplombée **German:** Möwenbussard **Spanish:** Busardo Semiplomizo

Taxonomy. *Leucopternis semiplumbeus* Lawrence, 1861, Caribbean slope of Panama.

Monotypic.

Distribution. Honduras S to W Colombia (E to Magdalena Valley) and NW Ecuador (Esmeraldas).

Descriptive notes. 31-35 cm; male 250 g, female 325 g. Small, stocky *Leucopternis* with distinctive plumage and yellow eye. Above entirely lead grey, blackish on wings and tail; tail has one, or sometimes two, narrow white bands; below immaculate white but with wingtips grey, barred dusky. Eye bright yellow, cere reddish orange, legs and feet orange or reddish orange. Female similar, but somewhat larger. Immature has entire breast narrowly streaked dark grey; tail sometimes with three white bands.

Habitat. Humid forests of tropical and lower subtropical zones; forest edge, in and around

forest fragments, and in tall second growth in Colombia. Very rarely soars.

Food and Feeding. Little known: lizards and snakes; one record of an *Ameiva* lizard; reported attacking birds at an army ant swarm, but presumably also feeds on arthropods fleeing from the ants.

Breeding. One anecdotal record from Costa Rica in Jan: nest building in crown of a tall tree.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Perhaps of little concern at present, as is the commonest hawk in some areas of primary forest, and is tolerant of second growth.

Bibliography. Amadon (1982b), Blake (1977), Brown & Amadon (1968), Davis (1972), Hilty & Brown (1986), Monroe (1968), Ridgely & Gwynne (1989), Slud (1964), Stiles & Skutch (1989), Thiollay (1991a), Wetmore (1965).

160. White Hawk

Leucopternis albicollis

French: Buse blanche **German:** Schneebussard **Spanish:** Busardo Blanco

Taxonomy. *Falco albicollis* Latham, 1790, Cayenne.

Forms superspecies with *L. occidentalis* and *L. polionota*, both of which have been considered races of present species. Four subspecies recognized.

Subspecies and Distribution.

L. a. ghiesbreghtii (Du Bus de Gisignies, 1845) - S Mexico (Oaxaca and Veracruz) to Guatemala and Belize.

L. a. costaricensis W. L. Slater, 1919 - Honduras to Panama and W Colombia.

L. a. williaminae Meyer de Schauensee, 1950 - NW Colombia (upper Sinú and lower Magdalena Valleys S to Valle) and extreme NW Venezuela (Perijá).

L. a. albicollis (Latham, 1790) - E Colombia, NW Venezuela (NW Zulia), Trinidad and the Guianas through Amazonia to E Peru, E Ecuador, N & E Bolivia (La Paz, Santa Cruz) and C & E Brazil (C Mato Grosso and N Maranhão).

Descriptive notes. 47-51 cm; male 600-650 g, female 710-855 g. Remarkable variation in plumage between subspecies: ranges from almost entirely white to mostly black above, white below. Underparts invariably white; wings-coverts and back vary from all white to all black with narrow white scalloping; flight-feathers black; tail either all white with thick or thin black subterminal band, or mainly black with white tip. Legs yellow, cere dark grey; race *ghiesbreghtii* has brown eyes, not yellow as generally stated. Female similar but larger. Immature tends to have variable amounts of dusky streaking, especially on

head: some males and immatures of race *ghiesbreghtii* more heavily flecked with black on wings than females. Races separated on plumage.

Habitat. Tropical and occasionally subtropical rain forest, up to 1400 m in Colombia; uses forest edge and also pastures with isolated trees. Regularly soars over the forest.

Food and Feeding. Reptiles (many snakes), amphibiae, caecilians, amphibians, small mammals, large insects and fish; one record of a toucan. In the Petén, well over half of identified prey items were reptiles, followed in numerical importance by mammals, birds, insects and amphibians. Hunts from a perch, often at the forest edge. Soars and perches conspicuously over the forest

Breeding. In Petén, courtship begins in Feb. with eggs laid in Mar (middle of dry season), fledging at beginning of rainy season; nests in Mar in Panama and Trinidad. Stick nest, average 50-90 cm wide, in tall tree, sometimes on bromeliads. 1 egg; incubation 34-36 days; 1 young fledged at 88 days. One fully-fledged immature, apparently of previous year's breeding effort seen begging for food near a nest; this suggests there may be an extended dependency period, as in other Neotropical raptors, resulting in breeding only every other year following a successful nesting effort. Breeding adult male used home range of 208 ha; a non-breeding bird used a home range of 46 ha.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. In no apparent danger: one of the commonest and most conspicuous forest raptors, occurring over a vast range; tolerates areas of disturbed forest. Apparently local in Colombia, where only known to be fairly common in extreme E. along R Orinoco.

Bibliography. Amadon (1964, 1982b), Blake (1977), Draheim (1993), Draheim & Barrera (1992), Draheim *et al.* (1991), French (1973, 1992), Herklots (1961), Hilty & Brown (1986), Lamm (1974), Meyer de Schauensee & Phelps (1978), Monroe (1968), Pinto (1964), Ridgely & Gwynne (1989), Sick (1985a, 1993), Slud (1964), Stiles & Skutch (1989), Terborgh & Weske (1975), Thiollay (1989a, 1989b), Voous (1969), Wetmore (1965).

161. Grey-backed Hawk

Leucopternis occidentalis

French: Buse à dos gris **German:** Graurückenbussard **Spanish:** Busardo Dorsigrís

Taxonomy. *Leucopternis occidentalis* Salvin, 1876, western Ecuador.

Has been considered a race of *L. albigollis*, to which it is closely allied; forms superspecies with *L. albigollis* and *L. polionota*. Monotypic.

Distribution. W Ecuador and adjacent NW Peru. Single record from E Andean slope now questioned by its authors.

Descriptive notes. 45-48 cm; female 660 g. Above blackish grey; head grey, nape streaked with white; tail white with broad black subterminal band. Iris dark brown, legs pale yellow. Separated from most congeners by tail pattern; from *L. albigollis williaminae* by grey head. Female similar, but slightly larger. Immature like adult, but brownish grey above rather than plumbeous; nape with dusky, not white, streaks. **Habitat.** Deciduous and evergreen forests, including cloud forest, generally at 100-1400 m, but also up to 2100. Avoids drier areas.

Food and Feeding. Only scattered anecdotal records available: land crabs, beetles, katy-

dids, frogs, snakes, lizards and small rodents. Seen hunting over streams.

Breeding. No nests known, but observations of display activity and birds with nesting material during the rainy season (Dec-Apr).

Movements. Sedentary.

Status and Conservation. ENDANGERED. CITES II. Massive deforestation affecting 90% of former range has reduced the population to only a few areas; largest are Machalilla National Park in Ecuador and Tumbes National Forest in Peru, neither of which is well protected; nor does Machalilla contain very suitable habitat. Some birds persist in very disturbed, fragmented forest mosaics in Ecuador.

Bibliography. Amadon (1964, 1982b), Best *et al.* (1993), Blake (1977), Collar & Andrew (1988), Collar *et al.* (1992), Dodson & Gentry (1991), King (1978/79), Meyburg (1986), Meyer de Schauensee (1982), Parker *et al.* (1982), Robbins & Ridgely (1990), Robbins *et al.* (1987), Wiedenfeld *et al.* (1985).

162. Mantled Hawk

Leucopternis polionota

French: Buse mantelée **German:** Mantelbussard **Spanish:** Busardo Blanquinegro

Taxonomy. *Buteo polionotus* Kaup, 1847, South America = São Paulo, Brazil.

Forms superspecies with *L. albigollis* and *L. occidentalis*; has been considered a subspecies of former. Monotypic.

Distribution. E Brazil (Alagoas and Bahia) S to E Uruguay and E Paraguay (Alto Paraná). Purported Argentinian distribution (in Misiones) apparently based on supposition, with no confirmed records or data.

Descriptive notes. 47-51 cm. Head, neck, upper back and entire underparts white; rest of upperparts and base of tail bluish slate; terminal half of tail white; white tips to secondaries and, more narrowly, to primaries. Iris brown, cere pale yellow, legs and feet pale orange-yellow. Tail pattern separates from congeners, especially *L. albigollis* and *L. lacemulata*. Female similar to male, but larger. Immature spotted or barred with white on lower back and dusky streaking on head and hindneck.

Habitat. Forests in tropical zone; typically in mountainous areas.

Food and Feeding. Some birds, small snakes and geckos, guinea pigs (*Kerodon rupestris*) and other small mammals recorded.

Breeding. No information available.

Movements. Presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Status poorly known; rare or locally distributed; with massive deforestation going on throughout range, further surveys and careful monitoring of species highly desirable; preference for more mountainous regions will probably result in at least some suitable habitat remaining.

Bibliography. Albuquerque (1986), Amadon (1964, 1982b), Belton (1984), Blake (1977), Collar & Andrew (1988), King (1978/79), Meyburg (1986), Olrog (1985), de la Peña (1992), Pinto (1964), Ruschi (1979), Sick (1985a, 1993), Straube & Bomschein (1991).

Genus *BUTEOGALLUS* Lesson, 1830

163. Rufous Crab-hawk

Buteogallus aequinoctialis

French: Buse buson German: Rotbauchbussard Spanish: Busardo-negro del Atlántico
Other common names: Aequinoctial Crab-hawk, Rufous Hawk

Taxonomy. *Falco aequinoctialis* Gmelin, 1788, Cayenne.

Genus allied to *Harpyhaliaetus*. Sometimes associated with *B. anthracinus* superspecies, but apparently more distantly related. Monotypic.

Distribution. Orinoco Delta in E Venezuela along coast to Paraná, S Brazil.

Descriptive notes. 42.5-46 cm; male averages 595 g, female 796 g. Head, throat and hind-neck sooty black; deep fuscous brown on wings and back with rufous edging; tail black, narrowly tipped white, with faint narrow whitish median band; below rufous with fine fuscous barring. Eyes brown, cere and feet yellow. Female similar, but larger. Immature mostly brown above, with tawny wing patches; tail greyish with obscure bands; below white streaked dusky, with thighs barred.

Habitat. Coastal lowland swamps, mangroves, wet savannas and river edges; predominantly in mangroves.

Food and Feeding. Mostly, or exclusively, crabs, e.g. *Ucides cordatus* and *Callinectes bocourti* in Surinam. Crabs caught after short dive from low perch; taken to stump, low branch or dry ground for consumption; birds sometimes use favoured spot.

Breeding. In Surinam, nests in rainy season. Twig nest, lined with leaves. Vocal and aerial display reported. Normally 1 egg, sometimes 2.

Movements. Sedentary; usually seen in pairs.

Status and Conservation. Not globally threatened. CITES II. Commonest raptor (within its range) in mangroves of South America. Status of no immediate concern, but restricted habitat makes it highly susceptible locally to any form of deterioration or loss of this habitat.

Bibliography. Amadon (1949, 1961c, 1982b), Blake (1977), Haverschmidt (1962), Meyer de Schauensee & Phelps (1978), Pinto (1964), Sick (1985a, 1993), Snyder (1966), Tostain *et al.* (1992).

164. Common Black Hawk

Buteogallus anthracinus

French: Buse noire German: Krabbenbussard Spanish: Busardo-negro Norteño
Other common names: (Lesser) Black Hawk; Cuban Black Hawk (*gundlachii*)

Taxonomy. *Falco anthracinus* Deppe, 1830, Veracruz, Mexico.

Taxonomy controversial: sometimes considered to include *B. subtilis*; race *gundlachii* may be valid species; races *gundlachii* and especially *utilensis* sometimes included in nominate; populations of St Vincent (Lesser Antilles) and SW USA sometimes awarded separate races, respectively *cancrivor* and *micronyx*. Forms superspecies with *B. subtilis*. Three subspecies currently recognized.

Subspecies and Distribution.

B. a. anthracinus (Deppe, 1830) - SW & S USA (S Utah and Arizona to Texas) through Central America to Panama and N Colombia, then along Caribbean coast to NW Guyana, Trinidad and St Vincent (Lesser Antilles); penetrates inland to Huila, Colombia.

B. a. gundlachii (Cabanis, 1855) - Cuba and I of Pines.

B. a. utilensis Twomey, 1956 - Cancún I and Cozumel I, off Yucatán; Utila I and Guanaja I, in Gulf of Honduras; and perhaps other adjacent islands.

Descriptive notes. 43-52 cm; male averages c. 793 g, female 1199 g. Blackish to deep fuscous brown overall, depending on race and plumage wear; very short tail has broad white band through middle and narrow white tip; underwing mottled with white at base of primaries. Cere, lores and long legs chrome yellow; cere can be white. Differs from smaller *B. subtilis* in wing markings, from larger *B. urubitinga* in tail pattern. Female similar to male, but averages larger. Immature dark brown above, with white to buff streaks and spots; below buff to ochraceous heavily streaked brown, with thighs finely barred; tail

has numerous narrow dark and pale bars. Race *gundlachii* smaller and generally browner, with whitish malar stripe; race *utilensis* intermediate between nominate race and *A. subtilis*.

Habitat. Tropical and lower subtropical zones, up to 500 m in Colombia, dense, mature riparian wooded areas dominated in N of range by mesquite and *Pithecellobium*, even occurring in hilly desert; mangroves (especially *gundlachii*) and tidal flats. On St Vincent affects mountain forest.

Food and Feeding. Reptiles and fish usually important, but diet varies between pairs in a population and from year to year, as dictated by changes in prey availability. In Durango, Mexico, 10% reptiles, 86% fish (of one species, *Maxostoma austrinum*), amphibians and invertebrates in small amounts, in coastal SE Mexico, almost exclusively crabs; on a beach in Costa Rica, a major predator of ghost crabs; elsewhere rodents. 1 bat and birds represented 6% of diet; Cuban population feeds heavily on crabs; also fish, rarely rodents and perhaps iguanas. Soars frequently, often in pairs, but usually hunts from a perch or on foot, an area will be surveyed for some time from a perch c. 15 m high, but most attacks initiated from closer to ground.

Breeding. Pair formation in Mar, in Cuba; laying in May, in S USA; nests Jan-Mar, in Panama; female in breeding condition in Jan, in Colombia. Bulky stick nest lined with twigs and always

trimmed with greenery; 5-33 m high in mangrove, palmetto, cypress or other tree. Acrobatic aerial courtship displays. 1-3 eggs (average 1.67 in Petén, Guatemala), laid at 2-3 day intervals; incubation 39 days, by both sexes; chick has grey down, with whiter head and breast; fledging 43-50 days. Density of 0-35 pairs/km of river along R Bavispe (NW Mexico). In coastal forest, territories well defined and very small (c. 15 ha).

Movements. Northernmost population of N Mexico and S USA leaves breeding area for winter, but further details lacking. Other populations not known to migrate, and presumed to be sedentary.

Status and Conservation. Not globally threatened. CITES II. Generally fairly common throughout much of range, e.g. Caribbean coast of Colombia; species in no apparent danger overall. In 1960's, was commonest hawk in suitable habitat in Honduras. Island races, with restricted ranges, naturally vulnerable to certain extent.

Bibliography. Abramson (1967), Amadon (1961c, 1982b), Biaggi (1983), Blake (1977), Carter & Wauer (1965), Daniels *et al.* (1989), Hilty & Brown (1986), Hiraldo, Delibes *et al.* (1991), Johnson (1990), Meyer de Schauensee & Phelps (1978), Monroe (1968), Palmer (1988), Ridgely & Gwynne (1989), Rodríguez-Estrella (1990), Rodríguez-Estrella & Brown (1990), Schnell (1979), Sherfy (1984), Sherrod (1978), Slud (1964), Stiles & Skutch (1989), Thollay (1980b), Tostain (1986b), Tostain *et al.* (1992), Voous (1969), Wauer & Russell (1967), Weimore (1965), Wol/kow (1985).

165. Mangrove Black Hawk

Buteogallus subtilis

French: Buse des mangroves German: Mangrovebussard Spanish: Busardo-negro del Pacífico
Other common names: Pacific Black Hawk

Taxonomy. *Urubitinga subtilis* Thayer and Bangs, 1905, Gorgona Island, Colombia.

Taxonomic status remains uncertain: until recently considered a race of *B. anthracinus*, but elevated to specific level based on apparent lack of hybridization with *anthracinus*; however, there may be contact in Panama where the forms are practically indistinguishable, making detection of hybridization very difficult. Forms superspecies with *B. anthracinus*. Three subspecies normally recognized.

Subspecies and Distribution.

B. s. rhizophorae Monroe, 1963 - Pacific coast of El Salvador and Honduras; probably from extreme SW Mexico (Chiapas) locally to Nicaragua.

B. s. bangsi (Swann, 1922) - Pacific coast of Costa Rica and Panama, including Pearl Is.

B. s. subtilis (Thayer & Bangs, 1905) - Pacific coast of Colombia (and offshore islands), Ecuador and adjacent extreme N Peru (Tumbes).

Descriptive notes. c. 39-47 cm. All sooty black; tail with one broad white median band; a pale morph occurs in birds which lack melanin. Somewhat smaller than *B. a. anthracinus*; base of primaries mottled with more white; usually more rufous mottling at base of secondaries. Female similar to male, but slightly larger. Immature similar to that of *B. anthracinus*, with more white and rufous in wings, making separation from *B. anthracinus* more difficult. Races distinguished by size and presence or absence of rufous in wings.

Habitat. Reportedly restricted to mangrove swamps and beach scrub; in Panama, birds will venture away from mangroves. May be confined to mangroves for breeding.

Food and Feeding. Primarily crabs, but also fish, sometimes as carrion. Feeding habits apparently similar to those of *B. anthracinus*.

Breeding. Unknown, but presumably similar to very closely allied *B. anthracinus*.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Status poorly documented, partly due to taxonomic confusion. In places is fairly common, but few records for Colombia; common in Pearl Is, off Panama.

Bibliography. Amadon (1961c, 1982b), Davis (1972), Hilty & Brown (1986), Monroe (1963, 1968), Ridgely & Gwynne (1989), Slud (1964), Stiles & Skutch (1989), Weimore (1965).

166. Great Black Hawk

Buteogallus urubitinga

French: Buse urubu German: Schwarzbussard Spanish: Busardo-negro Urubitinga

Taxonomy. *Falco urubitinga* Gmelin, 1788, northeastern Brazil.

Two subspecies recognized.

Subspecies and Distribution.

B. u. ridgwayi (Gurney, 1884) - Mexico (C Sonora and S Tamaulipas) S to W Panama.

B. u. urubitinga (Gmelin, 1788) - E Panama, W of Andes S to W Ecuador, and E of Andes E to the Guianas, Trinidad and Tobago, and S through E Bolivia and Brazil to Paraguay, Uruguay and N Argentina (Tucumán, Santiago del Estero, Santa Fe).

Descriptive notes. 51-64 cm; male 853-996 g, female 900-1250 g. Dull black overall; tail white with broad black subterminal bar. Legs very long, toes short. Iris dark brown to red, cere and legs dull yellow. Larger than congeners, with different tail pattern. Female similar to male, but larger. Immature dark brown, marked lightly or heavily with buff or cinnamon on head, hind-neck and upper back; below ochraceous, spotted and streaked with dark brown, thighs finely barred; tail and remiges narrowly barred. Race *ridgwayi* smaller, with two black bands in tail, and buff and underwing coverts finely barred white; cere greyish slate.

Habitat. Broad range of habitats from tropical to lower subtropical zones, from dry Chaco to rain forest, savanna with forest patches and gallery forest, and old pastures with scattered trees; usually near water. Regularly soars over forest.

Food and Feeding. Rodents, birds, fish, land crabs, amphibians and carrion; also fruit (*Spondias lutea*) in Brazil. In one study in Costa Rica, frogs were main prey; other items included basilisk lizards, grebe, dove and nestling tiger-heron (*Tigrisoma*). In Petén, Guatemala, of 106 prey items identified: 31% lizards (2 species), 28% snakes (c. 10 species), 14% birds, 8% anurans, 8% bats, 7% mammals; snakes were most important prey type by biomass. In Pantanal of SW Brazil, recorded chasing Plumbeous Ibis (*Theristicus caerulescens*) off nest, and then eating eggs. In forested areas, feeds both in canopy and on forest floor; also forages at forest edge, marshy areas and in more open country. Makes short flights between clumps of aquatic vegetation, where long legs help to catch prey in shallows.

Breeding. Most nests reported in rainy season: Mar-Apr in Panama; Aug in Venezuela; Oct in Argentina; in Petén, laying in latter part of dry season, with hatching near start of rainy season in May. Stick nest in trees, e.g. palms; in Argentina, nests on power poles, and also on top of nests of Monk Parakeet (*Myiopsitta monachus*). 1-2 eggs, but usually only 1 young reared; incubation c. 40 days; young seen perched near nest begging for food 7 months after fledging.

Movements. Primarily sedentary; individuals of N race may wander into Chocó of Colombia. **Status and Conservation.** Not globally threatened. CITES II. Very widely distributed and adapts well to man-modified habitats; no reason for concern at present. Among the commonest species at one forest in French Guiana, with estimated average density of at least 17 individuals/10,000 ha. Habit of nesting on power poles in Argentina sometimes causes problems.

Bibliography. Amadon (1982b), Belton (1984), Blake (1977), Brodie & Baness (1993), Contreras *et al.* (1990), Dickey & Rossem (1938), Gerhardt *et al.* (1992, 1993), Harris *et al.* (1991), Hilty & Brown (1986), Lewis & Timm (1991), Lowery & Dalquest (1951), Mader (1981), Meyer de Schauensee & Phelps (1978), Monroe (1968), Olmos (1990b), Olrog (1985), de la Peña (1992), Pinto (1964), Ruschi (1979), Sick (1985a, 1993), Slud (1964), Stiles & Skutch (1989), Thiollay (1989a, 1989b), Tostain *et al.* (1992), Trail (1987), Voous (1969), Wetmore (1965).

167. Savanna Hawk

Buteogallus meridionalis

French: Buse roussâtre German: Savannenbussard Spanish: Busardo Sabanero

Taxonomy. *Falco meridionalis* Latham, 1790, Cayenne.

Often placed in monotypic genus *Heterospizias*, mainly due to longer legs and wings. Population of Paraguay, SE Brazil and Argentina has been awarded separate race, *rufulus*, but differs only in size, and not generally considered valid; Argentinian birds have alternatively been in equally dubious race *australis*. Monotypic.

Distribution. W Panama (Chiriquí) through tropical South America W of Andes to NW Peru, and E of Andes E to the Guianas and Trinidad, and S through Ecuador, E Peru, E Bolivia and Brazil to N Argentina (Tucumán, Córdoba and Santa Fe).

Descriptive notes. 46-60 cm; 825-1069 g. Head, neck and underparts rufous to cinnamon brown; hindneck streaked, back fuscous brown edged rufous; below finely barred black, except on throat; primaries and secondaries broadly edged black; tail black with narrow median band and narrow white tip. Iris reddish yellow to pale brown, cere pale yellow, legs pale orange yellow. Female similar to male, but larger. Immature sooty brown above, with prominent white eyestripe; mottled rufous on shoulder; below tawny buff streaked blackish on breast, and barred on belly and thighs; tail black with irregular banding.

Habitat. Tropical to subtropical zones, up to 1000 m in Colombia, in open country, wooded and palm savannas, swamplands, forest edge, riparian and mangrove forests; often near water.

Food and Feeding. Opportunistic, taking wide range of small mammals, birds, crabs, frogs, toads, lizards, snakes and large insects. In rainy season in Venezuela, semi-terrestrial freshwater crabs and also eels are very important prey. Said to hunt from low perches and plunge clumsily down onto prey, but significant number of birds in the diet of a Venezuela population suggest a more agile predator. Pirates food from other birds, including a stork. Feeds at grass fires, where will search on foot for toasted prey only a few metres behind the fire.

Breeding. Lengthy breeding season, with laying Feb-Sept (rainy season) in Venezuela; in S of range, nests in austral spring, with egg in Sept, and well feathered young in Nov, in Argentina. Stick nest, often in isolated tree. 1 egg; incubation 39 days; fledging 45-50 days; post-fledging dependency 4-7 months. Density in palm savanna was 1 pair/0.41 km². High rate of nest failure (52.9%), but re-nesting does occur, albeit not very successfully. Long post-fledging dependency and relatively high adult survivorship of 71% compensate for low nesting success.

Movements. Resident over most of range, with high degree of territory fidelity; apparently migratory in S, with very large individuals (S population) reported in Colombia during austral winter. Most common along Paraguay R in Jun, when probably attracted by more abundant prey associated with high water levels. Transition between migratory and resident populations in S undocumented.

Status and Conservation. Not globally threatened. CITES II. Apparently uncommon in Colombia, except in *llanos*. Generally common in savanna situations further S. Species seems secure, and numbers likely to increase as result of continuing deforestation.

Bibliography. Amadon (1964, 1982b), Belton (1984), Blake (1977), Gore & Gepp (1978), Hayes (1991), Hilty & Brown (1986), Mader (1982), Meyer de Schauensee & Phelps (1978), de la Peña (1992), Pinto (1964), Plotnick (1956), Ridgely & Gwynne (1989), Ruschi (1979), Sick (1985a, 1993), Tostain *et al.* (1992), Voous (1969), Wetmore (1965).

Genus *PARABUTEO* Ridgway, 1874

168. Harris' Hawk

Parabuteo unicinctus

French: Buse de Harris German: Wüstenbussard Spanish: Busardo Mixto
Other common names: Bay-winged Hawk

Taxonomy. *Falco unicinctus* Temminck, 1824, Boa Vista, western Minas Gerais, Brazil. Population of SW USA and NW Mexico has been recognized as distinct race, *superior*, but not generally accepted. Two subspecies normally recognized.

Subspecies and Distribution.

P. u. harrisi (Audubon, 1837) - SW USA (S California to Texas) through Mexico and Central America (except Belize and Honduras) to drier Pacific slope regions of W Colombia, Ecuador and Peru. *P. u. unicinctus* (Temminck, 1824) - NE Colombia and W Venezuela S through E Bolivia and C & NE Brazil (Maranhão and Ceará) to S Argentina (Río Negro) and SC Chile (Aisén).

Descriptive notes. 48-56 cm; male 725 g, female 834-1047 g. Blackish to deep sooty brown overall, with shoulders, thighs and underwing-coverts bright chestnut rufous; underparts flecked white, thighs barred dusky; long black tail white at base and tip, uppertail- and undertail-coverts also white. Iris brown, cere and legs bright yellow. Female similar to male, but larger. Immature buffy white below, boldly streaked and spotted fuscous, sides and thighs barred rufous; head streaked buff to cinnamon; shoulder rufous with black variegation; tail more or less finely barred fuscous. Race *harrisi* lacks white markings on breast and belly.

Habitat. Seasonally dry desert, Chaco and savanna, sometimes in swampy areas, often near large water bodies in more arid habitats; up to 1500 m in Colombia, to 1000-1900 m in open chaparral in Chile. **Food and Feeding.** Mostly mammals, including large prey, e.g. rabbits and, to lesser extent, larger black-tailed jackrabbits (*Lepus californicus*); also birds, e.g. flickers, guans, rails. Seems to be opportunistic generalist, taking different prey species in quantities roughly proportional to relative local abundance of prey: in Arizona (USA), 60% ground squirrels, 28% Gambel's Quail (*Callipepla gambelii*), and 11% reptiles; another site in Arizona, 74% mammals, 17.5% birds, and 8.5% lizards; C Chile, 92% small mammals, some lizards and snakes and very few birds; and near Santiago, C Chile, 67% mammals (including European rabbit), 21% birds, 7% herps, and 3% insects. Apparently does not take snakes; one record of a group feeding on fish refer to carrion. Co-operative hunting for larger prey (see page 71).

Breeding. Co-operative breeding in some populations of S USA, but not recorded elsewhere (see page 75). Nesting Jun-Jul, in Colombia; recently fledged young Feb and Jul, in Venezuela; nestlings Aug-Dec, in Argentina; extended breeding season in S USA, starting Feb-Nov. Stick nest lined with weeds, shoots, leaves, grass and Spanish moss; built in mesquite, ironwood or other trees, shrubs, saguaro cactus, or man-made structures. Average 3 eggs (2-4); incubation 33-36 days; chicks have pale brown down; fledging c. 40 days; young stay near nest for 3-4 months after fledging, and may integrate into next breeding cycle, dispersing from natal territory after 3 years. In New Mexico (USA), 29-70% of pairs re-nested in late summer or early autumn, even after successful spring breeding attempts; second clutch can be laid before young from first nest fledge. Extended breeding season in S USA may be insurance against unpredictability of climate and prey abundance, as violent summer storms during period of peak prey availability often lead to nest failure. Young of co-operative groups do not have higher survival rate, but are slightly larger than those raised by pairs; groups have higher failure of eggs, but re-nest and eventually have similar productivity to pairs. Retention of young in group may be stepping stone to polyandry. Recorded density of 0.5 nesting groups/km²; Arizona population in prime area reached density of 1 breeding group/5 km². Conflicting reports on territoriality: non-territorial; adjacent groups wander through neighbours' ranges; groups defend territories. During breeding season, group members stay within 0.8 km from nest or less, and rarely encounter neighbouring groups; winter aggregations (individuals from adjacent territories and wandering birds) form in between territories.

Movements. Somewhat confused. In general sedentary, but may be nomadic at limits of range; Texas population seems to shift in response to fluctuating population levels of prey. Individuals recorded on migration in Panama, but population as close as NW Costa Rica is resident; "migrants" in Panama may be stragglers, perhaps birds recently fledged further N.

Status and Conservation. Not globally threatened. CITES II. Common in many parts of extensive range; broad tolerance in terms of both habitat and food suggest species secure. Fairly common in S USA; common in NE Colombia; not uncommon locally in C and SE Brazil; locally common in W Ecuador. Has declined in parts of S Argentina where strychnine used by sheep ranchers. Small population of SE California (USA) has been re-established by means of reintroduction.

Bibliography. Amadon (1982b), Bednarz (1986, 1987a, 1987b, 1988a, 1988b), Bednarz & Ligon (1988), Belton (1984), Blake (1977), Brannon (1980), Contreras *et al.* (1990), Dawson (1988), Dawson & Mannan (1991a, 1991b), Ellis *et al.* (1993), Ellis & Whaley (1979), Fjeldså & Krabbe (1990), Gaudin (1993), Griffin (1976), Hammerstrom & Hammerstrom (1978), Hauke (1971), Hilty & Brown (1986), Jakde & Gatz (1984), Jakšic & Delibes (1987), Jakšic & Jiménez (1986), Jakšic, Greene & Yáñez (1981), Jakšic, Jiménez *et al.* (1992), Jakšic, Yáñez & Schlatter (1980), Jiménez & Jakšic (1993), Johnson (1990), Johnson (1965), LeSassier & Williams (1959), Mader (1975a, 1975b, 1977, 1978, 1979a), Mays *et al.* (1991), Meyer de Schauensee & Phelps (1978), Olrog (1979), Pache (1974), Palmer (1988), Pennycook *et al.* (1989), de la Peña (1992), Pinto (1964), Radke & Klimoszewski (1977), Ridgely & Gwynne (1989), Sherrod (1978), Sick (1985a, 1993), Slud (1964), Stiles & Skutch (1989), Tucker & Heine (1990), Vleck *et al.* (1991), Wetmore (1965), Whaley (1986).

Genus *BUSARELLUS* Lesson, 1843

169. Black-collared Hawk

Busarellus nigricollis

French: Buse à tête blanche German: Fischbussard Spanish: Busardo Colorado
Other common names: Collared Fishing Hawk/Buzzard, Chestnut Hawk

Taxonomy. *Falco nigricollis* Latham, 1790, Cayenne.

Allied to *Buteogallus* and *Parabuteo*. Two subspecies recognized.

Subspecies and Distribution.

B. n. nigricollis (Latham, 1790) - C Mexico (Sinaloa and Veracruz) S through Central America to Amazonia, W to E Ecuador and E Peru, E to the Guianas and Trinidad, and S through E Bolivia to S Brazil.

B. n. leucocephalus (Vieillot 1816) - Paraguay, Uruguay and N Argentina (S to Salta, Santa Fe and Corrientes).

Descriptive notes. 45.5-49.5 cm; male 695 g, female 796 g. Broad wings and fairly short tail; head and neck white to buff, streaked above; black band across upper breast; rest of body bright rufous cinnamon; black shaft streaks on back; primaries and tail black, tail basally barred rufous. Eye reddish brown, cere black, legs and feet bluish white. Female similar, but larger. Immature fuscous brown above, spotted and barred rufous; breast tawny with fuscous streaks, belly sooty brown to rufous, finely barred fuscous. Race *leucocephalus* larger, with whiter head.

Habitat. Tropical zone, near fresh or brackish water; open country to dense tropical rain forest along larger rivers; up to 500 m in Colombia.

Food and Feeding. Mostly fish, but also some aquatic insects (Belostomatidae) and snails; perhaps, exceptionally, lizards and rodents. Sometimes soars, but most hunting from perch; usually drops onto prey in shallows, or amongst aquatic vegetation; spiny feet aid in grabbing fish.

Breeding. Very poorly known. Laying in Jun-Sept in Surinam, Apr in Guyana, Aug/Sept in Paraguay; nest in Sept. El Salvador; female in breeding condition in Apr. Colombia. Stick nest (conflictingly described as large or small) in mangroves or tall trees; apparently trimmed with greenery. 1 egg. No further information available.

Movements. Mainly sedentary, but may move nomadically in response to changing water levels; most common along R Paraguay in June.

Status and Conservation. Not globally threatened. CITES II. Quite common in appropriate habitat in many parts of extensive range. Apparently declining in Panama, due to drainage of wetlands; same may well be true elsewhere.

Bibliography. Amadon (1964, 1982b), Belton (1984), Blake (1977), Contreras *et al.* (1990), Gore & Gepp (1978), Haverschmidt (1962, 1968), Hayes (1991), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Monroe (1968), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Sick (1985a, 1993), Slud (1964), Stiles & Skutch (1989), Tostain *et al.* (1992), Voous (1969), Wetmore (1965).

Genus GERANOAEETUS Kaup, 1844

170. Black-chested Buzzard-eagle

Geranoaetus melanoleucus

French: Buse agüia

German: Agula

Spanish: Aguila Mora

Other common names: Black/Grey Buzzard-eagle/Eagle-buzzard/Eagle

Taxonomy. *Spizaetus melanoleucus* Vieillot, 1819, Paraguay.

Mistakenly placed in *Buteo* formerly; closer to *Buteogallus* and *Leucopternis*, and clearly merits separate generic status. Two subspecies recognized.

Subspecies and Distribution.

G. m. australis Swann, 1922 - NW Venezuela (Mérida Andes) through W South America S to Tierra del Fuego.

G. m. melanoleucus (Vieillot, 1819) - S & E Brazil (Alagoas, Rio de Janeiro and São Paulo) to Paraguay, E Argentina (N of Buenos Aires) and Uruguay.

Descriptive notes. 62-80 cm; 2000 g; wingspan 175-200 cm. Wings very long and broad; tail short and wedge-shaped. Head and back bluish to slate black or deep sooty brown; black tail tipped narrowly greyish white; shoulders ashy grey finely barred black; breast black, and rest of underparts white, with or without fine dark barring. Female much larger. Immature deep brown to blackish; lacks grey shoulder of adult; below white to tawny or buff, breast heavily streaked black, belly and thighs barred; transition to adult plumage takes several years. Race *australis* smaller; always has some barring on white undersides.

Habitat. Chiefly mountains in N of range, at 1600-3500 m in Colombia, occasionally to 4600 m elsewhere. Ventures into lowlands in S Chile and Argentina, from Buenos Aires S to Tierra del Fuego; grassy foothills, valleys, shrub-steppe and *Nothofagus* woodland; occurs up to 2200 m in Chile.

Food and Feeding. Mostly mammals, accounting for 95% of prey items reported, especially degu (*Octodon degus*) and European rabbit (*Oryctolagus cuniculus*); latter amounted to 44% of prey items, 82% of biomass in one study. Also some birds, e.g. Burrowing Owl (*Speotyto cunicularia*) and carrion; seasonally insects, a few snakes and lizards. Will take fairly large prey, e.g. Chilean Tinamou (*Nothoprocta perdicaria*), guans (*Penelope*) grey fox (*Dusicyon*) and Patagonian hog-nosed skunk (*Conepatus*). Most active mid-morning and mid-afternoon; except during winter, most time spent soaring, often in pairs, both on thermals and along north- and west-facing slopes and ridgetops that produce best updrafts, rather than being attracted to highest concentrations of prey or sparser vegetation, where prey might more easily be spotted.

Breeding. Breeding throughout year in Ecuador; nestlings Nov-Jan in Chile and Argentina, May and Aug in Peru, Mar-Jul in Venezuela; young in Apr and Jul, with recent fledgling also in Jul, in Colombia. Nests on cliffs, often very high, when available; in lower areas, stick nest in top of tall tree, if no trees, on cacti, lower bushes or even reportedly on the ground; nest c. 85 cm in diameter; will reuse nest, but often builds new one, so several may be found within 150 m of occupied site. Courtship flights; copulation over a period of at least 2 weeks, 1-3 eggs (usually 2); incubation c. 30 days; down of chicks thought to be white.

Movements. No indication of any movements.

Status and Conservation. Not globally threatened. CITES II. Generally fairly common; e.g. numerous in region of Torres del Paine National Park, S Chile. Range expanding in Brazil into decimated Atlantic forest in Alagoas. Declines reported in S Argentina, in areas where strychnine used by sheep ranchers.

Bibliography. Amadon (1963, 1982b), Barros (1967), Belton (1984), Blake (1977), Contreras *et al.* (1990), Donzar, Ceballos *et al.* (1993), Fjeldså & Krabbe (1990), Gonnard *et al.* (1957), Gore & Gepp (1978), Houssé (1926, 1945),

Humphrey, Bridge *et al.* (1970), Humphrey, Péfaur & Rasmussen (1993), Iriarte *et al.* (1990), Jaksic & Delibes (1987), Jaksic & Jiménez (1986), Jaksic, Greene & Yáñez (1981), Jaksic, Jiménez *et al.* (1992), Jiménez & Jaksic (1989, 1990b), Johnson (1965), Lehmann (1945), Meyer de Schauensee & Phelps (1978), Olog (1979), Pavez *et al.* (1992), Pearson & Ralph (1978), de la Peña (1992), Pinto (1964), Schlatter, Yáñez & Jaksic (1980), Schoonmaker (1984), Sierra (1986), Teixeira *et al.* (1988), Vuilleumier (1985).

Genus HARPYHALIAETUS Lafresnaye, 1842

171. Black Solitary Eagle

Harpyhaliaetus solitarius

French: Buse solitaire

German: Einsiedleradler

Spanish: Aguila Solitaria

Other common names: Solitary Eagle(!)

Taxonomy. *Circaetus solitarius* Tschudi, 1844, Río Chanchamayo, Junín, Peru.

Closely allied to *Buteogallus*. Formerly considered race of *H. coronatus*. Two subspecies recognized.

Subspecies and Distribution.

H. s. sheffleri (van Rossem, 1948) - locally in highlands from W Mexico (Sonora) to Panama.

H. s. solitarius (Tschudi, 1844) - locally from Colombia (Santa Marta Mts) E to N Venezuela and S through humid Andes to NW Argentina; also occurs in the Guianas, where limits of range virtually unknown.

Descriptive notes. 66-71 cm; 3000 g. Wings long and broad. All dark slate grey; short crest tends to be inconspicuous; rather short tail has bold white median band and white tip. Cere, legs and feet bright yellow. Female larger, with brownish wash and feather edgings. Immature dark brown above, with head and neck heavily streaked white, feathers of back tipped rufous; below yellowish white streaked black or fuscous, with almost complete blackish breastband; thighs fuscous. Race *sheffleri* larger in all dimensions, and darker grey on head, breast and mantle.

Habitat. Forested mountain slopes and cloud

forest. Tropical deciduous forest in Mexico at 750-2500 m, with one sighting at 200 m in Colombia. **Food and Feeding.** Very few data. Mostly snakes: one chachalaca (*Orealis*) in a nest in Sonora (Mexico).

Breeding. Very poorly known. Young in nest in May-Jun in Mexico. Stick nest in crotch of tall tree: one nest only 1 m off the ground; nest in Sonora in huge Mexican yellow pine (*Pinus ponderosa*), on steep slope of wooded canyon. Nests trimmed with greenery, 70-100 cm wide, c. 30 cm deep. Only 1 egg reported.

Movements. Presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Status very poorly known; apparently rare throughout its broad latitudinal range. In no immediate danger, but surveys and research required.

Bibliography. Amadon (1949, 1982b), Best & Clarke (1991), Best *et al.* (1993), Blake (1977), Clinton-Eitner (1986, 1991), Collar & Andrew (1988), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Harrison & Kiff (1977), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Monroe (1968), Morales-Peréz & Navarro-Sigüenza (1991), de la Peña (1992), Ridgely (1980), Ridgely & Gwynne (1989), Robbins & Ridgely (1990), Schulenberg & Parker (1981), Slud (1964), Smith (1982), Stiles & Skutch (1989), Thiollay (1985a), Vamini (1989), Wetmore (1965).

172. Crowned Solitary Eagle

Harpyhaliaetus coronatus

French: Buse couronné

German: Zaunadler

Spanish: Aguila de Azara

Other common names: Solitary Eagle(!), Crowned Eagle(!)

Taxonomy. *Harpyia coronata* Vieillot, 1817, Paraguay.

Closely related to *Buteogallus*. Sometimes considered to include *H. solitarius*. Monotypic.

Distribution. E Bolivia (Santa Cruz), W Paraguay and S Brazil (S from Mato Grosso and Goiás) to S Argentina (Mendoza and Río Negro); no definitive records from Uruguay, where probably occurs.

Descriptive notes. 75-85 cm (in one account only 66 cm); 2950 g. Broad wings, short tail and long legs; long, slightly darker occipital crest. Larger and paler than *H. solitarius*, with prominent crest. More or less uniform dark grey or ashy brown; tail black with white band and tip. Iris reddish brown, cere and legs yellow. Female similar, but averages larger. Immature brownish above, with pale cream supercilium and whitish streaking below; long crest as in adults.

Habitat. Most records deep into dry shrub Chaco and *caatinga*, and in moist Pantanal and palm savanna; in contrast, sometimes

claimed to be bird of thin woodland, forest and forest edge.

Food and Feeding. Not well documented. Takes armadillos and apparently also weasels, rodents, reptiles, birds (tinamous) and carrion (sheep, armadillos). Somewhat crepuscular, feeding on skunks (*Conepatus*) "and other sluggish animals". Hunts from low perches. Short toes are typical of a snake-eater, which is not incompatible with some of prey types recorded.

Breeding. Egg in Oct, young in May. Nest is platform of sticks c. 120 cm wide, 30 cm deep. One nest in Argentina built on top of Monk Parakeet (*Myiopsitta monachus*) colony. 1 egg. No further information available.

Movements. Mainly sedentary, but densities seem to decrease in southernmost portion of range during austral winter.

Status and Conservation. VULNERABLE. CITES II. Very poorly known. Occurs over large area, but at very low densities. Little hard evidence available on populations and trends; further documentation required, to permit adequate assessment of conservation status. There are a few records from protected areas, including Emas and Brasília National Parks, in Brazil, and Beni Biosphere Reserve, in Bolivia.

Bibliography. Albuquerque (1986), Amadon (1949, 1982b), Belton (1984), Blake (1977), Canevari *et al.* (1991), Cheber (1989), Collar & Andrew (1988), Collar *et al.* (1992), Contreras *et al.* (1990), Hayward (1967), Kratter *et al.* (1993), Olog (1985), de la Peña (1992), Remsen & Traylor (1989), Sick (1985a, 1993).

Genus *BUTEO* Lacépède, 1799

173. Grey Hawk

Buteo nitidus

French: Buse cendrée

German: Zweifindenbussard

Spanish: Busardo Gris

Other common names: Shining Buzzard-hawk; Grey-lined Hawk (*nitidus*); Mexican Goshawk (*plagiatus*)

Taxonomy. *Falco nitidus* Latham, 1790, Cayenne.

Sometimes placed in *Asturina*, partly due to distinctive moult pattern; appears to form clade with *B. magnirostris*, *B. ridgwayi* and *B. lineatus*, and this group may be more closely allied to *Leucopternis* than to *Buteo*. Race *plagiatus* sometimes awarded specific status, due to differences in size and plumage, but evidence remains rather weak. Four subspecies usually recognized.

Subspecies and Distribution.

B. n. plagiatus (Schlegel, 1862) - SW USA (Texas to New Mexico) to NW Costa Rica.

B. n. costaricensis (Swann, 1922) - SW Costa Rica to N Colombia and W Ecuador.

B. n. nitidus (Latham, 1790) - E Colombia and E Ecuador, E to Venezuela and the Guianas, and S through Amazonian Brazil to N Maranhão.

B. n. pallidus (Todd, 1915) - SC Brazil (Piauí to Rio de Janeiro and Mato Grosso) and E Bolivia, S to Paraguay and NC Argentina (Tucumán and Chaco).

Descriptive notes. 38-43 cm; male 465 g, female 554 g. Grey overall, with or without obscure fine dark grey barring above and fine white barring below; tail black with 1-2 prominent white bands. Eye yellow or dark brown, cere and legs yellow. Female averages slightly larger. Immature blackish brown above, with white and buff mottling; below buffy white, with brown streaks on breast, spots on belly; tail brown with darker bands and whitish tip. Races separated on size, shade of grey, and presence or absence of barring.

Habitat. Adaptable: lowland tropical to subtropical zones, from rain forest edge and disturbed forest to arid, open country; up to 600 m in Colombia, to 1200 m in Panama.

Food and Feeding. Mostly lizards and small snakes; birds, including small species of both understorey and canopy, and a parakeet (*Aratinga*); also rodents, large Orthoptera and beetles. Soars for short periods, but usually hunts from a perch; agile hunter in forest, taking lizards from branches. More powerful and faster than *B. magnirostris*.

Breeding. Season Jan-May in Colombia and Venezuela; Feb in Panama and Surinam; Apr in Trinidad; laying May with fledging Jul in S USA, earlier in Mexico. Relatively small stick nest lined with sprigs, high in tree at forest edge, or more isolated, or in low thorny mesquite. Aerial courtship, with stoops from great heights (up to 500 m) and mock chases. Usually 2 eggs (1-3); more than 1 young can be raised; incubation 32 days; chicks have white down, greyish above fledging c. 42 days. Aggressively drives other raptors from nest area.

Movements. Generally sedentary, but mostly migratory in N limit of range. Guatemalan birds resident all year round.

Status and Conservation. Not globally threatened. CITES II. Generally widespread and relatively numerous. Uncommon and local in Arizona (USA), with total population of c. 45 pairs; uncommon to fairly common in Colombia. Adaptable, using variety of habitats.

174. Roadside Hawk

Buteo magnirostris

French: Buse à gros bec German: Wegebussard Spanish: Busardo Caminero
Other common names: Insect Hawk, Tropical Broad-winged Hawk, Large-billed Hawk

Taxonomy. *Falco magnirostris* Gmelin, 1788, Cayenne.

Sometimes placed in genus *Rupornis*, or alternatively in *Asturina*. Appears to be closely allied to *B. ridgwayi*, *B. lineatus* and *B. nitidus*, all of which may be more closely tied to *Leucopternis* than to *Buteo*. Many more races have been recognized: race *griseocauda* includes *argutus*, *direptor*, *xantusi* and *petersi*; race *magnirostris* includes *insidiatrix* and *ecuadoriensis*; race *occiduus* includes *inca*; and race *pucherani* includes *gularis*. Twelve subspecies recognized.

Subspecies and Distribution.

- B. m. griseocauda* Ridgway, 1873 - Mexico (S from Colima, Nuevo León and Tamaulipas, except Yucatán and Tabasco) S to NW Costa Rica and W Panama (Chiriquí).
- B. m. conspectus* (Peters, 1913) - SE Mexico (Tabasco and Yucatán Peninsula) and N Belize.
- B. m. gracilis* (Ridgway, 1885) - Cozumel I and Holbox I, near Yucatán (Mexico).
- B. m. sinuohonduri* Bond, 1936 - Bonacca I and Ruatan I, off Honduras.
- B. m. petulans* van Rossem, 1935 - SW Costa Rica and Pacific slope of W Panama to R Tuira, and adjacent islands.
- B. m. alius* (Peters & Griscom, 1929) - San José and San Miguel, in Pearl Is (Gulf of Panama).
- B. m. magnirostris* (Gmelin, 1788) - Colombia S to W Ecuador, E to Venezuela and the Guianas, and S to Amazonian Brazil (R Madeira E to Atlantic coast).
- B. m. occiduus* (Bangs, 1911) - E Peru, W Brazil (S of Amazon, W of R Madeira) and N Bolivia.
- B. m. saturatus* (P. L. Slater & Salvin, 1876) - Bolivia, through Paraguay and SW Brazil (SW Mato Grosso) to W Argentina (S to La Rioja).
- B. m. nattereri* (P. L. Slater & Salvin, 1869) - NE Brazil S to Bahia.
- B. m. magniplumis* (Bertoni, 1901) - S Brazil, N Argentina (Misiones) and adjacent Paraguay.
- B. m. pucherani* (J. & E. Verreaux, 1855) - Uruguay and NE Argentina (S to Buenos Aires Province).

Descriptive notes. 33-41 cm; male 251 g, female 303 g (Surinam). Rufous patch at base of primaries conspicuous in flight. Plumage varies considerably over large range: head, upperparts and upper breast grey to greyish brown, or deep chocolate brown to blackish above, with breast tawny or cinnamon rufous; belly barred with various combinations of white, tawny, grey and brown; tail grey to rufous, with 4-5 broad black bands and white tip. Iris yellow to orangish red, cere dull orange to yellow, legs dull orange to bright yellow. Female similar, but larger. Immature streaked white or tawny on neck and upper back; underparts white to buff, streaked

on breast and barred on belly with variable shades of brown. Races separated on plumage coloration and size, with largest forms in S of range.

Habitat. Very catholic in taste: quite common in most lowland tropical to subtropical habitats, except primary forest, desert and open plains; frequents forest edge, open forest, disturbed areas in second growth, savanna with gallery forest, and scattered patches of forest; even in large cities in Brazil, if enough trees available. Never found in interior of large patches of dense forest. Reported in both moist and dry forests in Colombia; in C Amazonia very rare or absent from unbroken *terra firme* forest. Occurs up to 2500 m in Colombia.

Food and Feeding. Mainly insects, reptiles and small mammals. A fairly typical buteonine generalist: in Argentina, 81% of samples included insects (mostly Orthoptera), 25% amphibians, 12% rodents, and 12% miscellaneous, including fish; in Surinam, mostly lizards, also frogs, snakes and large insects, but no evidence of birds in diet; in Petén (Guatemala), rats, lizards, birds and snakes in roughly equal proportions. Usually catches prey by perch-hunting from prominent branch, fence post, etc. Feeds on insects fleeing army-ant swarms; also along line of grass fires, sometimes singeing its flight-feathers so much as to render it nearly flightless.

Breeding. Nesting Mar-Jun (middle to late dry season) in Petén (Guatemala); birds in breeding condition Mar-May in Belize; Apr-Aug in Colombia and Venezuela (rainy season); Nov-Dec in Argentina. Very conspicuous and vocal around nest, with aerial display and courtship above nest-site. Fairly bulky stick nest 20-46 cm wide, 6-36 cm deep, lined with leaves; placed near top of tree, sometimes in bromeliads. Usually 1 egg in Venezuela, 2 eggs in Mexico, average 1-7 eggs from 3 clutches in Petén; incubation c. 37 days, beginning with first egg. Will renest after failed attempt.

Movements. No evidence of any movements.

Status and Conservation. Not globally threatened. CITES II. Widespread and generally very common; commonest hawk in wide variety of habitats throughout much of extensive range, e.g. Brazil, most of Colombia, and generally throughout much of Amazonia.

Bibliography. Aguilar-Rodríguez (1993), Belton (1984), Belzter (1990a), Blake (1977), Contreras *et al.* (1990), Feldsá & Krabbe (1990), Gore & Gepp (1978), Haverschmidt (1962), Hilty & Brown (1986), Howell (1972), Mader (1981), Marroquín & Moreno (1992), Meyer de Schauensee & Phelps (1978), Monroe (1968), Palmer (1988), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Rowley (1984), Russell (1964), Sick (1985a, 1993), Slud (1964), Stiles & Janzen (1983), Stiles & Skutch (1989), Thiollay (1980b), Tostain *et al.* (1992), Vannini (1989), Wetmore (1965).

175. Red-shouldered Hawk

Buteo lineatus

French: Buse à épaulettes German: Rotschulterbussard Spanish: Busardo Homborrrojo
Other common names: Red-shouldered Buzzard, Red-bellied Hawk

Taxonomy. *Falco lineatus* Gmelin, 1788, Long Island, New York.

Sometimes placed in *Asturina*. Apparently close to *B. ridgwayi*, *B. magnirostris* and, to lesser extent, *B. nitidus*. Five subspecies normally recognized.

Subspecies and Distribution.

- B. l. elegans* Cassin, 1856 - S Oregon (NW USA) to N Baja California (Mexico).
- B. l. lineatus* (Gmelin, 1788) - E North America, from S Canada to C USA.
- B. l. texanus* Bishop, 1912 - S Texas (USA) to Veracruz (CE Mexico).
- B. l. alleni* Ridgway, 1885 - SC Texas to South Carolina and N Florida.
- B. l. eximius* Bangs, 1920 - Florida and Florida Keys.

Descriptive notes. 43-61 cm; male averages 550 g, larger female averages 701 g; wingspan 90-127 cm. Medium-sized, tan to rufous woodland buzzard, with bold black and white pattern on wings and tail. Juvenile brown to tannish, with streaked underparts. Races differ in coloration and, to lesser extent, size.

Habitat. Mature lowland mixed deciduous-coniferous woodlands with nearby open water, clearings and rivers. In W USA shows high adaptability to human-altered habitats, even moving into urban areas.

Food and Feeding. Varied; takes small mammals, reptiles, birds (including nestlings), am-

phibians and insects. Content varies regionally, but overall invertebrates c. 55% and lower vertebrates 21% by frequency. Hunts mainly by direct search in flight, but also by still-hunting from perches. In Missouri (USA) 22% of time spent hunting in forests c. 25 m from water.

Breeding. Laying mainly Apr-May in Canada; Feb-Jun in California; Jan-Jun in Texas and Florida. Solitary. Stick nest in deciduous tree (90%) or conifer, c. 50 m from water in E North America; exotic eucalyptus favoured in S California, cabbage palmetto in Florida; nest lined with greenery. 2-5 eggs in N, 2-3 eggs in Texas; incubation c. 33 days; chicks have pale buffy white down, with black bill; fledging c. 45 days, in California where fledgling fed by adults for 8-10 weeks. Usually breeds first at 2 years, but some females breed at 1 year old. Oldest ringed bird 19 years 11 months; first year mortality c. 58%. Fledging success of c. 1.3-1.8 young per attempt.

Movements. N populations migrate to winter from C USA, where populations resident, to NE Mexico. Autumn migration from mid-Sept to Oct. Spring movement may start late Feb or Mar, with most pairs back at nests by middle to late Mar. In California and Florida, birds remain on breeding territory all year round.

Status and Conservation. Not globally threatened. CITES II. May have undergone slight overall decline since 1946; thought to be result of alterations and loss of habitat; Christmas Bird Counts show winter populations have declined, except in California. Range expansion out of California into S Oregon; in California increasingly adapted to urban settings.

Bibliography. Bednarz & Dinsmore (1981), Bloom (1989), Bloom *et al.* (1993), Bock & Lephien (1977), Brown, W.H. (1971), Campbell (1975), Castrale (1991), Cohen (1970), Friedmann (1950), Glinski (1982), Harlow & Brown (1989), Henny *et al.* (1973), Johnson (1990), Johnson & Peeters (1963), Kiltie (1987), Kimmel & Fredrickson (1981), McCrary (1981), McCrary & Bloom (1984a, 1984b), Mitchell & Millisap (1990), Morris & Lemon (1983), Palmer (1988), Parker, M.A. (1986), Portnoy & Dodge (1979), Snyder & Snyder (1991), Snyder & Wiley (1976), Stewart, R.E. (1949), Titus & Mosher (1981), Titus *et al.* (1989), Wilbur (1973), Wiley (1975).

176. Ridgway's Hawk

Buteo ridgwayi

French: Buse de Ridgway German: Haitibussard Spanish: Busardo de la Española

Taxonomy. *Rupornis ridgwayi* Cory, 1883, Santo Domingo.

Appears closely allied to *B. nitidus*, *B. magnirostris* and especially *B. lineatus*; this group perhaps more closely tied to *Leucopternis* than *Buteo*. Monotypic.

Distribution. Hispaniola and several adjacent islets.

Descriptive notes. 35-40 cm. Chestnut upper-wing-coverts, different tail pattern and lack of rufous in primaries separate from *B. magnirostris*; heavier claws and feet. Above greyish brown with bright rusty "shoulder"; head and neck grey, throat whitish; rest of underparts washed rufous and barred white; tail grey with 3-4 narrow white bars and white tip. Iris brownish yellow, legs yellow. Female drabber brown above; has reddish pink wash on belly and vent, with whitish barring, especially on thighs; tail more heavily barred; slightly larger than male. Immature lacks rufous "shoulder"; greyish brown above, buffy white below with

dusky and tawny streaking.

Habitat. Most common in virgin forests, including rain forest, subtropical dry and moist forest, pine forest and lower montane limestone karst forest. Tolerant of wide range of more disturbed agricultural and second growth habitats; also lowland scrub and montane pasture, from lowlands up to 2000 m.

Food and Feeding. Mostly vertebrates (more than similar *B. magnirostris*) and some insects; lizards (*Anolis*, *Leiocephalus*, *Ameiva*) and snakes (*Uromacer*) most numerous items at nest, but mammals (rats, mice, bats) more important by biomass; also takes birds, including Common Ground-dove (*Columbina passerina*) and Red-legged Thrush (*Turdus plumbeus*). Prey captured by perch-hunting; also by slow, gliding flight, reaching into cavities and vegetation to flush prey, and stooping from a soar.

Breeding. Nest building Feb-Apr. Nest of twigs, c. 50 cm wide, lined with moss, small roots; often in prominent tree, including palms, pines and hardwoods; male does most nest building; female trims nest with greenery, even 1 month after young fledge. Aerial display over nesting territory, with both birds soaring and male making shallow undulating stoops; copulation preceded by aerial display but not courtship feeding. 2 eggs; incubation at least 28-29 days; chicks have white down; fledging c. 12 weeks. Apparently no sibicide, as 2 young fed well into nesting period. Male provides 91% of food; only incubates when female is feeding. Territory averages c. 60 ha, with nests 300-1000 m apart; vigorously defended against conspecifics, crows and other raptors.

Movements. Resident.

Status and Conservation. INDETERMINATE. CITES II. Conflicting evidence; situation might be urgent. Locally common, yet rare over its entire range, which itself is limited to a few islands. Formerly widespread, but shooting and extensive deforestation must have taken substantial toll on population, despite tolerance of disturbed areas; continuing deforestation suggests species in decline; rate and extent of habitat destruction in Haiti leave little hope for future of species there. May persist in good numbers on some outlying islands, although most are now densely populated and heavily disturbed. Best populations now found in Los Haitises range, including a nominally, but poorly, protected national park.

Bibliography. Bond (1979), Collar & Andrew (1988), Collar *et al.* (1992), Davis (1972), Meyburg (1986), Stockton (1978), Wiley (1985, 1986), Wiley & Wiley (1981).

177. Broad-winged Hawk

Buteo platypterus

French: Petite Buse German: Breitflügelbussard Spanish: Busardo Aliancho
Other common names: Broadwing

Taxonomy. *Sparvius platypterus* Vieillot, 1823, near Schuylkill River, Pennsylvania. Six subspecies normally recognized.

Subspecies and Distribution.
B. p. platypterus (Vieillot, 1823) - C & S Canada to S USA; winters S to Brazil.
B. p. cubanensis Burns, 1911 - Cuba.
B. p. brunnescens Danforth & Smyth, 1935 - Puerto Rico.
B. p. insulicola Riley, 1908 - Antigua (Lesser Antilles).
B. p. rivierei A. H. Verrill, 1905 - Dominica, Martinique and St Lucia (Lesser Antilles).
B. p. antillarum Clark, 1905 - St Vincent and Grenada to Tobago.

Descriptive notes. 34-44 cm; 265-560 g; wingspan 86-100 cm, female slightly larger. Small, stoutish woodland *Buteo*; adult has brown upperparts and reddish barred underparts, reminiscent of *Accipiter cooperi*. Rare dark morph uniform blackish all over. Juvenile brownish, with streaked underparts, similar to juvenile *A. cooperi*. Races differ on pattern and intensity of underpart coloration.

Habitat. Inconspicuous bird of deep to semi-open deciduous and mixed woodlands. Frequent edges, openings and wet areas. Often nests near wet or mesic shaded areas with good canopy cover.

Food and Feeding. From spring to autumn, regularly takes over 30 species of small mammals, from size of mouse to small rabbit; birds of at least 25 species (to size of small grouse), and reptiles, amphibians and invertebrates (e.g. grasshoppers, dragonflies). More invertebrates apparently taken in austral non-breeding grounds, but food in non-breeding grounds poorly documented. Practices still-hunting from perch, concealed in tree, or more often at edge of opening or clearing, or even on exposed utility poles or from electric power lines; also direct searching in flight, generally at tree top level.

Breeding. Mar-Jul. Solitary. Carelessly built stick nest, usually in first main crotch of deciduous tree, or in conifer (sometimes in pine plantations); placed 6-14 m above ground; lined with greenery and bark chips. Sometimes uses nests of other raptors, crows (*Corvus*) or squirrels. Usually 2-3 eggs; incubation 28-31 days; chicks have white down and conspicuous black bill; nestlings may engage in siblicide; first leave nest 29-31 days, but fed by parents for c. 50 days. Can breed first at 1 year old, but normally at 2 years. Oldest ringed bird 14 years. Nest success: c. 83% of nests produced average of 1.8 young; average 1.5 fledged.

Movements. Highly migratory in North America, where entire population departs for winter, except birds in S Florida; sedentary in Caribbean. During boreal winter mainly occurs from Guatemala to S Peru and Brazil; some birds move 8800 km, mostly following overland route through C America. Migration patterns highly correlated with wind speed and direction. Autumn peak between mid-Sept and early Oct; spring peak mid-Mar in Panama, late Mar to early Apr in S Texas. During days of peak movement, daily flights may number 1000's, with up to estimated 100,000 seen in single day in E Mexico; along with *B. swainsoni* perhaps the most conspicuous North American raptor migrant, because of large concentrated flocks. Some migration concentration points in North America differ in spring and autumn.

Status and Conservation. Not globally threatened. CITES II. Common, with one estimate of over 1,000,000 individuals in North America. No evidence of decline in North American range during pesticide era. Caribbean populations may be under threat because of habitat alterations and loss of primary forests; *cubanensis* has also been reduced by shooting. In Puerto Rico, race *brunnescens* thought to number only 124 birds at three locations; currently proposed for listing as endangered.

Bibliography. Bednarz *et al.* (1990), Biaggi (1983), Blake (1977), Bond (1956), Burns (1911), Crocoll & Parker (1989), Fjeldså & Krabbe (1990), Friedmann (1950), Heintzelman (1975), Hilty & Brown (1986), Janik & Mosher (1982), Johnsgard (1990), Johnson & Peeters (1963), Keran (1978), Kerlinger (1989), King (1978/79), Lyons & Mosher (1982), Matray (1974), Meyer de Schauensee & Phelps (1978), Monroe (1968), Mosher & Matray (1974), Palmer (1988), Peck & James (1983), Pinto (1964), Ridgely & Gwynne (1989), Rosenfield (1978, 1984), Rosenfield *et al.* (1984), Rusch & Doerr (1972), Sick (1985a, 1993), Slud (1964), Smith, N.G. (1980), Snyder (1987), Snyder & Snyder (1991), Snyder & Wiley (1976), Stiles & Skutch (1989), Thibault & Guyot (1988), Thiollay (1980a), Titus & Mosher (1981), Wetmore (1965), Wiley (1986a, 1986b).

178. White-rumped Hawk

Buteo leucorrhous

French: Buse cul-blanc German: Weißbüßelbussard Spanish: Busardo Culiblanco
Other common names: Rufous-thighed Hawk

Taxonomy. *Falco leucorrhous* Quoy and Gaimard, 1824, Rio de Janeiro, Brazil. Monotypic.

Distribution. Apparently disjunct distribution: mountains of Venezuela and Colombia through Ecuador and Peru to NW Bolivia (Cochabamba, La Paz); Paraguay, S Brazil (N to Minas Gerais) and N Argentina (Salta, Tucumán, Chaco and Misiones).

Descriptive notes. 33-38 cm; male 290 g; wingspan 85 cm. Small *Buteo*; deep blackish overall, with conspicuous white rump and undertail-coverts and creamy white underwing-coverts; thighs rufous; tail, from above has single narrow greyish brown band in distal half, from below 2-3 white bands. Existence of pale morph, similar to that of *B. brachyurus*, has been claimed, but no clear evidence. Iris, cere, legs and feet yellow. Female similar to male, but slightly larger. Immature brown above, mottled with rufous; below heavily mottled rufous.

Habitat. Dense forest, forest edge and Chaco; in subtropical zone, prefers dense forest. Occurs at 1700-2900 m in Colombia, 1650-2500 m in Peru, and up to 3000 m in Bolivia; at lower elevations in Argentina (Misiones) and Paraguay.

Food and Feeding. Very little information available; known to take reptiles, frogs, insects and rats.

Breeding. 1 nest Feb-Mar in Colombia. 2-3 eggs (Argentina). No further information available.

Movements. Nothing known.

Status and Conservation. Not globally threatened. CITES II. Very little known, and status uncertain; generally rather local and nowhere common, but tolerates somewhat disturbed forest, so probably not threatened. In Argentina, seems to have decreased in response to deforestation; no recent records in NE Argentina. More data needed.

Bibliography. Belton (1984), Blake (1977), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Navas & Bó (1991), Olog (1985), Parker & O'Neill (1980), Parker *et al.* (1980), de la Peña (1992), Pinto (1964), Remsen & Traylor (1989), Ruschi (1979), Sick (1985a, 1993).

179. Short-tailed Hawk

Buteo brachyurus

French: Buse à queue courte German: Kurzschnanzbussard Spanish: Busardo Colicorto

Taxonomy. *Buteo brachyurus* Vieillot, 1816, Cayenne.

Has been considered to include *B. albigula*, either as subspecies or within single monotypic species, but no intergradation reported, despite possible overlap of ranges; these two form superspecies. Two subspecies normally recognized.

Subspecies and Distribution.

B. b. fuliginosus P. L. Sclater, 1858 - S Florida (USA); E Mexico to Panama.
B. b. brachyurus Vieillot, 1816 - Colombia S to W Ecuador, E to the Guianas and Brazil, and S through E Peru and E Bolivia (La Paz and Cochabamba) to Paraguay and N Argentina (Jujuy, Tucumán, Misiones).

Descriptive notes. 37-46 cm; male 450-470 g, female 530 g; wingspan 90 cm. Polymorphic, with pale and dark morphs. Normal (pale) morph has upperparts and sides of head deep fuscous brown or slate black, narrow white forehead, and underparts nearly all white; tail greyish brown with several fuscous bands and whitish tip; differs from *B. albigula* in essentially pure white sides of breast and thighs. Rare dark morph has blackish body, white forehead, and wings and tail as normal morph. Iris brown, cere, legs and feet yellow. Female as male, but slightly larger. Immature streaked and spotted brown below, with more tail bands and some white feather edging above (normal morph). Race *fuliginosus*, in pale morph, browner with rufous brown on hindneck and sides of breast.

Habitat. Fairly catholic in requirements. Tropical lowlands through foothills into subtropical zone; occurs in humid tropical and deciduous forest, around interface between primary forest and pastures, and in open terrain, often near marshes. Generally at lower altitudes than *B. albigula*, mostly below 1800 m, but recorded up to 2500 m in Colombia.

Food and Feeding. Few data available, except from Florida (USA). Mainly birds: 96.3% of prey in one study in Florida, mostly Red-winged Blackbirds (*Agelaius phoeniceus*), but at least 23 other species; other birds recorded include *Falco sparverius* and *Accipiter striatus*; also rodents (3% in Florida), lizards and insects (wasps and grasshoppers). Said to soar 100-200 m up, then stoop at prey, taking birds off canopy of trees. Rarely seen perched.

Breeding. Poorly known. Laying Mar-May in Florida; nests Feb in Panama, Mar in Trinidad. Relatively large stick nest c. 70 cm wide built by both adults; lined with finer sticks and green leaves; placed 2-30 m high in tree. Courtship displays include high circling, sky-dancing and tumbling. Usually 2 eggs (1-3); incubation c. 34 days by female; chicks have whitish first down, grey second down.

Movements. Florida population shifts to S part of state in winter, but apparently does not cross much water, and not recorded from Cuba. Situation in Central America rather confusing, with coastal Mexican populations partly resident, but migratory flights reported in S Veracruz, and also in Honduras and Costa Rica, but not in Panama. No migration documented in rest of range, where presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Nowhere common, e.g. uncommon and thinly spread over Colombia; uncommon to rare in Florida (USA). Occurs over very large range, and is tolerant of disturbed habitat; situation apparently secure.

Bibliography. Amadon (1964), Andrie (1967), Belton (1984), Blake (1977), Brown, M. (1987), Cabot & Serrano (1986), Contreras *et al.* (1990), French (1973, 1992), Fjeldså & Krabbe (1990), Herklots (1961), Hilty & Brown (1986), Howell & Webb (1992a), Jaksic & Jiménez (1986), Johnsgard (1990), Lehman & Haffer (1960), Meyer de Schauensee & Phelps (1978), Mitchell & Millsap (1990), Monroe (1968), Ogden (1974), Olog (1985), Palmer (1988), de la Peña (1992), Pinto (1964), Rand (1960), Ridgely & Gwynne (1989), Robbins & Ridgely (1990), Slud (1964), Stiles & Skutch (1989), Stresemann (1959a), Thiollay (1980b, 1991a), Wetmore (1965), Willis (1988).

180. White-throated Hawk

Buteo albigula

French: Buse à gorge blanche German: Weißkehlbussard Spanish: Busardo Gorgiblanco

Taxonomy. *Buteo albigula* Philippi, 1899, Valdivia, Chile.

Higher altitude representative of *B. brachyurus*, with which forms superspecies, and in which present species is sometimes included, but no hybridization reported, despite possible range overlap. Monotypic.

Distribution. Andes, from Venezuela and Colombia S to C Chile and WC Argentina.

Descriptive notes. 38-48 cm, wingspan c. 95 cm. Markings on sides of breast and thighs separate from *B. brachyurus*; tail noticeably longer. Brownish black above and on sides of head; white below, with sides of body chestnut, faintest and belly streaked brown, and thighs barred with rufous; tail dark brown above, greyish below, with 8-10 narrow dark bands. Dark morph unknown. Female as male, but somewhat larger. Immature has large blackish spots on breast and flanks.

Habitat. Generally from 1700 m to 3500 m in N half of range, but occasionally down to sea-level in Chile; humid mountain forest to

stunted forest and cloud forest at higher altitudes and adjacent open country, frequents areas with *Eucalyptus* in Ecuador, *Araucaria* in S of range.

Food and Feeding. Very few data available. Known to take rodents and birds.

Breeding. Season unknown. Nests on cliffs or in shrubs. No further information available.

Movements. Possibly migratory from southernmost parts of range; elsewhere presumably sedentary.
Status and Conservation. Not globally threatened. CITES II. Very poorly known. Generally rare and local throughout range, e.g. in Colombia. Preferred altitudinal range relatively less affected by human activities, especially transformation; also shows tolerance of disturbed habitat. Surveys and research required.

Bibliography. Blake (1977), Fjeldså & Krabbe (1990), Hilty & Brown (1986), Johnson (1965), Lehman & Haffer (1960), Meyer de Schauensee & Phelps (1978), de la Peña (1992), Stressemann, E. (1959).

181. Swainson's Hawk

Buteo swainsoni

French: Buse de Swainson **German:** Präriebussard **Spanish:** Busardo Chapulinero

Taxonomy. *Buteo Swainsoni* Bonaparte, 1838, Fort Vancouver, Washington.

Monotypic.

Distribution. W & C North America from Alaska SE to Minnesota, and S to N Mexico. Winters mostly in South America, especially in N Argentina, S Brazil and Paraguay; also some birds in S & W USA.

Descriptive notes. 48-56 cm; male 683-936 g, female 937-1367 g; wingspan 124-137 cm. Extremely variable: adult pale morph has brown upperparts and bib, with white throat and belly; dark morph blackish overall; intermediate reddish morph similar to pale morph, but underparts with variable amounts of reddish barring; reddish morph grades into both of other morphs. Pale morph commonest. Juvenile has upperparts similar to adult, but with pale edgings; underparts streaked and blotched with yellowish brown.

Habitat. Most habitats, from woodland of aspen, oak and conifers to steppes and deserts;

most common in prairies and intermountain zone of W USA.

Food and Feeding. Seasonally variable diet: in breeding season, mainly mammals (rabbits, ground squirrels, voles and bats), but also birds, reptiles and some insects; in non-breeding season, mainly insects (grasshoppers, dragonflies, "locusts", beetles), some other invertebrates, occasional mammals (rodents) and birds. Perch-hunting is commonest technique; also hawks insects in flight. Often gregarious, especially in winter quarters, with sizeable flocks gathering where insects (e.g. grasshoppers) abundant; birds may snatch up prey while moving about rather clumsily on ground.

Breeding. Apr-Aug. Solitary, but often associated with *B. regalis*. Flimsy stick nest, typically in solitary tree, bush or small grove, sometimes on magpie (*Pica*) nest; often placed low down, close (2-3 m) to ground, with frequent use of shelterbelts planted by man; nest often lined with greenery. Usually 2-3 eggs (1-4); incubation 34-35 days; chicks have white down; fledging 42-44 days. Sexually mature at 2 years. Oldest ringed bird 16 years old. Nest success c. 65-75%; hatching success up to 93%; fledging success 60-75% of eggs laid; c. 1-7 young fledged per attempt.

Movements. Highly migratory. Main non-breeding grounds (boreal winter) in Argentina; migration follows a land route through C America, with some scattered wintering grounds in other open habitats of Neotropics. Some autumn migrant flocks in C America in 1000's; total of 400,000 recently recorded over Veracruz, E Mexico. May fly without feeding between S USA and winter quarters in South America. Increasingly some birds winter in Florida, California and also Texas.

Status and Conservation. Not globally threatened. CITES II. Total population conservatively estimated at 40,000-55,000 breeding pairs, but much higher numbers counted on migration through Mexico and Panama. Serious local declines, e.g. in California (90%) and Oregon; often attributed to pesticides, but local habitat problems more likely. Listed as possibly threatened (although with insufficient data) in USA in 1982, but removed from list in 1991.

Bibliography. Ambrosetti (1919), Bechard (1982, 1988), Bednarz (1988a), Blake (1977), Browning (1974), Clark & Wheeler (1987), Delius (1953), Dunkle (1977), Estep & Teresa (1992), Fitzner (1980), Fjeldså & Krabbe (1990), Gilmer & Stewart (1984), Henny & Kaiser (1979), Hilty & Brown (1986), Houston, C.S. (1974), Houston & Millar (1981), Houston *et al.* (1991), Janes (1985), Jaramillo (1993), Johnson (1960), Kirkley (1991), Littlefield *et al.* (1984), Olendorf (1973), Palmer (1988), Pinto (1964), Ridgely & Gwynne (1989), Risebrough *et al.* (1989), Rudolph & Fisher (1993), Schmutz (1984), Schmutz & Hungle (1989), Sick (1985a, 1993), Skutch (1945), Slud (1964), Smith, D.G. & Murphy (1973), Smith, N.G. (1980), Smith, N.G. *et al.* (1986), Snyder & Wiley (1976), Stendell & Gilmer (1988), Stiles & Skutch (1989), Thurow & White (1983), Thurow *et al.* (1980), Wetmore (1965), White *et al.* (1989), Woffinden (1986), Zotta (1931).

182. White-tailed Hawk

Buteo albicaudatus

French: Buse à queue blanche **German:** Weißschwanzbussard **Spanish:** Busardo Coliblanco

Taxonomy. *Buteo albicaudatus* Vieillot, 1816. South America = Rio de Janeiro.

Closely allied to *B. galapagoensis*, with which forms superspecies, possibly also including *B. polyosoma*, which present species may replace at lower altitudes, and *B. poecliochrous*. Three subspecies recognized.

Subspecies and Distribution.

B. a. hypospodius Gurney, 1876 - SC USA (S Texas) and NW Mexico (Sonora) to N Colombia and NW Venezuela.

B. a. colonus Berlepsch, 1892 - E Colombia E to Surinam (except NW Venezuela), and S to Amazon, E from at least Manaus to Atlantic coast; Aruba, Curaçao, Bonaire and Trinidad.

B. a. albicaudatus Vieillot, 1816 - extreme SE Peru & S Brazil (S from Mato Grosso, Goiás and Bahia) through N & E Bolivia, Paraguay and Uruguay to N & C Argentina (S to Rio Negro).

Descriptive notes. 51-61 cm; 850-884 g. Polymorphic, with pale and dark morphs. Wings rather long for a *Buteo*; in pale morph, rufous shoulders, not upper back, separate from *B. poecliochrous* and smaller *B. polyosoma*. Pale morph has upper back, neck and head ashy grey; to blackish slate, shoulders prominently rufous; rump and tail white, black band near tip of tail; below nearly immaculate white, including underwing-coverts, but fine barring on sides and thighs. Dark morph greyish to dark slate below, belly finely barred white, and thighs often barred rufous and white; tail as in pale morph, usually some rufous on shoulders. Iris

hazel, cere pale green, feet yellow. Female marginally larger. Immature dark brown to black above; shoulders sometimes rufous, possibly in older individuals; rump buffy white barred rufous; underparts blackish (presumably immature dark morph) to dark brown with varying amounts of white; flanks and undertail white; tail pale grey to brown, with numerous narrow dark bands, becomes whiter with age. Race *hypospodius* slightly paler above, with white throat; *colonus* smaller and paler.

Habitat. Tropical to subtropical zones. Usually in semi-arid open country, but also found in dry, open woodland and moist palm savanna; exclusively shrub-steppe in N Argentinian Patagonia. Up to 1800 m in Colombia, to 2400 m in Bolivia.

Food and Feeding. Broad range of prey types and species, including snakes, lizards, cottontail rabbits (extensively when available), ground squirrels, rats, some birds (doves and young poultry), frogs, toads, crabs, cicadas, beetles, large earthworms (up to 1 m long in Brazil) and sometimes carrion. Regularly soars and hovers; perches on low shrubs or on ground. Recorded pirating food from *Elanus leucurus*. Frequently feeds at grass fires, commonly in groups of up to 20 birds, soaring and gliding through smoke, or perched near fire line.

Breeding. Most of data from N of range, in S USA. Laying Jan-Aug in S USA (late nests may be replacement clutches); most often dry season in Venezuela, but some rainy season records; nests in Jan-Aug in Colombia. Stick nest, up to 80 cm wide, lined with grass or sprays in palms, hardwoods or low shrubs if necessary; will reuse nests. Displays in air and on ground often associated with copulation; courtship, copulation and nest building take c. 1 month to complete. Usually 2 eggs (1-3); incubation averages 31-2 days (29-32), beginning with first egg; chicks have buff down, washed smoky brown; fledging c. 49-52 days.

Movements. Poorly known. Presumably sedentary over most of tropical range. Northernmost birds are not migratory, but populations further S in North America may be; purported migration may refer to irruptive movements in response to population declines of prey species.

Status and Conservation. Not globally threatened. CITES II. Extensive range; apparently on increase as result of deforestation. Relatively common in open areas in Brazil; expanding in E due to deforestation, and occurs near some large cities, e.g. Rio de Janeiro. Fairly common to locally common in Colombia. Declines reported in S Argentina in areas where strychnine used by sheep ranchers.

Bibliography. Belton (1984), Blake (1977), Contreras *et al.* (1990), Cottam & Knappen (1939), Donazar, Ceballos *et al.* (1993), Farquhar (1986, 1988, 1992, 1993), Fjeldså & Krabbe (1990), Graham *et al.* (1980), Haucke (1971), Heredia & Clark (1984), Hilty & Brown (1986), Howell (1971, 1972), Johnson (1990), Kopeny (1988a, 1988b), Mader (1981), Meyer de Schauensee & Phelps (1978), Monroe (1968), Morrison (1978), Olrog (1979), Palmer (1988), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Ruschi (1979), Sherrod (1978), Sick (1985a, 1993), Slud (1964), Snyder & Wiley (1976), Stevenson & Meizen (1946), Stiles & Skutch (1989), Tewes (1984), Thiollay (1980b), Voous (1968, 1969), Wetmore (1965).

183. Galapagos Hawk

Buteo galapagoensis

French: Buse des Galapagos **German:** Galapagosbussard **Spanish:** Busardo de Galápagos

Taxonomy. *Polyborus galapagoensis* Gould, 1837, Galapagos Archipelago.

Closely related to *B. albicaudatus*, with which forms superspecies, perhaps also including *B. polyosoma* and *B. poecliochrous*. Monotypic.

Distribution. Galapagos Is.

Descriptive notes. 55 cm; wingspan c. 120 cm. Sooty brown overall; tail grey with narrow blackish bars. Iris brown, legs and cere yellow. Female similar, but appreciably larger. Immature blackish brown above, heavily mottled white and buff; below buff, heavily spotted blackish brown; tail buffy white, with numerous narrow blackish bars.

Habitat. All island habitats from shoreline to barren lava fields, open areas, closed deciduous forest and mountain peaks; nesting restricted to dry zones.

Food and Feeding. As the only diurnal raptor in Galapagos, it is not surprisingly a broad

generalist. Most important prey types are rodents (mostly indigenous *Oryzomys*, but also introduced *Rattus*), ground doves and lava lizards (*Tropidurus albamarensis*). Wide variety of other food sources also exploited: finches and mockingbirds (including plundered nests); young of seabirds from nesting colonies; young goats; iguanas (both marine and terrestrial, mostly taken by the more powerful females); hatchling tortoises and sea turtles; locusts; caterpillars; giant centipedes; carrion (seal placentas, goats, fish); and poultry. Prey habits idiosyncratic, as food delivered to adjacent nests (or even to same nest by different males) can be quite different. Usually hunts from the air at height of 50-200 m, mostly gliding but sometimes hovering.

Breeding. Recorded at various times of year; may not have well defined breeding season, instead being linked to weather patterns. Stick nest 80-100 cm wide, lined with grass, leaves, or bark, on prominent lava outflow, rocky outcrop or low tree: nest-site provides panorama of territory and used repeatedly, nest at times becoming quite large, up to 3 m deep. 1-3 eggs; incubation 37-38 days; fledging 50-60 days; incubation and fledging substantially longer than in comparable mainland *Buteo* species. Parents expel young within 3-4 months of fledging; juveniles spend at least 2-3 years away from territorial breeding areas before reaching sexual maturity at c. 3 years old. One of only c. 12 bird species with stable co-operative polyandrous mating system. 1-3 (up to 7) extra males participate in copulation, incubation, feeding of young and group defence of territory; groups appear stable, with birds remaining in territory in successive years; not all females have extra males. Usually only 1 young raised per group. Breeding success varies with climate; polyandrous groups produce more young than monogamous pairs, but pairs produce more young per male. Group-living males live longer than monogamous birds, so may have greater overall fitness, despite lower annual productivity; may also outlive other males to wind up in monogamous pair. On small Santa Fe I, a small population of juveniles (roughly even sex ratio) was present, with few non-breeding adults. On larger Santa Cruz I, with more varied terrain, a non-breeding population of well over 100 individuals was present, including a pool of 30-75 adult females; when these birds were added to breeding population, sex ratio almost even, suggesting that polyandry did not evolve as result of lack of potential mates for males. Ultimate cause for this system may be shortage of suitable breeding territories. On larger islands, where non-breeders stay in highlands, group size larger.

Movements. Sedentary.

Status and Conservation. RARE CITES II. According to early reports, was once very common, but subjected to severe persecution by settlers: as many as 250 nesting pairs on Santa Cruz in past now reduced to just a few pairs. Formerly on all large islands, and many of smaller islands, but range now greatly reduced and may now have been extirpated from five islands. Seems secure on Santiago and Santa Fe. Might be a species readily responsive to manipulative intervention, should populations reach dangerously low levels.

Bibliography. Butler (1979), Collar & Andrew (1988), Faaborg (1984, 1986), Faaborg *et al.* (1980), Harris (1982), King (1978/79), Meyburg (1986), Voous & de Vries (1978), de Vries (1973, 1975, 1976, 1984, 1989).

PLATE 18

inches 12
 cm 30

184. Red-backed Hawk

Buteo polyosoma

French: Buse tricolore German: Rotrückenbussard Spanish: Busardo Dorsirrojo
Other common names: Juan Fernandez Hawk (*exul*)

Taxonomy. *Falco polyosoma* Quoy and Gaimard, 1824, Falkland Islands.

Forms superspecies with *B. poecilochrous*, with which sometimes considered conspecific; much remains to be resolved about taxonomy of these species. May also be closely related to *B. galapagoensis* and *B. albicaudatus*, and all four sometimes included in superspecies; said to replace *B. albicaudatus* at medium altitude. Race *exul* may be approaching species status. Nominant race includes possible races *erythronotus*, *aethiops* and *peruviansis*. Two subspecies recognized.

Subspecies and Distribution.

B. p. polyosoma (Quoy & Gaimard, 1824) - C Andes of Colombia S through Andes to Patagonia and Tierra del Fuego; also Falkland Is.

B. p. exul Salvin, 1875 - Alejandro Selkirk I (Más Afuera) in Juan Fernández Is. off SC Chile.

Descriptive notes. 46-56 cm; 950 g; wingspan 110-120 cm. Whitish tail with black subterminal band. Highly variable, with tendency for sexes to differ in plumage: head, thighs and undertail dark brownish grey, back dark grey with upper back and most of underparts rufous; or similar, but with underparts white, finely barred on sides and belly; or entire body blackish to pale slate; or grey to slate above, white below; or brown to grey below with rufous band across breast, and rufous mantle. Rufous backed birds usually female, grey birds apparently males. Iris brownish (maybe yellowish), cere greenish yellow, legs and feet yellow.

Very similar to *B. poecilochrous*, which shows very similar range of plumage variation, but smaller, with longer, narrower wings and longer tail; 3rd primary (counting inwards towards body) longer than 5th. Female similar than male. Immature also variable: mostly brown with more or less white mottling; buff below streaked brown; sometimes has rufous in mantle; tail greyish with numerous dark bands. Race *exul* larger and darker, lacking rufous back of female.

Habitat. Tropical zone up to puna; 1800-3200 m, probably higher, in Colombia; up to 4600 m in Bolivia. Temperate zone forests in N of range, lower altitudes in Peru and S of range. Arid coastal lowlands of Ecuador; temperate and arid valleys; treeless shrub-steppe of Argentinian Patagonia; river valleys with gallery forest. Occupies broader altitudinal range (coastal lowlands and Chaco up to Altiplano) and more diverse habitats than *B. poecilochrous*; generally occurs at lower altitudes than latter species, although in Colombia confusingly seems to occupy higher elevations (1800-3200 m); in overlap zone in Bolivian Altiplano, present species tends to frequent flatter land, while *B. poecilochrous* prefers steeper, mountainous regions.

Food and Feeding. A generalist mammal predator, taking most prey roughly in proportion to its relative abundance. In Chile, 90% rodents, especially degu (*Octodon degus*); some (introduced) rabbits, mostly juveniles; also, to lesser extent, birds. In another study: 97% mammals; also lizards, Orthoptera and frogs. In Juan Fernández Is. feeds heavily on introduced mice (*Mus*), petrels and other birds, carrion (seals) and occasionally fish. Hunts actively, often hovering. Active all day, in contrast to *Geranoaetus melanoleucus*, with which it shares habitat. Prefers to fly and soar along, or perch on, north-facing slopes, where most updraughts seem to be, but also where vegetation sparsest.

Breeding. Nesting Dec-May in Ecuador; Sept-Oct in Chile; Nov-Dec in Argentina. Bulky stick nest lined with moss, lichens, leaves and trash; built on cliffs, in cacti, on shrubs or on telegraph poles. 1-3 eggs, with largest clutches in S of range; incubation apparently by both sexes; chicks have salmon pink down; fledging 40-50 days or more.

Movements. In Bolivia, birds in valleys may be permanent residents, while those in puna may be migrants from S. During austral winter, birds from Chilean Andes and Patagonia move N to subtropical lowlands of N & E Argentina, Paraguay and perhaps Uruguay. Formerly thought to be only a migrant to Colombia, but recently reported nesting there.

Status and Conservation. Not globally threatened. CITES II. Status poorly known, but in general appears to be relatively secure, and locally common, e.g. EC Ecuador. Apparently declining in Chile.

Bibliography. Blake (1977), Cabot (1991), Cabot & Serrano (1986, 1988), Contreras *et al.* (1990), Donazar, Ceballos *et al.* (1993), Fjeldså & Krabbe (1990), Fuentes *et al.* (1993), Hilty & Brown (1986), Humphrey, Bridge *et al.* (1970), Humphrey, Péfaur & Rasmussen (1993), Jaksic & Delibes (1987), Jaksic & Jiménez (1986), Jaksic, Greene & Yáñez (1981), Jaksic, Jiménez *et al.* (1992), Jiménez & Jaksic (1991), Johnson (1965), Koepeke (1970), Marchant (1960), de la Peña (1992), Schlatter, Yáñez & Jaksic (1980), Thillay (1991a), Vaurie (1962), Woods (1988).

185. Puna Hawk

Buteo poecilochrous

French: Buse du puna German: Punabussard Spanish: Busardo Puneño
Other common names: Gurney's Buzzard, Variable Hawk

Taxonomy. *Buteo poecilochrous* Gurney, 1879, Yanayacu, Ecuador.

Forms superspecies with *B. polyosoma*, of which sometimes considered a race; taxonomy of these species uncertain. May also be related to *B. galapagoensis* and *B. albicaudatus*, and all four sometimes included in superspecies. Monotypic.

Distribution. Andes from S Colombia (C Andes and Cauca) S to N Chile and NW Argentina.

Descriptive notes. 51-61 cm; c. 1000 g; wingspan 125-150 cm. Whitish tail with black subterminal band. Plumage highly variable: dark morph, all dark slate grey except tail, apparently commonest form; females frequently have chestnut mantle, and sometimes breast. Cere, legs and feet yellow. Larger than *B. polyosoma*, with broader wings and shorter tail; 3rd primary (counting inwards towards body) shorter than 5th; plumage variation virtually identical, but lacks colour morph with brownish grey throat, thighs and undertail, and rufous breast and belly. Female similar to male, but larger. Immature also variable: some birds all dark; others mostly whitish below, with some brownish mottling; many intermediate forms.

Habitat. Puna and páramo zones, mostly above 3000 m, and ranging up to 5000 m in Bolivia. Tends to frequent open areas, including deserts and semi-deserts, in Altiplano, and steep rocky areas in higher mountains. Also high altitude Polylepis woodlands. Peruvian puna and surrounding mountains. More specialized in habitat than *B. polyosoma*, normally occurring at higher altitudes; in Colombia, situation may be reversed, with present species occupying lower elevations (900-2000 m) than *B. polyosoma* (1800-3000 m).

Food and Feeding. Small mammals, insects and birds; wide variety of other items, including earthworms, toads and fish (trout). Both during and outside breeding season, small rodents, especially caviés (Caviidae), make up 15-20% of prey items recorded, and the substantial proportion of biomass consumed; in Ecuador, especially forest rabbit (*Sylvilagus brasiliensis*) and *Thomasomys* mice. Over half of recorded prey items were insects (mostly Tenebrionidae and Curculionidae) at two study sites, but these represent small percentage of biomass. Birds constitute up to 7% of prey items on breeding ground. Often searches for prey by hanging in updraught, low over ground, or quite high up; often soars high over mountains.

Breeding. In puna, breeds in warm and rainy season; eggs in most months in Ecuador. Monogamous, but also co-operative and perhaps polyandrous; in 2 different groups, 3 males simultaneously shared duties with 1 female, over 3 seasons. Stick nest c. 20 m up on cliff, typically on ledge or in cave. Clutch of 2+ eggs; incubation 36 days, by female and male(s); chicks have cream-coloured down; fledging 74 days. In study in Ecuador, of 6 breeding attempts by monogamous pairs, 3 failed at egg stage; of 6 attempts by co-operative groups, all successful.

Movements. Some local movements recorded, e.g. in N Chile breeds on high Andean plateau at 4500 m, and moves down to 3000 m outside breeding season. Somewhat confusing situation in Colombia, where species suspected to be migrant, because no breeding reported, but populations in Bolivia and Peru reported to be resident all year round, leaving source of any migrants to Colombia as a mystery.

Status and Conservation. Not globally threatened. CITES II. Generally common; particularly common in region of Mt Antisana (NC Ecuador), where several breeding groups have been object of detailed research in recent years; rare in Chile. Relatively extensive range in habitat that is not subject to excessive human encroachment suggests species secure at present.

Bibliography. Amadon (1964), Balke (1977), Cabot (1991), Cabot & Serrano (1986, 1988), Coello (1993), Contreras *et al.* (1990), Fjeldså & Krabbe (1990), Hilty & Brown (1986), Jaksic & Jiménez (1986), Jaksic *et al.* (1991), Jiménez & Jaksic (1990a), Johnson (1965, 1967), Koepeke (1970), Macedo (1964), Meyburg (1986), de la Peña (1992), Vaurie (1962).

186. Zone-tailed Hawk

Buteo albonotatus

French: Buse à queue barrée German: Mohrenbussard Spanish: Busardo Aura

Taxonomy. *Buteo albonotatus* Kaup (ex G. R. Gray), 1847, Mexico.

Populations from E Panama and South America sometimes awarded separate race, *abbreviatus*, but not generally accepted. Monotypic.

Distribution. Range disjunct or incompletely known: NW & NC Mexico (from Baja California) and adjacent USA. S through Yucatán (not recorded in Belize) and Guatemala (including W highlands) to Panama, including Pearl Is. In South America, distribution incompletely encircles Amazon Basin: W Ecuador; C Peru, near Lima; N Colombia (Sta Marta Mts to Magdalena) E through N & SE Venezuela to the Guianas and Trinidad; N, E & SE Brazil (from Amazon Delta and I de Marajó, S and E through Ceará, Pernambuco, Alagoas and Bahia to Paraná) W through Paraguay to N & E Bolivia (Beni, Santa Cruz).

Descriptive notes. 45-56 cm; male 607-667 g, female 845-937 g; wingspan 121-140 cm. Uniform black or brownish black; relatively long blackish tail narrowly tipped white, with three bands, greyish above, whitish below; from below, greyish flight-feathers contrast with blackish underwing and body. Birds from South America average somewhat smaller. In flight recalls larger Turkey Vulture (*Cathartes aura*), especially from below. Iris reddish brown or dark brown, cere and legs yellow. Female similar to male, but larger. Immature browner, with white spotting on underparts.

Habitat. A habitat generalist, in tropical to

subtropical lowlands: savannas or scrub, *caatinga*, dry deciduous forest, humid forest, coniferous and mixed pine and oak forest, riparian woodland and ranchland; up to 500 m in Colombia.

Food and Feeding. Prey includes small mammals, birds (both adults and nestlings) and lizards. In Durango, NC Mexico: 38% of prey items were birds, roughly half of which were Red-shafted Flickers (*Colaptes cafer*) and rest unidentified; 43% mammals, predominantly cotton rats (*Sigmodon*); and 19% reptiles. Lizards particularly important in S USA. Also said to take frogs and fish, but these records may be due to confusion with *Buteogallus anthracinus*. Typical hunting behaviour very active: involves slowly soaring c. 15-30 m up and suddenly diving on prey, either on the ground or in tree canopy. In underwing coloration and flight pattern, remarkably similar to Turkey Vulture (*Cathartes aura*), which it may mimic; soars with wings flat as in most *Buteo* species, then raises them in dihedral, in style similar to *C. aura*; function may be to appear innocuous to potential prey, which consequently does not seek cover in time to avoid capture. Further support for suggested mimicry in resemblance to *C. aura* in both adult and immature plumages. Often soars in company with *C. aura*, and ranges overlap extensively, with present species invariably less common.

Breeding. Laying in late Apr. USA: Feb-Mar, Trinidad; incubation in Aug. Colombia: small chick in May, Venezuela; fledging mid-Jul. Mexico. Bulky stick nest trimmed with green leaves; placed 7-30 m high in trees, or on cliffs; in Texas (USA), most nests in tall trees in steep-sided canyons.

Usually 2 eggs (1-3); incubation c. 35 days; chicks have greyish down; fledging c. 6-7 weeks. One adult does most of the feeding, while the other defends the brood. In Mexico, young left nesting area c. 1 month after fledging.

Movements. Northernmost birds mostly migratory but some individuals overwinter at N limit of range. In Panama, most birds migrants, but reports throughout year suggest a resident breeding population may have developed. Birds in South America have been claimed to be migrants from N, but species regularly breeds in Venezuela, and perhaps on Trinidad; status of birds further S requires confirmation.

Status and Conservation. Not globally threatened. CITES II. Rather patchy distribution, but widespread and locally common. Relatively common in NE Brazil; apparently local in Colombia. Tendency to use wide variety of habitats, together with extensive range, suggests species secure at present.

Bibliography. Blake (1977), French (1973, 1992), Friedmann & Smith (1950, 1955), Hilty & Brown (1986), Hiraldo *et al.* (1989), Johnsgard (1990), Matteson & Riley (1981), Meyer de Schauensee & Phelps (1978), Millsap (1981b), Monroe (1968), Mueller (1972), Orias & Paulson (1969), Ornat *et al.* (1989), Palmer (1988), Pinto (1964), Ridgely & Gwynne (1989), Sherrod (1978), Sick (1985a, 1993), Slud (1964), Stiles & Skutch (1989), Teixeira *et al.* (1987a), Vannini (1989), Wetmore (1965), Willis (1963, 1966), Wilson *et al.* (1993), Zimmerman (1976a).

187. Hawaiian Hawk

Buteo solitarius

French: Buse d'Hawaï **German:** Hawaiiibussard **Spanish:** Busardo Hawaiano
Other common names: 'Io

Taxonomy. *Buteo solitarius* Peale, 1848, Kealakekua Bay, Hawaii.

Mistakenly identified as *Onychotes gruberi*, a new species from California by Ridgway in 1885. Monotypic.

Distribution. Endemic to Hawaiian Is; known to breed only on Hawaii I, but vagrants seen on at least three other islands of archipelago.

Descriptive notes. 41-46 cm; 385-650 g, male averages 441 g, female 606 g. Medium-sized buzzard, with most pronounced sexual size dimorphism in *Buteo*. Distinct pale and dark morphs and intermediate plumages. Pale morph adult has pale underparts, more or less streaked with brown on breast; immature unmarked golden buff on head and breast. Dark morph adult uniform dark brown; immature has tawny mottling on head and breast.

Habitat. Broad range of habitats up to 2700 m, from lowland agricultural areas to all types of forest, including exotic lowland forests near sea-level; virtually absent from arid regions

with little woody vegetation.

Food and Feeding. Varied diet, including mammals, birds and insects; sometimes large numbers of introduced spider *Agriopae avara*. Avian prey taken more frequently (60-68%) by birds at low altitude nests located in forested and agricultural areas; mammals are most common prey taken by pairs at medium altitude nests in pastureland. Usually seen soaring over forest or agricultural lands, but spends much time perched below forest canopy; juveniles frequently observed catching cockroaches.

Breeding. Mar-Aug. Bulky nest 50-78 cm wide, 13-50 cm deep, lined with green leaves; built 3.5-18 m above ground in small or large tree, often on top of bird's nest ferns (*Asplenium nidus*), on trunk crotches or on large or medium-sized branches. Clutch size reported as 2-3 eggs, but no indication of more than 1 egg laid in 30 nesting attempts recorded; incubation 38 days; chicks have dingy white to grey down; fledging 59-63 days; much extended post-fledging dependency, of up to 30+ weeks. Age of sexual maturity unknown; most pairs do not breed annually, although territories are maintained. Hatching success c. 88%; fledging success 62-73% of eggs laid.

Movements. Breeding adults generally sedentary; males typically remain within a discrete home range (48-562 ha) throughout the year, whereas female home range size larger (459-642 ha); females appear to roam widely within home range during non-breeding season, and some leave normal home range for extended periods during autumn and early winter.

Status and Conservation. RARE. CITES II. Currently listed as endangered by government of USA, but recently (1993) proposed for down-listing to threatened. Total population thought to be fairly stable and roughly estimated at 2700 birds, but figure principally from extrapolations of home range sizes of radio-tagged birds. Lack of accurate information on historical and current numbers makes assessment of population trends impossible. While species is well adapted to introduced flora and fauna of the islands, extensive clearing of forests for agriculture has undoubtedly decreased nesting habitat. In past, species protected by local beliefs; subsequently suffered extensively from shooting, but apparently infrequent now; repeated disturbance of nests can also be severe problem, causing nesting failure.

Bibliography. Anon (1984), Banko (1980), Berger (1981), Collar & Andrew (1988), Ehrlich *et al.* (1992), Ferguson-Lees & Faull (1992), Griffin (1985, 1989), King (1978/79), Munro (1960), Olson & James (1991), Peale (1848), Pratt *et al.* (1987), Ridgway (1885), Scott *et al.* (1986).

188. Red-tailed Hawk

Buteo jamaicensis

French: Buse à queue rousse **German:** Rotschwanzbussard **Spanish:** Busardo Colirrojo
Other common names: Harlan's Hawk (*harlani*)

Taxonomy. *Falco jamaicensis* Gmelin, 1788, Jamaica.

Forms superspecies with *B. ventralis*. Some authors include *B. buteo*, *B. oreophilus* and *B. brachypterus* in same superspecies. Race *harlani* has variously been treated as full species, or colour morph of *calurus*. Likewise, *keideri* sometimes considered a morph, mainly within range of *calurus*, but also in boundary region between *calurus* and *borealis*; however, *kriderii* is a pale form inhabiting an area also occupied by similarly pale race *richardsoni* of Merlin (*Falco columbarius*). Fourteen subspecies normally recognized.

Subspecies and Distribution.

B. j. atacensis Grinnell, 1909 - SE Alaska (USA) and coastal British Columbia (W Canada).
B. j. harlani (Audubon, 1830) - interior of Alaska, SW Yukon and N British Columbia.
B. j. calurus Cassin, 1856 - W North America W of Great Plains.
B. j. borealis (Gmelin, 1788) - N America E of Great Plains of C USA and Canada.

B. j. kriderii Hoopes, 1873 - plains of SC Canada S to Wyoming (NC USA).
B. j. fuertesi Sutton & Van Tyne, 1935 - Texas (S USA) to N Mexico.
B. j. hadropus Storer, 1962 - highlands of C Mexico.
B. j. kemsiesi Oberholser, 1959 - Chiapas (S Mexico) to N Nicaragua.
B. j. costaricensis Ridgway, 1874 - Costa Rica.
B. j. fumosus Nelson, 1898 - Tres Marias Is, off WC Mexico.
B. j. socorroensis Nelson, 1898 - Socorro I (Revillagigedo Is), off W Mexico.
B. j. umbrinus Bangs, 1901 - Florida (SE USA).
B. j. solitudinis Barbour, 1935 - Bahamas and Cuba.
B. j. jamaicensis (Gmelin, 1788) - Jamaica, Puerto Rico and Hispaniola E to N Lesser Antilles.

Descriptive notes. Male 45-56 cm, 690-1300 g; larger female 50-65 cm, 900-1460 g; wingspan c. 105-135 cm. Typical large, stoutish soaring buzzard. Very variable; upperparts usually dark brown, underparts from buffy-whitish to red or black, sometimes mottled; tail ranges from reddish chestnut to marbled with red, brown, grey and white. Juvenile has pale to dark brown upperparts; underpart colours variable in same fashion as adult, with vertical streaking usually visible, except in extreme melanistic individuals; tail barred, similar in colour to upperparts. Races separated by size and coloration. Presence and percentage

of colour morphs varies regionally, sometimes by race: in Alaska, mainly melanistic (*harlani*); in W North America, highly variable, but characteristically with rufous underparts (*calurus*, *socorroensis*); in E North America and Cuba predominantly or totally pale morph (*borealis*, *solitudinis*). **Habitat.** Ubiquitous; most habitats from desert, agricultural land, forest and woodland to tropical rain forest and even urban areas. Usually requires some elevated perches, e.g. trees or bluffs, in areas of open plains and grasslands.

Food and Feeding. Mainly small to medium-sized mammals, birds and reptiles. Major mammalian food in North America includes voles (*Microtus*), mice (*Peromyscus*), squirrels (*Spermophilus*) gophers (*Thomomys*) and lagomorphs (*Sylvilagus*, *Lepus*); frequently caught birds are Ring-necked Pheasant (*Phasianus*), quails (*Colinus*, *Callipepla*) and passerines around size of Starling (*Sturnus*). Locally, snakes may constitute 50% of biomass. In Caribbean, diet varies with habitat: 88% mammals in dry lowlands; 49% herps in cloud forest. Lizards, birds and crabs are main natural foods of *socorroensis*, since no native mammals occur in range. Prey size varies normally from 15 g to 2000 g (not accounting for arthropods and small amphibians). Most hunting (60%-80%) from elevated perch, but may use soaring, and 80% of attacks in rain or cloud forest from flight; also uses flap-and-glide flight only 10-50 m above ground.

Breeding. Late Apr-Jul in Alaska, Dec-May in S USA, Nov-May in Caribbean. Solitary. Stick nest placed in trees, cliffs or saguaro cactus, or on artificial structures (towers, electric power poles), or even buildings in urban areas. Nest large (71-76 cm) and may be refurbished during several years; usually lined with greenery or bark. Clutch size averages 2.9 in N Canada and NW USA; 2.1 in Florida; 2.3 in Caribbean; and 1.9 in low food years in Alaska, where main prey is cyclical; incubation 28-35 days; nestlings have white to greyish brown down, with white occipital spot; fledging 42-48 days; chicks stay with parents for additional 30-70 days. Co-operative breeding recorded, with 2 females and 1 male. May breed first at 2 years. Oldest ringed bird 21.5 years. Nest success c. 73-83% but as low as 60% in rain forests; c. 0.7-1.8 young fledged per attempt, with minimum in rain forest.

Movements. Variable: sedentary from S USA to S edge of range in C America and Caribbean; migratory in N of range, but resident over most of USA. From W boreal areas may move as far S as Panama to winter. Autumn migration starts in Aug and ends in Dec, peak (involving 75% of birds) in New Jersey between late Oct and late Nov. In W North America, migrates over broad front, but may follow leading lines, e.g. rivers, mountain ranges. Spring migration may start Feb, and birds may arrive in far N as late as Jun.

Status and Conservation. Not globally threatened. CITES II. Commonest *Buteo* over most of North America; locally increasing and expanding range, at expense of *B. lineatus* and perhaps *B. swainsoni*, in areas where habitats are modified. Between 1970's and 1980's, numbers in winter estimated to have increased by 33% in S Canada and USA to 350,000 birds. No comprehensive estimates for S part of range.

189. Rufous-tailed Hawk

Buteo ventralis

French: Buse de Patagonie **German:** Magellanbussard **Spanish:** Busardo Patagón
Other common names: Red-tailed Buzzard(!)

Taxonomy. *Buteo ventralis* Gould, 1837, no locality = Santa Cruz, Patagonia.

Long considered colour morph of *B. polyosoma*; alternatively race of *B. jamaicensis*, with which forms superspecies, some authors also including *B. buteo*, *B. oreophilus*, and *B. brachypterus*. Includes synonymous *B. pictus*. Monotypic.

Distribution. From SC Chile (Ñuble) and SC Argentina (Río Negro) S through Patagonia to Straits of Magellan.

Descriptive notes. 54-60 cm; 950 g; wingspan 130 cm. Polymorphic, with pale and dark morphs. Pale rufous morph has upperparts dark brown to blackish; throat white, rest of underparts russet to rusty with black streaks and hatching, and russet thighs; tail rufous with 8-10 black bars, the last broadest, and white tip. Dark morph sooty black, paler below, with undersides of wings and tail mottled grey. Iris dark reddish brown, legs and feet yellow. Female similar to male, but larger. Immature is fuscous brown above, with feathers edged rufous and whitish; below white, with sides of breast and belly streaked black; tail lacks rufous; indistinguishable from juvenile *B. jamaicensis*.

Habitat. Seems to be poorly understood, or species is generalist; reported from (dense) forest, open parkland and tree-lined fields, open coastal grassland, stunted *Nothofagus* forest and ridges and plateaux of Patagonian brush-steppe. From sea-level up to 1200 m.

Food and Feeding. Very few data available. Rabbits and one Southern Lapwing (*Vanellus chilensis*) recorded, but probably also takes smaller prey, e.g. small rodents. A powerful species; mostly hunts from perch; sometimes soars, and also seen hovering.

Breeding. Laying probably in Oct-Nov. Only two nests reported, both over 33 m high, one in Chilean oak, one in laurel (*Lurelia aromatica*); built of sticks, lined with feathers and wool. 3 young collected from 1 nest.

Movements. Appears to be resident.

Status and Conservation. Not globally threatened. CITES II. Until recently red-listed

in category Insufficiently Known, but currently considered near-threatened. Apparently rare throughout range; status remains poorly known, but species does not appear to be in immediate danger. Lack of sightings in one area that had been logged might suggest that species requires fairly undisturbed areas, but elsewhere recorded in more humanized habitats. Holocene material indicates former presence on Tierra del Fuego, where species not otherwise recorded.

Bibliography. Amadon (1964), Blake (1977), Clark, W.S. (1986), Collar & Andrew (1988), Daciuk (1977), Fjeldså & Krabbe (1990), Goodall *et al.* (1957), Greer & Bullock (1966), Humphrey, Bridge *et al.* (1970), Humphrey, Péfaur & Rasmussen (1993), Jaksic & Jiménez (1986), Johnson (1965), Meyburg (1986), de la Peña (1992), Rasmussen *et al.* (1992), Rasmussen & López (1988), Venegas & Jory (1979), Vuilleumier (1985).

190. Eurasian Buzzard

Buteo buteo

French: Buse variable

German: Mäusebussard

Spanish: Busardo Ratónero

Other common names: Common Buzzard

Taxonomy. *Falco Buteo* Linnaeus, 1758, Sweden.

Sometimes considered conspecific with *B. oreophilus* and also *B. brachypterus*; forms superspecies with these two, and possibly also with *B. jamaicensis* and *B. ventralis*; *B. jamaicensis* has been included in present species. Races *vulpinus*, *menetriesi* and *japonicus* all approaching species threshold. Island races poorly defined and possibly better rejected; birds from Madeira have also been awarded dubious race, *harterti*; birds from Italy and Sicily sometimes lumped in same race as those of Corsica and Sardinia, with priority for name *pojana*. Eleven subspecies normally recognized.

Subspecies and Distribution.

B. b. buteo (Linnaeus, 1758) - Europe E to Finland, Romania and Turkey; also Madeira; winters in S of range, and irregularly S to Liberia.

B. b. arrigonii Picchi, 1903 - Corsica and Sardinia.

B. b. rothschildi Swann, 1919 - Azores.

B. b. insularum Floericke, 1903 - Canary Is.

B. b. bannermani Swann, 1919 - Cape Verde Is.

B. b. vulpinus Gloger, 1833 - N Scandinavia and European Russia E to R Yenisey, and S to N Caucasus and C Asia (Altai, Tien Shan); winters mainly in Africa S of Sahara, and also in S Asia.

B. b. menetriesi Bogdanov, 1879 - S Crimea and Caucasus S to E Turkey and N Iran.

B. b. japonicus Temminck & Schlegel, 1844 - L. Baikal area and Mongolia E through Amurland and Manchuria to Sakhalin, Japan and Kuril Is, and S to Tibet, and possibly NW India; winters in S Asia, from India to Japan.

B. b. refectus Portenko, 1929 - W China and perhaps Himalayas.

B. b. toyoshimai Momiyama, 1927 - Izu Is and Bonin Is.

B. b. oshiroi Nagahisa Kuroda, 1971 - Daito Is (to E of C Ryukyu Is).

Descriptive notes. 50-57 cm; male 525-1183 g, female 625-1364 g; wingspan 113-128 cm. Extremely variable. Generally dark brown above and on most of underbody and underwing-coverts; from below, wingtip and trailing edge of wing dark, flight-feathers barred, pale area in outer primaries. Juvenile lacks broad band at tip of tail; dark band along trailing edge of wing less noticeable; generally paler and streaked on underparts. Extensive geographical variation, partly clinal and confounded by individual variation; races separated on size, coloration and plumage pattern; race *vulpinus* normally smaller, often with rusty underbody, underwing-coverts and upperside of tail, generally separable from *B. rufinus* on darker head and faintly barred tail; race *menetriesi* rather similar to *vulpinus*, but larger.

Habitat. Very variable, but almost always with some degree of tree cover, as species needs trees for nesting and roosting in. Prefers edges of woods and areas where cultivation, meadows, pastures or moors alternate with coniferous or deciduous woods, or at least clumps of trees. In winter, ranges into areas with very few trees, e.g. open fields, steppe or wetlands. Mainly flat terrain or gentle slopes at low or moderate altitudes; also in mountains, where in summer may forage above tree-line. Regularly perches on trees, poles, posts, rocks and pylons.

Food and Feeding. Adaptable, basing diet on

different prey types, according to local and seasonal availability. Essentially a hunter of small mammals, which often constitute up to 90% or more of prey; particularly rodents, with voles main prey over much of range; also mice, rats, hamsters, shrews, moles, young rabbits and hares; where abundant, rabbits can be locally important. Sometimes dominant prey by number are invertebrates, e.g. beetles, crickets, locusts and earthworms; reptiles locally important, including lizards, slow-worms and snakes; few amphibians; birds can be important by mass, particularly when mammals scarce, and occasionally species up to size of pigeon, pheasant and partridge taken. Occasionally scavenges carrion, e.g. medium-sized mammals, such as sheep. Hunts in clearings and open areas near edges of woods; almost always captures prey on ground. Spends long periods perched, scanning or loafing; also spots prey from gliding or soaring flight; sometimes hovers or hangs on wind; also walks on ground, when hunting invertebrates.

Breeding. Laying from late Mar to May, varying with latitude. Normally nests in large tree, fairly close to edge of wood; occasionally (normally in some regions) on cliffs. Nest is bulky platform of sticks and twigs, lined with greenery; built in fork or on branch near trunk; nests of other raptors sometimes used; each pair normally has several nests, switching to a different one each year. Normally 2-4 eggs (1-5); incubation 33-38 days per egg, mainly by female; male brings food at first, but female too once chicks 3 weeks old; chicks have first and second down white or brownish grey; fledging 50-60 days; independence 6-8 weeks later. Up to 3 chicks fledge (average 1.0-2.4 per successful pair, in Germany). Sexual maturity normally at 3 years, unusually at 1 year old. Oldest recorded bird over 25 years old.

Movements. Migratory in Scandinavia (wintering in S Sweden), and in most of former USSR; partially migratory in C Europe (increasingly so with latitude); sedentary in Britain, S Europe, Turkey, Caucasus, Japan and in island populations. Winters in Africa, Israel and Arabia; easternmost breeding populations winter in India, Indochina and China; part of C European population move S and SW in autumn, with some migrants reaching NW or even W Africa. Race *vulpinus* completely migratory, travelling up to 13,000 km, to winter in S Europe and SW Asia, but mainly in sub-Saharan Africa, particularly in S; crosses over to Africa mainly via Bab al Mandab in autumn, and returns by Suez in spring; 465,827 birds recorded at Elat (Israel) in spring 1986. Race *menetriesi* apparently non-migratory. Length of migrants' absence from breeding grounds increases with latitude.

Status and Conservation. Not globally threatened, CITES II. Probably second (or third) commonest raptor species in Europe; greatest abundance in e.g. Poland and former USSR; rough estimates of 160,000-300,000 pairs in Europe (excluding former USSR), 400,000 pairs in European Russia, and 8000-11,000 pairs in Byelorussia; race *japonicus* numerous and stable at present in Asian Russia. Race *insularum* of Canary Is probably numbers over 400 pairs (1990). Decline during much of 20th century in Europe, but stabilization with local increases mainly from 1970's. Range much reduced in Britain by early 20th century; subsequent increase and expansion back towards E, but process slowed up in 1950's, when myxomatosis epidemic killed off c. 99% of rabbit population; 12,000-15,000 pairs in 1983. Most important cause of decline has been direct persecution; also affected by use of poisoned baits and pesticides, by habitat loss and increasing rarity of prey.

191. Mountain Buzzard

Buteo oreophilus

French: Buse montagnarde

German: Bergbussard

Spanish: Busardo Montañés

Other common names: Forest/Woodland/African Buzzard

Taxonomy. *Buteo oreophilus* Hartert and Neumann, 1914, Koritscha, Ethiopia.

Forms superspecies with *B. buteo* and *B. brachypterus*, and possibly also with *B. jamaicensis* and *B. ventralis*. Has been considered conspecific with *B. buteo*. Present species has alternatively been called *B. tachardus*. Race *trizonatus* may merit treatment as full species. Two subspecies normally recognized.

Subspecies and Distribution.

B. o. oreophilus Hartert & Neumann, 1914 - highlands of Ethiopia S to Tanzania and Malawi.

B. o. trizonatus Rudebeck, 1957 - S & E South Africa.

Descriptive notes. 45 cm; c. 700 g. Similar to migrant *B. buteo vulpinus*, but generally whiter below with uniform covering of large dark brown blotches. Juvenile has narrow bars across tail, and is finely streaked below on white underparts. Race *trizonatus* has pale band across breast and generally has smaller blotches or streaks; more rufous tone to upperparts.

Habitat. Montane forest patches, extending to exotic plantations and adjoining grassland, from sea-level in S South Africa to above 4500 m further N.

Food and Feeding. Mainly rodents, also gold-

en moles, reptiles, especially chameleons, and a few small birds, frogs and insects. Hunts from a perch within forest, often on the edge overlooking open habitat; drops onto prey on the ground below or snatches it from low foliage.

Breeding. Laying Mar-Jul in Uganda; Sept-Oct in Kenya; Sept-Oct in S Africa. Soars and calls above forest before nesting. Builds a large stick platform high in a forest tree, lined with green foliage. Usually 2 eggs (2-3); incubation unrecorded; chicks have white down; fledging c. 50 days; post-fledging period of up to 130 days.

Movements. In South Africa apparently breeds only in winter-rainfall area of S Cape Province, and moves N along Drakensberg escarpment to Natal and Transvaal in winter. No movements described for E Africa.

Status and Conservation. Not globally threatened. CITES II. Common in areas of most extensive habitat (South Africa, Rwanda). Vulnerable due to limited and patchy distribution of habitat, especially to forest cutting. Adopts plantations of exotic pine and eucalypt trees for nesting and hunting, which has extended range in South Africa. Not known to be affected by pesticides.

Bibliography. 192. Madagascar Buzzard

Buteo brachypterus

French: Buse de Madagascar

German: Madagaskarbussard

Spanish: Busardo Malgache

Taxonomy. *B. brachypterus* Hartlaub, 1860, Madagascar.

Forms superspecies with *B. buteo* and *B. oreophilus* and possibly also with *B. jamaicensis* and *B. ventralis*. Has been considered conspecific with *B. buteo*. Monotypic.

Distribution. Madagascar.

Descriptive notes. 48-51 cm. Individually variable, but most individuals have greyer head than somewhat similar African *B. oreophilus* and Palearctic *B. buteo*; large white patch on belly, and different tail pattern; differs from all other *Buteo* in bluish grey cere and yellowish white legs. Sexes similar, adult with pale yellow eye. Juvenile with orange-brown eye and narrow dark bars across tail.

Habitat. All types of forest and woodland, but largely absent from the deforested central plateau. Also uses rocky slopes up to 2300 m.

Food and Feeding. Mainly small vertebrates such as frogs, lizards, snakes, rodents and

small birds, but also crabs. Hunts mainly from a prominent perch. Spends much time soaring high above home range, often in pairs.

Breeding. Laying Sept-Oct. Stick nest placed in a high fork of a tree, such as a baobab (*Adansonia*), or wedged into an epiphyte, in primary forest or adjacent shifting agriculture. 2 eggs; incubation 4-5 weeks; fledging 6-7 weeks; only a single chick usually raised.

Movements. None recorded.

Status and Conservation. Not globally threatened, CITES II. The third most common raptor on Madagascar, based on road counts of one bird every 56 km. Eight pairs occupied about 20 km² on the Masoala Peninsula. Only uncommon on deforested central plateau.

Bibliography. Benson *et al.* (1976), Berkelman (1993, 1994), Dee (1986), Langrand (1990), Langrand & Meyburg (1984), Milon *et al.* (1973), Siegfried & Frost (1973).

193. Long-legged Buzzard

Buteo rufinus

French: Buse féroce

German: Adlerbussard

Spanish: Busardo Moro

Taxonomy. *Falco rufinus* Cretzschmar, 1827, upper Nubia, Shendi, Sennar and Ethiopia.

Forms superspecies with *B. hemilasius*, with which has been considered conspecific. Race *cirtensis* may be separate species. Two subspecies recognized.

Subspecies and Distribution.

B. r. rufinus (Cretzschmar, 1827) - SE Europe and Asia Minor E through Iran and Afghanistan to NW Mongolia and S to NW India (Garhwal); winters to NE Africa and N India.

B. r. cirtensis Levaillant, 1850 - N Africa, from Mauritania to Egypt; Arabia.

Descriptive notes. 50-65 cm; male 590-1281 g, female 945-1760 g; wingspan 126-155 cm. Polymorphic, with great variation, from dark morph through reddish morph to very pale morph. Typical morph shows pale head, breast and tail contrasting with rufous belly; lacks tail barring of most other buzzards; dark carpal patches, rusty underwing-coverts; flight-feathers paler, with black trailing edge and wingtip; tarsus somewhat elongated. Female slightly larger than male. Juvenile has faintly barred tail; black on trailing edge of wing less marked. Race *cirtensis* smaller, often paler; lacks dark morph.

Habitat. Steppe, semi-desert, rocky or stony country; also open woodland or woods with clearings; from plains and foothills to mountains, breeding from coast up to at least 2500 m, and observed above 3500 m. In winter, widely scattered in variety of habitats, from desert to cultivation and wooded areas. Uses prominent perches on trees, rocks, posts, etc.

Food and Feeding. Mainly small mammals, e.g. gerbils (*Meriones*), rats, voles, young rabbits and hares, pikas; also reptiles, e.g. lizards (*Uromastix*, *Agama*) and snakes; some small birds, amphibians and large insects, e.g. locusts, grasshoppers, beetles. Rather sluggish; often waits for long periods on perch or on ground; also forages with soaring flight; hangs on wind, without beating wings, to survey ground. Can take advantage of fires to prey on escaping animals.

Breeding. Laying mainly in Mar-Apr; from Jan in some coastal regions of Morocco. Nests on cliff ledges and crags, also in trees when available; sometimes on steep slopes. Bulky nest, c. 80 cm wide, 30-50 cm deep, of twigs and sticks, lined with green leaves, wool or other materials; sometimes several nests on same crag. Both adults build nest; nest can be reused; also uses old nests of other birds. Normally 2-4 eggs (mean 2.6 Morocco); incubation at least 28 days; chicks have white first down, white to creamy white second down; fledging c. 45 days.

Movements. N African *cirtensis* sedentary and dispersive, having reached Senegal on one occasion. Eurasian *rufinus* either totally migratory, or partially migratory in N of breeding range and sedentary in S; winters from Turkey, Middle East and Arabia to Pakistan, N India and S Tibet; some birds reach N Africa, mainly Nile Valley and E sub-Saharan Africa. Leaves breeding grounds mainly in late Aug and Sept; returns mid-Mar to mid-Apr. Local movements due to droughts have been reported.

Status and Conservation. Not globally threatened. CITES II. Population sizes and trends little known. In European Russia c. 1000 pairs estimated in early 1990's. Scarce in Balkans; in 1980's, c. 200 pairs in Bulgaria (increasing), c. 20 pairs in Macedonia, and c. 60 pairs in Greece. Fairly common in Israel, with at least c. 100 pairs in early 1980's, following recovery from poisoning of 1950's. In 1980's, perhaps c. 400 pairs in Tunisia, and over 1000 pairs each in Morocco and Turkey; rare breeder in mountains of N Pakistan.

Bibliography. Ali & Ripley (1978), Berger (1987), Brown *et al.* (1982), Cheng Tso-hin (1987), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Efimenko (1989), Eichécopar & Húe (1978), Flint *et al.* (1984), Gensbøl (1986), Goodman *et al.* (1989), Handrinos & Demetropoulos (1983), Hollom *et al.* (1988), Knyshatus (1993), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Meyer de Schauensee (1984), Mingozzi (1987), Patrikeev (1993), Pär (1987), Richardson (1990), Roberts (1991), Shiriha & Christie (1992), Simeonov *et al.* (1990), Strigunov (1984), Thillay (1989).

194. Upland Buzzard

Buteo hemilasius

French: Buse de Chine

German: Mongolenbussard

Spanish: Busardo Mongol

Other common names: Mongolian Buzzard

Taxonomy. *Buteo hemilasius* Temminck and Schlegel, 1844, Japan.

Forms superspecies with *B. rufinus*, of which has been considered a race, but ranges overlap without interbreeding. Monotypic.

Distribution. S Siberia and Mongolia E to Manchuria, and S to C China and SE Tibet. Winters in N India (Kashmir to Sikkim), E China and Korea.

Descriptive notes. 66-71 cm. Rather variable, from very dark to very pale. Larger and generally less rufous than *B. rufinus*; tarsi with smaller scales, and partially feathered. Pale morph juvenile brown above with pale feather edges, head white or pale, spotted brown; dark juvenile resembles dark morph adult.

Habitat. Open, normally dry, grassy areas, e.g. steppes, plateaux and grassy mountain slopes, with rocky areas for nesting. Tends to inhabit steeper slopes than *B. rufinus*, but also present in plains. Reaches great altitudes, e.g. over 5000 m in Tibet. Few observations in Japan, all from open agricultural lowlands.

Food and Feeding. Mainly rodents, e.g. ground squirrels, voles, gerbils, pikas and young marmots, but also young hares, to lesser degree small terrestrial birds such as larks, but sometimes larger birds, e.g. Willow Grouse (*Lagopus lagopus*). Tibetan Snowcock (*Tetrao galus tibetanus*); also birds' eggs, amphibians and insects, e.g. beetles, grasshoppers. Hunts prey from surveying flight or after spotting it from perch; sometimes catches insects on ground.

Breeding. Laying in Apr-May. Nests on ledges in rock faces, preferably protected by overhang or by vegetation; nest built with sticks and lined with wool, grass and other material. Normally 2-4 eggs, occasionally 5; replacement laying occurs; incubation c. 1 month; chicks have greyish brown down; fledging c. 45 days; 2 chicks normally fledge, although up to 4 recorded.

Movements. Mostly migratory, with some birds perhaps wintering in or near breeding areas; generally avoids snow-covered areas. In China, winters mainly N of R Yangtze, occasionally further

S. to Guangdong; records of 30 and 40 birds seen on consecutive days in NW Sichuan (C' China) in 1989; rare in winter on S slopes of Himalayas in N India and Nepal. Accidental to Japan, mainly in winter, almost certainly from Korea.

Status and Conservation. Not globally threatened. CITES II. Status very poorly known; apparently infrequent or rare throughout most of breeding range and in winter quarters, although locally abundant, e.g. in Tibet. Generally rare, but locally common in extreme S Siberia and Mongolia. Possibly subject to fluctuations related to abundance of rodents.

Bibliography. Ali & Ripley (1978), Brazil (1991), Brazil & Hanawa (1991), Cheng Tso-hin (1987), Dementiev & Gladkov (1951), Echécopar & Hùe (1978), Flint *et al.* (1984), Inskipp & Inskipp (1985), Knystautas (1993), Liu Huan-jin *et al.* (1986), Meyer de Schauensee (1984), Popov & Verzhutskii (1990), Ripley (1982), Rogacheva (1992), Sushkin (1938), Zhang Xiao-ai (1984).

195. Ferruginous Hawk

Buteo regalis

French: Buse rouilleuse **German:** Königsbussard **Spanish:** Busardo Herrumbroso
Other common names: Ferruginous Roughleg

Taxonomy. *Archibuteo regalis* G. R. Gray, 1844. Real del Monte, Hidalgo, Mexico. Formerly placed, together with *B. lagopus*, in now obsolete genera *Triorchis* or *Archibuteo*. Monotypic.

Distribution. S Canada from S Alberta to SW Manitoba, S through WC USA to N Texas; winters S to N Mexico.

Descriptive notes. 56-69 cm; 980-2030 g, male averages 1050, female 1230 g; wingspan 122-142 cm. Largest *Buteo*. Variable, with pale and dark morphs: pale adult has rufous upperparts and white underparts with distinctive rufous thighs that form "V" in flight; dark adult sooty or rufous brown except for grey tail. Juvenile pale morph has upperparts pale brown or greyish, with underparts (including thighs) white sparsely streaked dark, and tail greyish; dark morph similar to adult.

Habitat. Arid, semi-arid and grassland regions of W North America. Avoids high altitudes and forest interiors. Common in

agricultural land. Frequents cliffs, bluffs and rocky outcrops in area.

Food and Feeding. Mainly mammals (95% by biomass, 83% by frequency), particularly rabbits, hares, ground squirrels (*Spermophilus*), pocket gophers (*Thomomys*) and prairie dogs (*Cynomys*). Fledgling passerines frequently taken on ground; adult birds as large as grouse and pheasants also caught. Reptiles, amphibians and insects form c. 3% of diet. Breeding success and abundance closely tied to cycles and oscillations of major mammal prey species. Considerable food overlap (75-95%) with sympatric *B. swainsoni* and *B. jamaicensis*. In winter, feeds more often in cultivated agricultural areas. Takes most prey by perch-hunting or from low or soaring flight; also by hovering, or on ground after aerial survey.

Breeding. Mar-Jul; in Canada, laying c. 2 weeks later than in centre of range. Disproportionately large stick nest, often more than 100 cm wide and 100-200 cm deep, with inner bowl for eggs 17-32 cm deep, lined with bark, leaves or cow or horse dung; trees or large shrubs preferred (c. 49% of nests), with (in order of frequency) cliffs, utility power poles, dirt outcrops, ground, artificial nest platforms, haystacks and derelict buildings also used; nest tree usually isolated or at edge of stand of trees; use of artificial nest platforms on poles increasing, with up to 20-60% used, depending on area. Usually 3-4 eggs (1-8); incubation 32-33 days; chicks have white down; fledging 38-40 days. Sexual maturity at 2 years. Oldest ringed bird 20 years. Clutch size, success and number of pairs nesting varies widely with food supply; as many as 89% of pairs nested in high food year, but only 43% in low food year, in same area. Average fledging rate (per total attempt) ranges from 3-0 in high food years, to 0-7 in low food years.

Movements. Some young birds disperse as soon as fledged. N birds seem to move farthest with some Canadian ringed birds found in Mexico; birds from Alberta (W Canada) winter mainly in Texas (S USA), covering c. 2100 km, with movement through plains rather than mountains.

Status and Conservation. Not globally threatened. CITES II. Local losses and apparent reduction of entire population have led to calls for listing as threatened species; not listed because of insufficient supporting data. In 1979, breeding population estimated at 2800-3600 pairs; in 1992, estimated at 3000-5600 pairs. Especially sensitive to disturbance, which causes birds to abandon during egg-laying and incubation periods. Because of habitat alterations and local losses, population extensively managed by use of artificial nest platforms.

Bibliography. 196. Rough-legged Buzzard

Buteo lagopus

French: Buse pattue **German:** Raufußbussard **Spanish:** Busardo Calzado
Other common names: Rough-legged Hawk

Taxonomy. *Falco Lagopus Pontoppidan*, 1763, no locality = Denmark.

Variation clinal in Palearctic, with broad intergradation zones. Race *menzhieri* sometimes merged into *kamtschatskensis*. Four subspecies normally recognized

Subspecies and Distribution.

B. l. lagopus (Pontoppidan, 1763) - N Eurasia, from Scandinavia E to area of R Oh and R Yenisey; winters mainly in C Europe and C Asia.

B. l. menzhieri Dementiev 1951 - NE Asia E of R Oh and R Yenisey; winters S to C Asia, N China and Japan.

B. l. kamtschatskensis Dementiev 1931 - Kamchatka; presumably winters in EC Asia.

B. l. sanctijohannis (Gmelin, 1788) - Alaska and N Canada; winters S to C & S USA.

Descriptive notes. 50-60 cm; male 600-1377 g, female 783-1660 g; wingspan 120-150 cm. Plumage very variable, from all dark to rather pale. Conspicuous broad dark subterminal band on white tail. Female generally shows more contrasted plumage than male; just one narrow, inconspicuous bar (several in male) next to broad subterminal tailband. Juvenile paler, with single tailband broader and paler. Geographical variation clinal; races separated on size and intensity of pigmentation.

Habitat. Essentially found in tundra, mainly treeless, although also wooded tundra and even extreme N taiga, particularly in years of

lemming and vole abundance. Normally in flat lowlands; in Norway up to 1200 m or more. In winter, often in areas more modified by man, but still mainly in open terrain, e.g. prairies, cultivation, marshes; heavily dependent on abundance of rodents and availability of suitable nest-sites, basically rock faces.

Food and Feeding. Small mammals normally make up 80% or more of prey; mainly voles and lemmings in breeding range, and also many voles in winter quarters; of less importance are mice, shrews, hares, ground squirrels, pikas, weasels and even bats. To lesser extent takes small birds, particularly young birds in breeding season: from buntings and thrushes to grouse, waders and other waterbirds; importance of birds can increase when rodents scarce. Occasionally other vertebrates (including fish), insects (e.g. grasshoppers, crickets) and carrion, ranging in size from small animals through rabbits and ducks up to caribou and marine mammals. Awaits prey on perches, e.g. posts, rocks and other vantage points; may hover in flight to detect prey. Sometimes hunts crepuscularly, foraging in open areas; where inhabits woodland, forages in clearings and bogs; may visit rubbish dumps.

Breeding. Laying in May-Jun. Nests at vantage points, normally high on cliffs, rocky outcrops or riverbanks, preferring protected ledges; infrequently in trees, and occasionally on slopes. Bulky nest of sticks or twigs, lined with grass, sedges, hair and feathers; often several nests fairly close together, which can be used in turn in consecutive years. Normally 3-5 eggs (2-7), laid at interval of c. 2 days; clutch size varies with abundance of lemmings and voles, e.g. in Norway 2-3 eggs in bad years, 5-7 eggs in good years; replacement laying occurs; incubation 28-31 days per egg, almost exclusively by female; chicks have first down grey, second down darker brownish grey; fledging 34-45 days, males c. 1 week before females; independence 3-5 weeks later. Breeding success varies with food availability; on average, young from c. 50% of eggs reach fledging. First breeding probably at 2 years old. Oldest recorded bird 18 years.

Movements. Migratory, with breeding range and winter quarters usually quite separate. Date, duration and distance of migration can vary with southward extent of snow cover and abundance of rodents in breeding range; in certain years, some birds fly further S than normal winter quarters. In Europe and Asia most birds leave breeding areas from mid-Sept to early Nov, remaining in winter quarters Nov-Mar; birds return to breeding areas from late Apr to late May, although when food supply scant may make extensive nomadic movements on arrival; may also make movements in winter quarters, e.g. leaving areas with prolonged show cover.

Status and Conservation. Not globally threatened. CITES II. Widespread and fairly common in boreal regions of Holarctic, where neither species nor habitat are subject to excessive human pressure, although such pressure greater in winter quarters. Considerable fluctuations in range and numbers, but probably stable in medium and long term; accurate censuses lacking, and estimates subject to wide margins of error. Partial winter censuses suggest North American population of c. 50,000 birds in 1986; estimated c. 100,000 pairs in European Russia in early 1990's.

Bibliography. Armstrong (1983), Bieldstein (1978), Brazil (1991), Brazil & Hanawa (1991), Brown *et al.* (1982), Cade (1955), Cheng Tso-hin (1987), Clark, W.S. 197. Red-necked Buzzard

Buteo auguralis

French: Buse d'Afrique **German:** Salvadoribussard **Spanish:** Busardo Cuellirrojo
Other common names: (African) Red-tailed Buzzard(!)

Taxonomy. *Buteo auguralis* Salvadori, 1865, Ethiopia.

Monotypic.

Distribution. Sierra Leone E to Uganda and Ethiopia, and S to N Angola; outside breeding season, occurs in Sahel zone.

Descriptive notes. 35-40 cm; male 525-620 g, female 580-890 g. Head and neck chestnut, underparts either white or spotted with brown; smaller and in different habitat to *B. augur*. Juvenile shows similar differences, but is more uniform brown, becoming paler with wear.

Habitat. Forest edge and tall broad-leaved woodlands, including agricultural clearings and secondary forest.

Food and Feeding. Wide range of small animals; vertebrates predominate by weight, including rodents, snakes, chameleons and lizards, also small birds and frogs; arthropods taken prey by numbers, from termite alates to

crabs. Perches in the open for long periods, on dead trees or poles, taking most prey from the ground or occasionally from foliage. Sometimes hawks insects above bush fires.

Breeding. Laying Jan-Feb in W & NE Africa; Oct in Zaire and W Angola. Rocking and swooping display flight with shrill calling. Builds platform of sticks high in a tree, often in *Borassus* palm, rarely on cliff ledge; nowadays frequently on pylons in Ghana. 2-3 eggs; incubation plus fledging c. 50-60 days; chick has white down, with grey crown and face, cinnamon on back and wings, and long silky down on head.

Movements. Regular annual N-S migration in W Africa, moving S in Sept just after rains to breed along forest edge and woodland adjoining Guinea and Upper Congo forests. At commencement of

rains in Mar moves N into drier, more open savanna, where little studied. Movements in C & NE Africa not as obvious or well understood; possibly separate population in N Angola and SW Zaire.

Status and Conservation. Not globally threatened. CITES II. Generally common. Ability to move in conjunction with suitable habitat conditions during both breeding and non-breeding seasons offers considerable flexibility. Vulnerable to degradation of woodland but uses many secondary habitats and probably benefits from cutting of rain forest. Not known to be affected by pesticides.

Bibliography. Brown *et al.* (1982), Chapin (1932), Grimes (1987), Holman (1947), Lippens & Wile (1976), Louette (1981, 1991), Mackworth-Præd & Grant (1957-1973), Pinto (1983), Serle (1950), Serle *et al.* (1977), Snow (1978), Thiollay (1975a, 1976a, 1977b, 1978a, 1978c, 1985d).

198. Augur Buzzard

Buteo augur

French: Buse augure **German:** Augurbussard **Spanish:** Busardo Augur Oriental

Taxonomy. *Falco (Buteo) Augur* Rüppell, 1836, Ethiopia. Forms superspecies with *B. archeri* and *B. rufofuscus*; all three sometimes considered conspecific, but differ on calls and coloration, showing disjunct distribution; limited overlap with *B. rufofuscus* in C Namibia. Monotypic.

Distribution. Ethiopia S to Zimbabwe and W to S Angola and N & C Namibia.

Descriptive notes. 55-60 cm; 1097-1303 g; wingspan 132 cm. Broad wings with black trailing edge to white underside sometimes mistaken for *Circus pectoralis*, but short tail bright rufous; *Terathopus ecaudatus* has black underparts. In E African part of range, 10-25% comprise a melanistic morph; more numerous in areas of higher rainfall. Female similar, but larger; typically has more extensive black markings on throat. Juvenile with dark streaks on throat and breast unlike plain underparts of juvenile *B. rufofuscus*.

Habitat. Mountainous and hilly country covered in forest patches, open woodland, savanna and grassland, to over 5000 m, including some isolated hills in otherwise flat terrain.

Food and Feeding. Mainly lizards, snakes, rodents and mole-rats, together with some small birds, insects and carrion. Hunts mainly from a rock or tree perch, sometimes from soaring, hovering or gliding flight, rarely while walking about on the ground. Hunts both within forest or woodland, and over open habitats.

Breeding. Laying spread over all months in E & NE Africa (peak Jun-Sept); May in Zaire; Jul-Oct in S & C Africa. Spectacular aerial flight and calling display. Builds a substantial stick nest in a tree, or on a cliff ledge, or on a tree protruding from a cliff, lined with green leaves. Usually 2 eggs (2-3); incubation 39-40 days; chicks have pale grey down; elder chick usually kills younger sibling; fledging 48-55 days; some polygamy recorded.

Movements. Resident and sedentary; some movements reported outside breeding season in parts of E Kenya, Nov-Jan. Vagrant to S Zaire.

Status and Conservation. Not globally threatened. CITES II. Common in E Africa, with nests less than 1 km apart, and in suitable habitat in S Africa, with approximate density of 1 pair/17 km². Vulnerable to extensive afforestation of grassland habitat, or to lowered carrying capacity through overgrazing. However, adapts well to human settlement and extends onto grassland using small exotic plantations for nesting and roosting. Not known to be affected by pesticides.

Bibliography. Bataamba (1989), Benson & Benson (1975), Britton (1980), Brooke (1975), Brown *et al.* (1982), Ginn *et al.* (1989), Lendrum (1979), Lendrum & Lendrum (1982), Lewis & Pomeroy (1989), Louette (1991), Maclean (1993), Pickford *et al.* (1989), Snow (1983), Snow (1978), van Someren (1956), Steyn (1982), Weaving (1972).

199. Archer's Buzzard

Buteo archeri

French: Buse d'Archer **German:** Archerbussard **Spanish:** Busardo Augur Somali

Taxonomy. *Buteo jakal archeri* W. L. Sclater, 1918, Waghar, Somalia. Forms superspecies with *B. augur* and *B. rufofuscus*; all three sometimes considered conspecific, but differ on calls and coloration, showing disjunct distribution. Monotypic.

Distribution. Highlands of N Somalia.

Descriptive notes. 50-55 cm. Chestnut underparts quite distinct from larger, white-breasted neighbour *B. augur*. Rufous feathers on upperparts and white throat with black streaks also notable; some birds have blackish sides to upper breast. Juvenile pale rufous to whitish below with sparse streaking on upper breast.

Habitat. Mountainous and hilly savanna.

Food and Feeding. Unstudied, probably various small vertebrates and arthropods. Likely to hunt from perch, or from soaring flight on its broad wings.

Breeding. Laying at end of dry season, late Mar-early Apr. 1-2 eggs; further details un-

recorded. Chicks often in nest during start of rainy season.

Movements. None recorded, unlikely within limited range.

Status and Conservation. Not globally threatened. CITES II. Status uncertain. Appears vulnerable, due to small range and possibility of rapid degradation of habitat by cutting of trees and overgrazing. Virtually unstudied; on previous information lumped with related species *B. augur* and *B. rufofuscus*. Not known to be affected by pesticides.

Bibliography. Archer & Godman (1937), Ash & Miskell (1983), Brooke (1975), Brown *et al.* (1982), Grossman & Hamlet (1964), Snow (1978).

200. Jackal Buzzard

Buteo rufofuscus

French: Buse rounoir **German:** Felsenbussard **Spanish:** Busardo Augur Meridional

Taxonomy. *Falco rufofuscus* J. R. Forster, 1798, South Africa. Forms superspecies with *B. augur* and *B. archeri*; all three sometimes considered conspecific, but differ on calls and coloration, showing disjunct distribution; limited overlap with *B. augur* in C Namibia. Monotypic.

Distribution. South Africa, S & C Namibia, Lesotho, Swaziland, S Mozambique and S Botswana.

Descriptive notes. 45-55 cm; male 865-1080 g, female 1150-1695 g; wingspan 132 cm. Bold patterning distinctive in flight, with black and chestnut body against rufous tail and broad black and white wings. Individually variable. Sometimes mistaken for larger, narrow-winged *Terathopus ecaudatus*. Morph exists with pale, almost white, breast patch recalling *B. augur*. Juvenile pale rufous brown below.

Habitat. Open steppe and grassland, especially in hilly and mountainous terrain.

Food and Feeding. Mainly small mammals up to size of young hyrax, birds to size of francolin, and large snakes and lizards. Also takes some insects, and carrion important in winter. Hunts for much of the time on the wing, soaring and hanging expertly in updraughts and strong, gusty winds. Stoops at prey from foraging flight, or hunts from a perch.

Breeding. Laying May-Oct. Builds a large stick nest lined with leaves, usually on a cliff ledge, sometimes in a tall tree. Usually 2 eggs (2-3); incubation c. 40 days; chick has white down; elder chick often kills younger sibling; fledging 50-53 days.

Movements. No regular movements described, but some suggested by long distance (640 km) ringing recoveries of adults and juveniles, and appearance of birds on open plains away from nesting areas in non-breeding season.

Status and Conservation. Not globally threatened. CITES II. Common, at 1 bird/62 km on road transects through karoid steppe, and at densities of 1 pair/17-30 km² in mountainous Transvaal habitats in South Africa, where estimated 1100 pairs. Prefers areas of low human density and extensive small-stock farming. Not known to be affected by pesticides.

Bibliography. Barnard (1986), Brooke (1975), Brown *et al.* (1982), Ginn *et al.* (1989), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Norgar & Lasbrey (1953), Pickford *et al.* (1989), Schmitt *et al.* (1987), Snow (1978), Steyn (1982), Tarboton & Allan (1984).

Genus *MORPHNUS* Dumont, 1816

201. Guiana Crested Eagle

Morphnus guianensis

French: Harpie huppée German: Würgadler Spanish: Arpía Menor
Other common names: Crested Eagle

Taxonomy. *Falco guianensis* Daudin, 1800, Cayenne.

Includes *M. taeniatus*, a variant of dark morph with heavily banded underparts. Monotypic.

Distribution. Guatemala and Honduras through Central America to Colombia and S to Paraguay, extreme NE Argentina (Misiones) and S Brazil; W of Andes, ranges S only to Serranía de Baudó (WC Colombia).

Descriptive notes. 71-84 cm; 1750 g. A large, lanky eagle with prominent nuchal ruff and long, black occipital crest; polymorphic, with two distinct colour morphs, and several intermediate morphs. Pale morph has head, neck and breast ashy grey to brown; above blackish brown overall; belly and underwing-coverts white, finely barred cinnamon; tail black, narrowly tipped white and boldly barred pale greyish. Dark morph similar above, but all black below, or black with narrow white barring. Iris dark brown to grey or greyish yellow, cere black, legs and feet dull yellow. Pale morph differs from *Harpia harpyja* in smaller size, bill and talons, slimmer build, relatively longer tail and lack of dark breast band. Female similar to male, but substantially larger. Immature blackish above mottled white; head, neck and underparts white, crest tipped black; tail with narrower, less conspicuous bands than in adult; takes several years to reach adult plumage, gradually becoming darker.

Habitat. Lowland tropical and subtropical forest, including gallery forests in S of range. Occurs up to 600 m, and perhaps up to 1000 m, in Colombia.

Food and Feeding. Snakes, both arboreal and terrestrial; small to medium-sized mammals, especially arboreal rodents and marsupials and kinkajous (*Potos flavus*); also birds and a tree frog (probably *Phyllomedusa*). Porcupine quills impaled inside stomach of a bird found starving. Seen attacking Grey-winged Trumpeters (*Psophia crepitans*), Guianan Cocks-of-the-rock (*Rupicola rupicola*) on a lek, and monkeys. Two kinkajous (a strictly nocturnal species) were delivered to nest an hour or more apart one morning. One bird, seen gliding extremely slowly, with tail and wings fanned wide, c. 50 m over canopy, was perhaps hunting. Often soars over forest; said to sit still on high perch for long periods.

Breeding. Very few nests discovered, and only 1 studied in detail. Hatching in Apr (late rainy season) at Manaus, NC Brazil; nest trimming in Mar in Venezuela. Bulky stick nest in the crotch of a large tree. 2 eggs, but only 1 young raised. Vocal around the nest. 1 copulation witnessed in the nest, without courtship feeding; male provides food during incubation and first month after hatching, when female begins to deliver food, including larger prey items. Male calls on approaching nest, delivers food and remains only a few minutes; female very rarely returns to nest without food or fresh greenery with which to trim nest.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Formerly red-listed in category Rare, but currently considered near-threatened. Sparsely distributed throughout extensive tropical forests and gallery forests in S of range. Not immediately threatened, but large size and low population densities make species particularly sensitive to the hunting pressure that accompanies any human incursions into forests. Many old records from Chocó region (NW Colombia), which is now widely deforested; similar extensive deforestation in Central American parts of range suggest that local contraction of range or serious declines in population density have already occurred. Thought to be able to sustain small amounts of human pressure slightly better than *H. harpyja*, although apparently rarer than that species in several areas, e.g. Venezuela, Surinam.

Bibliography. Belton (1984), Bierregaard (1985), Blake (1977), Collar & Andrew (1988), Ellis & Whaley (1981), Friedmann (1950), Haverschmidt (1968), Hilty & Brown (1986), Kiff *et al.* (1989), King (1978/79), Lehman (1943), Meyburg (1986), Monroe (1968), Olrog (1985), Parker *et al.* (1982), de la Peña (1992), Phelps & Phelps (1958), Pinto (1964), Ridgely & Gwynne (1989), Sick (1985a, 1993), Stiles & Skutch (1989), Terborgh (1983), Thiollay (1984, 1989b), Tostain *et al.* (1992), Trail (1987), Wetmore (1965).

head and thighs as adult, tail bands reduced to 4-5. **Habitat.** Lowland tropical forest; normally below 800 m, but single record at 1600 m in Colombia. Occurs in uninterrupted expanses of forest, but will nest in areas where high-grade forestry has been practised, and will hunt through forest patches in a pasture/forest mosaic. Apparently rarely, if ever, soars; occasionally conspicuous while sunbathing on prominent emergent perches in early morning.

Food and Feeding. Preys on large, powerful vertebrates, including adult howler (*Alouatta*), capuchin (*Cebus*) and saki (*Pithecia*, *Chiropotes*) monkeys, two-toed sloths (*Choloepus*) and three-toed sloths (*Bradypus*), opossums (*Didelphus*), tayra (*Eira barbara*), and porcupines (*Sphiggurus spinosus*), anteaters, coatimundis and kinkajous; also reptiles, including snakes, tupinambis and iguanas, and amphibiaenids. Some terrestrial mammals taken, including agoutis, domestic pigs, and young brocket deer (*Mazama*). Birds recorded include parrots, curassows, Hyacinth Macaws (*Anodorhynchus hyacinthinus*) and Red-legged Seriema (*Caracara cristata*). Sloths particularly important, constituting up to one third of biomass of prey delivered; reason may be that sloths climb to tops of trees to warm up in early morning and are therefore conspicuous when present species actively hunting. In Guyana, cebid monkeys, especially adults, are most important primate prey. In Argentina, prey includes opossums, tayras and porcupines. Adults often return to nest with only portions of their prey. Females take larger prey (2.7-9 kg) than males (0.5-2.3 kg); males bring to nest pieces of prey estimated to weigh c. 1 kg, whereas females probably carry pieces up to 4 kg. One individual caught a subadult male red howler monkey, estimated to weigh c. 7 kg. Much hunting takes place around forest edge and clearings, and in the canopy itself; often waits beside rivers and salt-licks. Rapid attack, following which prey may be taken to top of tree; if too large, usually carried to fallen tree. Despite huge size, flies through forest with great agility. Excellent hearing may help in locating prey.

Breeding. Most of data from single nest-site studied over several years, but 13 nests now under observation by the Peregrine Fund. Laying in Jun (rainy season) in Guyana; Sept-Nov in Goiás (C Brazil); chicks in Nov in Argentina. Bulky nest up to 150 cm wide, built of large sticks, usually in enormous emergent trees, 50-75 m tall; in Guyana, silk-cotton trees (*Ceciba pentandra*), often towering above surrounding forest, offer ideal nest-sites; in Venezuela, often nests in Lecythidaceae; in Panama nests in Bombacaceae; nests in *Mauritia* palms also reported. 2 eggs (one record of 3); apparently only one young raised, as no nests found with two advanced young; incubation 56 days (in middle of rainy season); chick has dirty white down; fledging variously c. 140 days, or c. 6 months; juvenile remains within 100 m of nest for at least 12 months, so that adults can breed only every third year, when successful. 97% of incubation by female; male brings prey to nest once a week during incubation, and twice a week during first half of nestling period.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES I. Formerly red-listed in category Rare, but currently considered near-threatened. Sparsely distributed throughout extensive range, and generally rare. Has disappeared from large parts of former range, notably from most of N & C Central America; in Colombia, rare and local; in Brazil, still reasonably common in Amazonia, but rare elsewhere, with major decline (and possible extinction) in Rio Grande do Sul; persists in N Argentina, where 3 recent nest records. Former range has undoubtedly been reduced to some extent due to hunting and deforestation. Accurate knowledge of breeding density and home range size essential for planning conservation of species; published estimates of home range size based mostly on speculation. Peregrine Fund has brought various birds together in captive breeding programme; satellite transmitters now placed on 5 young birds, but no adults to date. Active nests reported to be as close together as 5 km in Venezuela, and only 3 km apart in both Guyana and Panama. Obviously susceptible to extensive deforestation, and consequently now missing from parts of former range in S Brazil, but could perhaps survive in disturbed forests or even perhaps forest mosaics, if large size and boldness in face of humans did not make them irresistible targets for hunters. Low overall population densities and slow reproductive rates make shooting the most significant threat over entire range; of the 5 young carrying radio transmitters in Venezuela, 1 has already been shot.

Bibliography. Alvarez (1993, 1994), Anon. (1991c), Belton (1984), Blake (1977), Bond (1927), Chebez *et al.* (1990), Collar (1989), Collar & Andrew (1988), Contreras *et al.* (1990), Eason (1989), Foerster (1972), Fowler & Cope (1964), Gochfeld *et al.* (1978), Hilty & Brown (1986), Iñigo-Elias *et al.* (1987), Izor (1985), King (1978/79), Malingreau & Tucker (1988), Meyburg (1986), Monroe (1968), Peres (1990), de la Peña (1992), Pinto (1964), Renig (1977, 1978), Ridgely & Gwynne (1989), Ruschi (1979), Sherman (1991), Sick (1985a, 1993), Slud (1964), Stiles & Skutch (1989), Thiollay (1984), Tostain *et al.* (1992), Voous (1969), Wetmore (1965).

Genus *HARPIA* Vieillot, 1816

202. Harpy Eagle

Harpia harpyja

French: Harpie féroce German: Harpyie Spanish: Arpía Mayor

Taxonomy. *Vultur Harpyja* Linnaeus, 1758, Mexico.

Only close relative appears to be *Morphnus guianensis*. Monotypic.

Distribution. S Mexico (from S Veracruz, Oaxaca and apparently Campeche) through Central America to Colombia, then E through Venezuela to the Guianas and S through E Bolivia and Brazil to extreme NE Argentina (Misiones).

Descriptive notes. 89-105 cm; male 4000-4800 g, female 7600-9000 g; wingspan up to 200 cm. A truly massive raptor. Head greyish with a dark, divided crest; relatively short, rounded wings, with long, barred tail. All dark above; very dark breast band separating grey head from white belly;

Genus *HARPYOPSIS* Salvadori, 1875

203. New Guinea Eagle

Harpypopsis novaeguineae

French: Aigle de Nouvelle-Guinée German: Papuaadler Spanish: Arpía Papúa
Other common names: New Guinea Harpy Eagle, Kapul Eagle

Taxonomy. *Harpypopsis novaeguineae* Salvadori, 1875, Andai, Arfak Peninsula, New Guinea.

Traditionally considered to be related to *Harpia* and *Pithecopaga*, but possibly part of old endemic Australasian clade (see page 55). Monotypic.

Distribution. New Guinea.

Descriptive notes. 75-90 cm; 1600-2400 g; wingspan of female 157 cm. Large forest eagle with erectile crest and facial ruff, and long bare legs; proportioned like giant *Accipiter*. Female larger than male. Juvenile similar, but washed brown on underparts; eyes and bill darker; tail has more and narrower bars.

Habitat. Rain forest from lowlands to 3200 m; local in gallery forest, in woodland and monsoon scrub. Largely confined to undisturbed forest, but visits nearby clearings and native gardens. Nests in forest.

Food and Feeding. Mainly terrestrial and arboreal mammals, including cuscus (*Phalanger*), possum (*Pseudocheirus*), wallabies (*Dorcopsis*, *Dorcopsulus*, *Thylogale*), tree-kangaroo (*Dendrolagus*), giant rats (*Mallomys*, *Uromys*), young dogs and pigs. Also birds and reptiles, including snakes and monitor lizards (*Varanus*). Contrary to some reports, all foraging diurnal and species does not soar to hunt. Forages from series of perches in forest canopy; searches for several minutes, peering about and using facial ruff to assist in detection of prey by sound; if prey not detected, flies 50-60 m through canopy, as far as 500 m low over canopy, to new perch. Swoops from perch onto prey below, if necessary pursuing it by running and leaping along ground. Also clambers among branches for arboreal prey; flushes prey from arboreal nests in epiphytes by striking with wings or tearing epiphytes apart with feet; shakes foliage to induce mammals to peer from hollows; uses feet to extract prey from holes.

Breeding. Apparently from late wet season through dry season (austral autumn to spring); specimen in breeding condition in Jun; active nest Apr-May; large nestling late Aug. Solitary. Large stick nest built high (20 m) in emergent tree, e.g. *Eugenia*, with no low branches; nest used for many years. Two records of single nestlings. Longevity more than 30 years in captivity. No further information.

Movements. Presumably sedentary.

Status and Conservation. VULNERABLE. CITES II. Low population density and apparently low reproductive rate; few detailed observations by ornithologists, and biology poorly known. Plumage avidly sought by natives armed with shotguns. Now rare or absent in areas of heavy (illegal) hunting pressure; also threatened by deforestation in lowlands.

Bibliography. Beehler (1985), Beehler *et al.* (1986, 1992), Bell (1984), Brown, L.H. (1976b), Clapp (1987), Coates (1985), Collar & Andrew (1988), Diamond (1972), Majnep & Bulmer (1977), Mayr & Gilliard (1954), Osborne & Osborne (1991), Peckover & Filewood (1976), Rand & Gilliard (1967), Schulz (1987).

Genus *PITHECOPHAGA* Ogilvie-Grant, 1896

204. Great Philippine Eagle

Pithecopaga jefferyi

French: Aigle des singes **German:** Affenadler **Spanish:** Aguila Monera
Other common names: (Philippine) Monkey-eating Eagle, Philippine Eagle

Taxonomy. *Pithecopaga jefferyi* Ogilvie-Grant, 1896, Samar, Philippine Islands.

Monotypic genus of uncertain affinities. Monotypic.

Distribution. Larger islands of N & E Philippines, on Luzon, Leyte, Samar and Mindanao.

Descriptive notes. 86-102 cm; 4700-8000 g. Huge eagle with large deep bill and long nape feathers forming ragged crest. Juvenile similar to adult, but with white edging to back feathers and upperwing-coverts.

Habitat. Primary dipterocarp forest and residual gallery forest up to 2000 m. Also patches of forest in cleared areas.

Food and Feeding. Feeds mainly on flying lemurs and palm civets; less often monkeys; wide variety of other prey, e.g. rats, flying squirrels, snakes, monitor lizards, birds (including hawks, owls and hornbills) and bats; a deer's leg also recorded. Hunts inside forest from perches in canopy; regularly moves gradually downhill from perch to perch; after reaching bottom, soars back to top to begin again. Co-operative hunting of pair reported: one bird distracts troop of monkeys, allowing other to sneak up and take one from behind.

Breeding. Breeding activity begins in Sept; laying Oct-Dec. Huge nest built by pair 30+ m up in canopy of enormous tree; nest usually placed on epiphytic fern. Invariably 1 egg; incubation 60-61 days, by both sexes, but mainly by female; chick has white down; fledging c. 23-24 weeks; chick remains dependent on parents for another year or more. Nestling fed, brooded and guarded by female, while male hunts; female begins hunting in latter part of nestling period. As result of long post-fledging dependency, successful breeding cycle usually lasts two years; unsuccessful pairs will re-nest.

Movements. Sedentary.

Status and Conservation. ENDANGERED. CITES I. Probably less than 200 individuals remain in wild. At present, healthiest population thought to occur in mountains of Sierra Madre (N Luzon), which hold greatest remaining expanses of forest in Philippines; former stronghold in Mt Apo National Park (Mindanao) currently suffering intense human pressure; small population of only a few pairs at Mt Katanglad (Mindanao) receives some protection, including vigilance of one nest, and in recent years (e.g. 1993) this has assured successful breeding. Throughout range, main factors in population reduction are: loss of forest habitat; shooting for trophies; and capture of eagles for pets. Most of lowland forest habitat now cleared; much of hill and low mountain habitat currently in process of being cleared. In some cases, pair surprisingly hanging on, in spite of forest clearance from most of their territory. Two chicks produced by captive breeding, in preparation for future reintroduction; however, as long as clear-felling of forests continues, together with subsequent

human settlement of cleared land, future of this emblematic species remains precarious. Other conservation initiatives to save species include local public awareness campaigns.

Bibliography. Brown, L.H. (1976b), Brown & Amadon (1968), Collar & Andrew (1988), Dickinson *et al.* (1991), DuPont (1971), Gonzales (1968), Kennedy (1977, 1981, 1983, 1985), King (1978/79), Krupa (1989), Lambert (1993), Lewis, R.E. (1986), McGregor (1909-1910), Meyburg (1986), Rabor (1977), Rand & Rabor (1960), Salvador (1994), Shuker (1993).

Genus *ICTINAETUS* Blyth, 1843

205. Indian Black Eagle

Ictinaetus malayensis

French: Aigle noir **German:** Malaenadler **Spanish:** Aguila Milana
Other common names: (Asian) Black Eagle

Taxonomy. *Falco malayensis* Temminck, 1822, Indian Archipelago = Java.

Monotypic genus of disputed affinities (see page 55). Two subspecies recognized.

Subspecies and Distribution.

I. m. perniger (Hodgson, 1836) - N India and Nepal; also S India (W & E Ghats, Orissa) and Sri Lanka.

I. m. malayensis (Temminck, 1822) - Burma, SC & SE China (Yunnan, Fujian) and Taiwan, S through Indochina and Malay Peninsula to Greater Sunda, Sulawesi and Moluccas; possibly also Banggai and Sula Is.

Descriptive notes. 67-81 cm; 1000-1600 g; wingspan 164-178 cm. Medium-sized black kite-like eagle; large paddle-shaped wings and long tail distinctive. Juvenile dark brown above, streaked on underparts. Race *perniger* slightly larger.

Habitat. Forested hills and mountains from sea-level up to 3100 m; often around forest edge, clearings and second growth.

Food and Feeding. Prey includes birds, especially nestlings, lizards, small mammals, frogs, bats and large insects; also birds' eggs. Hunts on wing with kite-like flight, sailing effortlessly and gracefully over tree tops and

grassy slopes. Foot structure, with short outer toe and less curved talons, thought to be specialized for snatching prey, including bird's nests, from tree tops.

Breeding. Season varies: Nov-Jan in S India; later in N India; Apr-Aug in Java; young bird in nest during Jul in Sulawesi; occupied nest in Aug in Sumatra. Large nest built by pair in crown of large tree in forest, often on slope; lined with green leaves. Display flights include spectacular diving plunge of 300 m or more, with wings folded into teardrop shape; more usually, undulating flight and chasing flights, the latter similar to those of *Milvus* kites. Usually 1 egg, very rarely 2. No further information available.

Movements. Mainly sedentary. Vagrant to Pakistan, where has bred.

Status and Conservation. Not globally threatened. CITES II. Widespread, usually uncommon to rare, but locally common; fairly common in Nepal; not uncommon, at any rate in past, in Chin Hills of NE Burma. Main threat is loss of forests.

Bibliography. Ali & Ripley (1978), Amadon (1982a), Bishop *et al.* (1994), Brown, L.H. (1976b), Cheng Tso-hin (1987), Deignan (1945), Henry (1971), Humphrey & Bain (1990), Inskipp & Inskipp (1985), King *et al.* (1975), MacKinnon (1988), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Roberts (1991), Round (1988), Smythies (1981, 1986), Stresemann (1940a), White & Bruce (1986).

Genus *AQUILA* Brisson, 1760

206. Lesser Spotted Eagle

Aquila pomarina

French: Aigle pomarin **German:** Schreiadler **Spanish:** Aguila Pomerana

Taxonomy. *Aquila Pomarina* C. L. Brehm, 1831, Pomerania.

Closely related to *A. clanga*, but specific status undoubted; recently confirmed by morphological and molecular genetic studies; these two sometimes considered to form superspecies. Present species may also be closely related to *A. wahlbergi*, but more research needed. In past, Indian race, *hastata*, often regarded as independent species, and its taxonomic status requires further study. Two subspecies recognized.

Subspecies and Distribution.

A. p. pomarina C. L. Brehm, 1831 - C, E & SE Europe through Turkey and Caucasus to S Caspian lowlands; E limit not well known. Winters in S Africa and perhaps E Africa.

A. p. hastata (Lesson, 1834) - India (mainly N), Bangladesh, and perhaps also N Burma and Pakistan.

Descriptive notes. 57-64 cm; c. 1100-2000 g; wingspan 145-170 cm. In field, perched bird appears rather uniform chocolate brown. In flight, most adults have upperwing-coverts paler than rather dark flight-feathers, but much individual variation; less conspicuous contrast between pale underwing-coverts and flight-feathers; these characteristics usually allow distinction from adult *A. clanga*. Differs from *A. nipalensis* in flight, by lack of barring on primaries and tail. Pale morph, variously named "*fulvescens*", "*fulviventris*" or "*pallida*", is very rare. Juvenile brown like adult, but generally darker, with yellow nape patch; spots on upperwing-coverts smaller and narrower than in immature *A. clanga*; spots retained till bird three years old, gradually diminishing. Race *hastata* has slightly longer wings and tarsi and browner iris; juvenile lacks spotting.

Habitat. Breeds near forest edges, preferring moist woods near meadows and fields; less dependent on bogs and water than *A. clanga*, and more adapted to cultivated areas. Highest breeding densities

in lowlands, but also breeds in dry mountain forests in Carpathians, Balkans, Anatolia and Caucasus, up to 2200 m.

Food and Feeding. Mammals, reptiles, amphibians, birds and some insects. In C Europe, mainly small mammals, especially voles (*Microtus*); also, to some extent, small to medium-sized birds, and many amphibians, mainly *Rana temporaria*, and reptiles. In humid lowland areas, amphibians can make up 42% of prey. In Slovakian hills, mammals form 85% of prey; in Greece, diet consists mainly of snakes (70%), especially *Natrix natrix*, with some birds, lizards and insects; in

Georgia, mammals (29%), reptiles (25%) and amphibians (34%) almost equally important, whereas birds only found in 8% of cases. In Indian race, mammals dominant (47%), mainly rats (*Millardina melitoda*) and palm squirrels (*Funambulus pennanti*), followed by birds (33%), reptiles (16%) and amphibians (3%). Carrion taken only rather rarely. On wintering grounds, diet apparently consists largely of Red-billed Quelea (*Quelea quelea*) nestlings and swarming termite alates; also small mammals and frogs. Mainly hunts in open areas, like *A. clanga*, using three different techniques: soaring c. 100 m high and diving down; still-hunting from perch; or walking on ground.

Breeding. In C Europe, laying in late Apr and early May, fledging in late Jul and early Aug. Occupied nests well spaced out, but in suitable habitat may be under 1 km apart. Almost always on trees, in most cases 12-15 m high, sometimes only 4-5 m, or as much as 30 m; extremely rarely on the ground. Normally only few hundred metres from edge of forest. Large stick nest, 50-150 cm in diameter; nest cup c. 30 cm wide, lined with green twigs or sometimes grass. Erynes often reused over several years, or up to 10 years consecutively. Normally 2 eggs, sometimes 1, rarely 3; incubation averages 38-85 days (36-41); chicks have greyish white down; second chick normally dies as result of cannibalism, and only extremely rarely do both young survive to fledging, without human intervention; fledging 8 weeks, but 11 weeks in single well studied case of race *hasitata*. Average 0.5-0.7 young fledge per clutch laid. Sexual maturity probably at 3 or 4 years; oldest ringed bird 26 years old.

Movements. Migratory; highly dependent on soaring and thus thermals, avoiding large bodies of water. C European birds leave around mid-Sept; European birds migrate over Bosphorus, Israel and Suez, where well studied, but migration in Africa little understood. A satellite-tracked juvenile covered 6000 km from Latvia to Sudan in barely a month, remaining there for over 6 weeks, before continuing to Kenya. Few birds cross sea from Italy and S Greece to N Africa. Adults arrive at breeding grounds in Apr. Race *hasitata* apparently not migratory.

Status and Conservation. Not globally threatened. CITES II. Has disappeared from much of former range in W, e.g. W Germany, or become very rare, e.g. E Germany, former Yugoslavia, Greece. Total population in mid-1980's estimated at c. 100,000 birds: 120 pairs in Germany; 3000-3500 birds in Byelorussia (1990's); 1300 in Poland; 1000 in Latvia; 500 in Lithuania; 150-200 in Estonia; 500 in Slovakia; 150 in Hungary; 70 in Greece; 220-250 in Ukraine; 50-80 pairs in Azerbaijan (1990's); and 85-90 in Georgia. High counts in Israel do not correspond to known breeding populations; E extent of range in Russia requires investigation. Problems include: habitat alteration, mainly drainage of forests and meadows; and hunting. Hunting particularly important during migration, especially in Syria and Lebanon, where hundreds or thousands are shot annually. International Symposium held on present species in Poland in 1991. Productivity can be increased artificially by preventing loss of second chick due to cannibalism. Race *hasitata* endangered; in Bangladesh, Burma and Pakistan, extinct or almost extinct; in India, extremely reduced and patchy distribution. Only recent nest record of this race was in Keoladeo National Park, Bharatpur, in 1986; prior to this, just 3 records of nesting more than 80 years ago.

Bibliography. Abuladze (1994a), Ali & Ripley (1978), Banzhaf (1938), Baumgart (1979, 1980, 1994), Bergmanis (1994), Bergmanis *et al.* (1990), Brooke *et al.* (1972), Brown, L.H. 207. Greater Spotted Eagle

Aquila clanga

French: Aigle criard

German: Schelladler

Spanish: Aguila Moteada

Other common names: Spotted Eagle

Taxonomy. *Aquila Clanga* Pallas, 1811, Russia and Siberia.

Sometimes considered to form superspecies with *A. pomarina*. Monotypic.

Distribution. EC Europe E through Russia to S USSR and Manchuria; isolated populations in N Iran and NC India. Winters from S Europe, NE & E Africa and Middle East through N Pakistan to S & E China and Indochina.

Descriptive notes. 60-70 cm; 1500-2500 g; wingspan 155-180 cm. Rather uniform dark brown to black, with strong purplish gloss on upperparts, especially in fresh plumage. Slightly larger than very similar *A. pomarina*, but overlapping in size; generally darker; wing-coverts contrast little or not at all in colour with flight-feathers. Tail and outer primaries not barred as in *A. nipalensis*. Bill size and length of middle toe (without talon) also help to distinguish from congeners. Pale morph, '*fulvescens*', very rare. Female only slightly larger than male. Juvenile and immature easily recognizable with white to yellow spots on scapulars, back and upperwing-coverts; spots larger and more numerous than in *A. pomarina*, sometimes almost obliterating dark brown background; juvenile lacks pale nape patch of *A. pomarina*.

Habitat. Large wet forests bordering humid meadows, bogs, marshes and other wetlands. Breeding mainly in lowlands, but sometimes in forests in mountains, up to 1000 m above sea-level.

Food and Feeding. Very variable, depending on availability of prey species. Mainly small mammals, amphibians, lizards, snakes, small fish, carrion and sometimes insects. In W Russia; 53% small mammals and 45% birds, in Oka Reserve; and 58% mammals, mostly voles (*Microtus*

analys). 35% birds, 3-6% reptiles, near Tula. Diet generally similar to that of *A. pomarina*, but often takes more and larger birds. Forages by soaring c. 100 m high and diving down, still-hunting from perch, or walking on ground.

Breeding. Season Apr-Aug. Solitary. Territory 15-30 km² in optimum areas, elsewhere much larger. Large platform of sticks typically 70-110 cm wide and up to 100 cm deep, with central cup lined with fresh green sprigs or grass; placed in tree inside forest, 5-20 m above ground, few hundred metres from forest edge; often used in successive years, although

many pairs have 2-3 nests used alternately. Usually 2 eggs (1-3); incubation period not exactly known, probably c. 6 weeks; chicks have pure white to greyish or grey-brown down; due to cannibalism, second chick rarely survives; fledging 63-67 days (late Jul). Breeding success c. 0-6 young raised per breeding attempt.

Movements. Migratory; leaves breeding areas later than *A. pomarina* in Oct/Nov, and does not move so far south, wintering in S Europe, Middle East, NE Africa and S Asia. During migration, much less frequent at concentration points than *A. pomarina*. Arrives on breeding grounds in spring earlier than *A. pomarina*. Recently found wintering S to Sumatra.

Status and Conservation. Not globally threatened. CITES II. Total world population certainly only some few thousand birds, but populations very little studied. Formerly bred in Finland, Hungary, Romania and Israel. Now very rare in C & E Ukraine, where formerly common; decline due to deforestation, especially of river valleys. Has disappeared from many areas in W of former range in Europe. Has declined in European part of former USSR from c. 1000 pairs in 1960's, to c. 700 pairs at present; in Byelorussia, only 10-15 pairs. Very sensitive to habitat alterations, especially drainage of wetlands.

Bibliography. Ali & Ripley (1978), Austin (1948), Bazutin (1990), Bergmanis (1989, 1994), Bokotey (1994), Brazil (1991), Brown, L.H. 208. Tawny Eagle

Aquila rapax

French: Aigle ravisseur

German: Savannenadler

Spanish: Aguila Rapaz

Taxonomy. *Falco rapax* Temminck, 1828, South Africa.

Forms superspecies with *A. nipalensis*, and sometimes considered conspecific. Race *vindhiana* has been considered separate species, but limited differences do not support this. Three subspecies normally recognized.

Subspecies and Distribution.

A. r. vindhiana Franklin, 1831 - Pakistan, India, and S Nepal; possibly also Burma.

A. r. belisarius (Levaillant, 1850) - Morocco and Algeria; S Arabia and tropical Africa S to N Zaire and N Kenya.

A. r. rapax (Temminck, 1828) - S Kenya and S Zaire S to South Africa and W to Angola and Namibia.

Descriptive notes. 65-75 cm; 1696-3100 g; wingspan 182 cm. Smaller, paler and with shallower gape than *A. nipalensis*. Individually variable in intensity of colour and extent of markings. Iris yellow amber. Female larger and usually darker and more heavily marked than male. Juvenile more plainly coloured, especially ventrally, and plumage fades to blond; often rather redder. Races differ on size, and also on markings and extent of rufous coloration, but considerable individual variation and extensive overlap; *vindhiana* smaller, generally tends to be darker, lacks tawny, and sometimes, perhaps always, has

brown iris; *belisarius* shares most plumage types with nominate race (notably very pale immature), but tends not to appear so scruffy.

Habitat. Open woodland, savanna and arid steppe; only absent from forest and true desert. In Nepal, virtually restricted to *terai*.

Food and Feeding. Mammals (to size of hare), birds (including gamebirds) and lizards form bulk of catholic diet. May also take carrion, insects, amphibia and fish when available. Dives on prey from a perch or stoops while soaring high overhead, but may also walk about collecting food on the ground. Regularly and boldly steals from other birds such as storks, other raptors and ground-hornbills (*Bucorvus*).

Breeding. Laying in dry season: Mar in NE Africa; Oct-Feb in W Africa; Mar-Oct in E Africa (peak May-Jul); Apr-Sept in S & C Africa; Nov-Mar in India. Builds a platform of sticks, lined with grass and leaves, on the crown of a thorny tree, the only African eagle to do so regularly; rarely nests on a power pylon. Often nests in vicinity of watering point for game or stock. Usually 2 eggs (1-3); incubation 39-44 days; chicks have white down; eldest chick frequently kills younger sibling; fledging 77-84 days.

Movements. Resident in most areas but perhaps some seasonal movement into more arid areas in NW and NE Africa during the rainy season; also some birds perform seasonal N-S movement in W Africa. Often mixes with flocks of migrant *A. nipalensis*. Rare vagrant to Bangladesh, NW Thailand and perhaps Sri Lanka.

Status and Conservation. Not globally threatened. CITES II. Common in many areas, including several large national parks, such as Gombe (Tanzania), Hwange (Zimbabwe) with an estimated 200 pairs, and Kruger (South Africa) with 292 pairs. Commonest eagle of Indian plains. Very

uncommon in Nepal, where presumed to be resident. Status in Burma unknown: may be mere vagrant; possibly very rare resident, e.g. along R Irrawaddy. Adaptable, breeding equally successfully at mean inter-nest spacing of 3.5–5.9 km and densities of 1 pair/64–300 km². Scavenging habits make it susceptible to poisoning and has declined in many farming areas of S and E Africa. Also declining in W and NE Africa. Not known to be affected by pesticides.

Bibliography. Ali & Ripley (1978), Benson & Benson (1975), Bergier (1987), Biggs & Biggs (1978), Boshoff *et al.* (1981), Brown, C.J. (1991), Brown, L.H. (1976b), Brown, L.H. *et al.* (1982), Clark (1992), Cramp & Simmons (1980), Dathe & Grunnt (1993), Gensbøl (1986), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Handrinos & Demetropoulos (1983), Howells & Hustler (1984), Hustler & Howells (1989), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957–1973), Maclean (1993), Osborne (1982), Paz (1987), Pickford *et al.* (1989), Pinto (1983), Roberts (1991), Smeenk (1974), Smythies (1986), Steyn (1973, 1980d, 1982), Tarboton & Allan (1984), Thiollay (1978c, 1985d).

209. Steppe Eagle

Aquila nipalensis

French: Aigle des steppes

German: Steppenadler

Spanish: Águila Esteparia

Taxonomy. *Aquila nipalensis* Hodgson, 1833, great valley of Nepal.

Often regarded as conspecific with *A. rapax*, but morphological studies have shown clear differences which should also be verified by molecular techniques. Two subspecies recognized.

Subspecies and Distribution.

A. n. orientalis Cabanis, 1854 - SE European Russia E to L. Balkhash and E Kazakhstan, or perhaps to Tien Shan and Altai; winters in Middle East, Arabia and E & S Africa.

A. n. nipalensis Hodgson, 1833 - Altai and Tibet E to Manchuria; winters in S Asia.

Descriptive notes. 72–81 cm; 2400–3900 g; wingspan 160–200 cm. Medium-sized to large *Aquila*. Separable from smaller *A. rapax* by width and length of gape. Overall dark brown, generally darker than *A. pomarina* but paler than *A. clanga*. Prominent rufous nape patch in most adults. Has oval nostrils, as opposed to round in *A. pomarina* and *A. clanga*: fleshy gape reaches far below eye; primaries banded; iris always brown. Female larger than male. Juvenile and immature almost always have characteristic broad whitish band along greater underwing-coverts; adult plumage reached by 4 years. Race *orientalis* slightly

smaller and paler.

Habitat. Steppe and semi-desert. Race *nipalensis* breeds in mountainous areas up to 2300 m; *orientalis* breeds in lowlands and low hills. Originally bred on ground in most cases, but in recent years increasingly in bushes or small trees or on artificial structures.

Food and Feeding. During breeding, race *orientalis* is most highly specialized Palearctic *Aquila*, depending on various species of suslik (*Citellus*), especially little suslik (*C. pygmaeus*), which may form up to 98.5% of its food. Also takes other small to medium-sized mammals, especially great gerbils (*Rhombomys opimus*), birds, reptiles and insects. In Transbaikalia, nominate race feeds mainly on: (54–77%) young Bobak marmots (*Marmota bobak sibirica*); and (11–37%) Daurian pikas (*Ochotona dauurica*). Much carrion eaten during migration and wintering, especially by immatures. Wintering birds in S Africa take many alate harvester termites (*Hodoterms mossambicus*) and nestling queleas (*Quelea quelea*); suspected to follow pattern of local rain showers and resultant termite flights. In E Africa, seems to eat chiefly mole rats (*Helophobius*, *Cryptomys*). Forages mainly by soaring c. 150–200 m high and diving down; also ambushes prey, by waiting at burrow entrance, and takes some prey while walking about on ground.

Breeding. Season Apr–Jul; timing of arrival in spring and start of breeding highly dependent on availability of chief prey species. Large platform of sticks typically 70–100 cm wide, but very variable in size depending on availability of nest material; nest cup often lined with smaller twigs and many other materials, e.g. old rags, bones, moulted feathers and camel dung. Usually (at least formerly) built on ground in position that allows good view of surroundings; nowadays, because of habitat alteration and persecution, often nests a few metres up on bushes, small trees, artificial structures, etc. 1–3 eggs (rarely 4, at least two cases of 5); incubation 45 days; chicks have white down after hatching, later greyish white; fledging 55–65 days. Breeding density variable, with 1 pair/7.5–53.5 km²; varies much more from year to year than in other eagles, depending upon prey availability. Breeding success also heavily dependent on food, but quite often 2–3 young fledged. Longevity of 41 years in captivity.

Movements. Race *orientalis* completely migratory, leaving breeding areas in late Aug and Sept; avoiding crossing of sea, with large concentrations observed in bottleneck areas, e.g. Israel, Suez, Bab al Mandab; winters in Middle East, Arabian Peninsula, E & S Africa. Race *nipalensis* less migratory, wintering mostly in S Asia.

Status and Conservation. Not globally threatened. CITES II. Common in suitable habitat, e.g. estimated c. 20,000 pairs in European Russia. Extirpated from large areas of former range in W; has disappeared from Romania, Moldavia and Ukraine due to habitat alteration, with conversion of steppes into fields, and persecution; also adversely affected by power lines. Trends of E populations unknown; 7852 birds recorded migrating over C Nepal in 1985. In any case, commonest eagle species of its size in the world.

Bibliography. Agafonov *et al.* (1957), Ali & Ripley (1978), Biggs & Biggs (1978), Brooke *et al.* (1972), Brown, L.H. (1976b), Cheng Tso-hin (1987), Christensen & Sorensen (1989), Clancey (1966), Clark (1992), Cramp & Simmons (1980), Davygora (1991), Dementiev & Gladkov (1951), Dobrunavov (1949), Etchécopar & Hite (1978), Fadjev (1965), Flint *et al.* (1984), Forsman (1991), Gensbøl (1986), Ginn *et al.* (1989), Goodman *et al.* (1989), Hintovt (1940), Jensen (1972), Ismagilov (1962), Ivanov (1952), Jankowitz (1976), Jensen (1972), Kharchenko & Krasovskiy (1966), Krasovskiy (1983), Korelov (1962), Kostin (1985), Lankin (1976), Lindeman (1977, 1985), Mironov (1962), Mironov (1946), Nankinov (1982), Pererva & Grazhdankin (1983), Petrov & Rozkov (1965), Pfander (1983), Postawski (1967), Richardson (1990), Roberts (1991), de Roder (1989), Rogacheva (1992), Ryabov (1969), Scapotev (1952), Semenov *et al.* (1959, 1962), Shirihai & Christie (1992), Shumner (1928), Simenon *et al.* (1990), Sludskij (1962), Smythies (1986), Survillo (1983), Suschkin (1895), Svensson (1987), Tarasov (1944), Thiollay (1989c), Treus & Strelchenko (1970), Tyurekhodzhev (1973, 1977), Varshavsky (1973), Varshavsky, Shilov *et al.* (1980), Varshavsky, Varshavsky *et al.* (1980), Vinogradov *et al.* (1977).

210. Spanish Imperial Eagle

Aquila adalberti

French: Aigle ibérique

German: Spanischer Kaiseradler

Spanish: Águila imperial ibérica

Other common names: White-shouldered/Adalbert's Eagle

Taxonomy. *Aquila adalberti* C. L. Brehm, 1861, Spain.

Often considered conspecific with *A. heliaca*; relationship only recently studied in detail by means of morphological comparison and molecular techniques; molecular data and substantial differences in morphology and ecology support full species status for present form. Forms superspecies with *A. heliaca*. Monotypic.

Distribution. C, W & S Spain; formerly more widespread, occurring in Portugal and Morocco.

Descriptive notes. c. 74–85 cm; 2500–3500 g; wingspan c. 177–220 cm. Similar to *A. heliaca*, but with very conspicuous white leading edge of wing. Immature much less streaked than that of *A. heliaca*, almost uniform tawny buff; at four years old, more mottled, with irregular pattern of pale and dark brown feathers on back, breast and belly, and some white feathers on shoulders; full adult plumage at 5–6 years.

Habitat. Persists in more forested areas of Spain, with low levels of human land use, and higher densities of rabbits. Associated with areas dominated by typical Mediterranean climates.

mate, with relatively warm, dry summers and temperate, rainy winters. Most regularly found in areas with limited amount or absence of irrigated farmlands. Rapid growth of human population in previously depopulated areas, and human presence in fields where irrigated cultures have been developed, have negative effects on distribution of species. Nests found in areas with predominant undergrowth brush of *Cistus*, *Erica*, *Phyllirea*, etc.

Food and Feeding. Total of 98 prey species recorded, of which most important is rabbit (*Oryctolagus cuniculus*), comprising 58% before myxomatosis. As consequence of myxomatosis, trophic diversity increased: in Doñana, 42% mammals, 54% birds, 3% reptiles; in Sierra Morena, 44% mammals, 41% birds, 14–6% reptiles; and in C Spain, 39% mammals, 57% birds, 3% reptiles. Most important bird species in diet are Greylag Goose (*Anser anser*), Black Coot (*Fulica atra*), Mallard (*Anas platyrhynchos*), Woodpigeon (*Columba palumbus*) and Black-billed Magpie (*Pica pica*). Prey caught mainly on ground by perch-hunting or by soaring.

Breeding. Laying from mid-Feb to end Mar. Nests only on trees, except 2 pairs on electric tower structures; prefers dominating trees, mainly cork oaks (*Quercus suber*) and pines, away from human disturbance. Large structure of sticks; nest cup lined with green twigs. Each pair has 2–6 nests. Density one pair per 52 km². Average 2.6–2.7 eggs (1–4); incubation c. 44 days; chicks have white down; fledging c. 75 days. Young birds leave natal area at 116–162 days old. Almost 10% of pairs breed in subadult plumage. Hatching success 2.4 (1–4); breeding success 1.3 per active nest, and 1.7–1.8 per successful nest; lower in mountains in N of range, higher further S. Sibling aggression reduces number of chicks during first half of nesting period; breeding success can be artificially increased, if sibicide reduced by removal and transfer of doomed chicks.

Movements. Adults sedentary. Young birds, when they become independent, leave natal areas, dispersing in all directions and travelling up to 350 km, especially to NW Africa.

Status and Conservation. ENDANGERED. CITES I. One of rarest of all birds of prey. Total population down to c. 150 pairs. Extinct in Morocco, Portugal and many parts of Spain, and now restricted to C, W & S Spain: 32% of breeding pairs in mountains of Toledo and Extremadura. Of all pairs, 22% occur in protected areas, mostly in three, El Pardo, Monfragüe and Doñana, which total only 1050 km²; protection of at least 50% highly desirable. Four areas, 15,000–40,000 ha each, with high densities of pairs and well preserved habitat remain unprotected; these areas require protection. At beginning of present century, range extended over most of Iberian Peninsula and N Morocco; drastically reduced over last 80 years. Problems include: electrocution, single most important mortality factor, causing death of up to 80% of young birds in their first year; unintentional trapping of birds in rabbit traps; poisoning; decrease of rabbit populations; and habitat alterations. In captivity, 20 birds distributed between 2 centres in Spain; no breeding success yet. Major conservation programme in progress.

211. Eastern Imperial Eagle

Aquila heliaca

French: Aigle impérial

German: Kaiseradler

Spanish: Águila Imperial Oriental

Other common names: Imperial Eagle

Taxonomy. *Aquila heliaca* Savigny, 1809, upper Egypt.

Often considered conspecific with *A. adalberti*, but recent studies indicate that they are distinct species, differing notably in morphology and ecology. Forms superspecies with *A. adalberti*. E populations have occasionally been separated in race *ricetti*. Monotypic.

Distribution. C Europe and Turkey E to Transbaikalia and Mongolia. Winters S to E Africa, Arabia, N India and E China.

Descriptive notes. 72–84 cm; 2450–4530 g; wingspan c. 180–215 cm. Generally dark brown; crown, nape, sides of head and neck have pale tawny buff lanceolate feathers producing a pale patch. White shoulder patch, or *plumette*, much smaller than in *A. adalberti*. Immature starts pale brown with variable dark streaking, and blackish light-feathers, passes through darker, very patchy plumages over several years, before attaining adult plumage after 5–6 years.

Habitat. Originally bred on old isolated trees in plains of C & SE Europe, but has subsequently retreated to large forests in moun-

tains, as result of persecution and habitat alteration. In Slovakia and Hungary, where now well protected, starting to reoccupy former habitats. Hunts in open, often cultivated, areas.

Food and Feeding. Small to medium-sized mammals; in most areas main prey species are susliks (*Citellus*) and hamster (*Cricetus cricetus*). Birds generally taken in small proportions: 22% in Hungary, compared to 65% *C. cricetus*; nowadays main prey in Ukraine. In N Aral region, feeds mainly on rodents, especially (70-74%) great gerbils (*Rhombomys opimus*), but also susliks (7-25%), reptiles (19-23%) and birds (7-15%). In S Urals, 27 species of vertebrates recorded, with more birds than mammals. Carrion also eaten, especially in winter and during migration. Prey caught mainly on ground by perch-hunting or by soaring.

Breeding. In Hungary, adults appear in breeding areas in late Feb or early Mar, depending on weather conditions; laying completed by late Mar or early Apr. Solitary. Large stick nest, 100-150 cm in diameter; nest cup lined with green sticks, but also other materials, e.g. grass, fur, wool; almost always nests on trees, very rarely on ground or cliffs in Kazakhstan. 2-3 eggs (1-4); incubation 43 days; chicks have white down; fledging 60-77 days. Sexual maturity before adult plumage acquired at 5-6 years; pairs with both partners in subadult plumage have successfully reared young. Longevity 21 years in captivity; record of 56 years in captivity not confirmed; another case of a bird, first held in captivity for several years, later free-living for 55 years, but equally unconfirmed. Breeding success: in Slovakia, 1-6 young per successful brood, or 0-76 young per pair per year; in Hungary 1-5 young per successful brood, but 36% of breeding attempts unsuccessful.

Movements. Mostly migratory. Birds migrate to S Turkey, Iran, Israel, Iraq, Egypt and Arabia, and to Pakistan, India, Laos and Vietnam. Leaves breeding grounds mid-Sept to mid-Oct; in Slovakia and Hungary, adults often seem to remain at or near breeding areas.

Status and Conservation. RARE. CITES I. Rapid decline in Europe since World War II; total world population now down to a few thousand pairs, possibly only c. 2000. Formerly very common in many

areas, e.g. 19 occupied eyries in 1000 km² near Sofia (Bulgaria). Now very rare or extinct in many areas of SE Europe. Only in Slovakia and Hungary is species well protected and increasing. European population now only c. 350 pairs: 30-35 in Slovakia; 36 in Hungary; 10 in Serbia; 4 in Macedonia; 0-2 in Greece; 15-20 in Bulgaria; probably few in Romania; 10-12 in Moldavia; 130-150 in European Russia; 35-40 in Ukraine; few in Turkey; 9-11 in Georgia; 40-50 in Azerbaijan; c. 10 in Armenia. Larger numbers in Asia, with perhaps c. 1200 pairs in C & W Kazakhstan; estimated total for Asian part of former USSR as low as 800-1200 pairs. Problems include: shooting, especially of young birds, in many areas, most intensively in Syria; poisoning, intended for wolves and foxes; removal of young from nest, for zoos and other raptor keepers; habitat alteration, including cutting down of old forests; decrease in suslik population, due to habitat loss; mortality through electrocution or injury caused by collisions with power lines. International working group for species has been formed, and 3 meetings held in Hungary. Conservation Action Plan in preparation.

212. Wahlberg's Eagle

Aquila wahlbergi

French: Aigle de Wahlberg

German: Silberadler

Spanish: Aguila de Wahlberg

Taxonomy. *Aquila wahlbergi* Sundevall, 1851, Mohapvani, Botswana.

May be associated with genus *Hieraaetus*, and has on occasion even been transferred to it, on grounds mainly of behaviour. Monotypic.

Distribution. Mauritania E to Ethiopia and S to South Africa.

Descriptive notes. 55-60 cm; 437-1400 g; wingspan 141 cm. Smallest member of genus *Aquila*. Polymorphic: dark brown morph most numerous (can be even darker than illustrated); paler morphs individually variable, with plain cream form most common; various intermediate morphs exist, some looking rather patchy. Slight crest, dark brown eye and small size distinctive. Juvenile indistinguishable from adult.

Habitat. Woodland and tree savanna, avoiding desert and dense forest.

Food and Feeding. Feeds mainly on reptiles, especially lizards, birds, including gamebirds,

and small mammals up to size of hare; also some insects. Hunts from perch or by stooping from soaring flight. Attacks with speed and agility, taking most prey on ground but some in aerial pursuit.

Breeding. Laying suspected Jul-Aug in W Africa; Sept-Oct in NE Africa; Aug-Nov in E Africa; Sept-Oct in S Africa; all in wet season. Builds a small stick platform in the upper open fork of a tall tree, often along a watercourse, on a hillside or on the edge of woodland. Same or adjacent site reused over many seasons. Single egg (rarely 2); incubation 44-46 days; chicks have dark brown or blond down depending on morph; elder chick kills younger sibling when present; fledging 70-75 days. Known to have lived almost 12 years.

Movements. A regular trans-equatorial, intra-African migrant, usually laying its eggs (or eggs) within a month of arriving in E, C and S Africa and departing within a month of fledging a chick. Bulk of population breeds S of equator, moving S through Uganda and Rwanda in Jul-Sept, N through Zambia and Kenya in Feb-Mar, to winter NE of equator. Relatively few breeding records in W and NE African savannas; probably a separate sub-population with limited seasonal movements, S into Guinea savannas in dry season and N to breed in Jul-Sept. A few apparently resident around equator.

Status and Conservation. Not globally threatened. CITES II. The commonest eagle in S and C Africa; generally less common in W Africa. In Transvaal (South Africa), attains mean inter-nest spacing of 2.8 km, and nesting densities of up to 1 pair/4.3 km², with estimated total of 9000 pairs. Vulnerable to clearing of woodland; not known to be affected by pesticides, but accidental poisoning may result in local population declines.

Bibliography. Auburn (1988, 1991), Benson & Benson (1975), Brown, L.H. (1952, 1953, 1955, 1976b), Brown *et al.* (1982), Gargett (1968), Gaugris *et al.* (1981), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Kemp & Mendelsohn (1975), Lees (1968), Lewis & Pomeroy (1989), Mackworth-Przed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Simmons (1991b, 1991c, 1992, 1993a, 1993b), Steyn (1962, 1980c, 1982), Tarboton (1977b, 1986), Tarboton & Allan (1984), Thiollay (1975a, 1975d, 1977a, 1977b, 1978b, 1978c, 1985d), Tuer (1973).

213. Gurney's Eagle

Aquila gurneyi

French: Aigle de Gurney

German: Molukkenadler

Spanish: Aguila Moluqueña

Taxonomy. *Aquila* (? *Heteropus*) *gurneyi* G. R. Gray, 1860, Batjan (Bacan) Island, Moluccas.

Sometimes transferred to genus *Spizaetus* on account of wing and tail proportions, but clearly an *Aquila* on plumage. Has been associated with possible *A. chrysaetos* superspecies. Monotypic.

Distribution. New Guinea, W Papuan Is and Aru Is; also Moluccas, where recorded on Morotai, Halmahera, Ternate, Bacan and Ambon, and recently on Seram.

Descriptive notes. 66-79.5 cm; female 3060 g. Medium sized *Aquila*, with slightly shorter wings and longer tail than congeners. Distinguished from *A. audax* by yellow feet, rounded (or only slightly wedge-shaped) tail and lack of rufous in plumage. Female larger than male. Juvenile shows shades of grey and brown, paler on underparts; distinction from juvenile *A. audax* as for adults.

Habitat. Lowland and hill primary rain forest and swamp forest, including littoral zone; forest edge and adjacent grassland; visits near-by clearings and cultivation. From sea-level up to 2970 m.

Food and Feeding. Little known. Reportedly mammals, such as cuscus (*Phalanger*); one record of eating cuscus on ground. Forages by low, slow quartering of forest canopy or ground, sometimes using ridge lift to soar along face of cliffs or hillsides.

Breeding. No information available.

Movements. Unknown, but breeding adults presumably sedentary. Occasional visitor to islands in Torres Strait, but extralimital records may represent incomplete knowledge of species' normal distribution, rather than movements.

Status and Conservation. Not globally threatened. CITES II. Apparently presents low population density; seldom encountered by ornithologists; biology unknown. Possibly threatened by deforestation in lowlands.

Bibliography. Amadon (1978), Beehler *et al.* (1986), Bowler & Taylor (1989), Brown, L.H. (1976b), Coates (1985), Diamond (1985), Garnett (1987), Jollie (1957), Mackay (1988), Melville (1980), Osborne & Osborne (1991), Rand & Gilliard (1967), Smith, G. (1992), White & Bruce (1986).

214. Golden Eagle

Aquila chrysaetos

French: Aigle royal

German: Steinadler

Spanish: Aguila Real

Taxonomy. *Falco Chrysaetos* Linnaeus, 1758, Sweden.

Has been considered to form superspecies with *A. audax*, and perhaps also with *A. gurneyi*. Race *kamtschatica* often included in *canadensis*. Six subspecies normally recognized.

Subspecies and Distribution.

A. c. homeyeri Severtsov, 1888 - Iberian Peninsula, NW Africa and large Mediterranean islands E through Egypt, Asia Minor and Arabia to Caucasus and Iran.

A. c. chrysaetos (Linnaeus, 1758) - NW & C Europe E to W & C Siberia and Altai.

A. c. daphanea Severtsov, 1888 - Turkestan E to Manchuria, and S to Pakistan, Himalayas and SW China.

A. c. japonica Severtsov, 1888 - Korea and Japan.

A. c. kamtschatica Severtsov, 1888 - W & C Siberia and Altai E to Kamchatka.

A. c. canadensis (Linnaeus, 1758) - North America, from Alaska S to Durango (WC Mexico), and E to Labrador, Quebec and New York.

Descriptive notes. 75-90 cm; male 2840-4550 g, female 3630-6665 g; wingspan 190-227 cm. Fairly uniform dark brown throughout crown, nape and median upperwing-coverts normally pale yellowish tawny. Female larger. Juvenile darker chocolate brown, with characteristic white bases to flight-feathers; tail basally white, with dark terminal band; white areas of plumage progressively replaced with brown over 4-5 years, although full adult plumage not until 6-8 years. Races vary slightly in size and coloration, particularly in darkness of plumage and extent and shade of pale areas; crown and nape, at least rear portion,

always clearly paler, ranging from yellowish to rufous brown.

Habitat. Open, deserted terrain, e.g. mountains, plateaux and steppe; locally marshy areas; prefers low or sparse vegetation to wooded areas. From desert areas to edge of tundra, and from sea-level up to considerable altitudes, occasionally over 2000 m in Alps and Pyrenees; may occur over 5500 m in Himalaya, roughly up to summer snow-line. For nesting normally requires remote, peaceful sites, e.g. rock faces, large trees; perches on vantage points on rocks or trees.

Food and Feeding. Prefers medium-sized mammals, mainly rodents, rabbits and hares; also, normally to lesser degree, birds, particularly gamebirds, including large grouse; much less frequently reptiles, e.g. lizards, snakes; also carrion, especially in winter. Hares, rabbits, ground squirrels (*Spermophilus*, *Citellus*) or, in mountainous areas, marmots tend to be most numerous mammal prey; domestic stock (e.g. sheep) and wild ungulates (e.g. deer) may be important in diet as carrion, whereas young and vulnerable animals are sometimes hunted; carnivores (mustelids, foxes, cats, etc.) are sometimes taken regularly. Birds range in size from small passerines up to cranes, storks or swans, but species prefers grouse and partridges. Normally captures prey on ground, using low hunting flight. Sometimes pairs hunt together. In some areas captures tortoises, dropping them onto rocks to break shells.

Breeding. Laying starts Feb in S Europe and S North America, until May in more N regions. Nests on ledges of cliffs and crags, or in trees, tendency varying regionally. Eyries traditional; normally several per pair, which are used alternately. Large nest of sticks and branches lined with greenery, up to 200 cm wide and deep. Normally 2 eggs (1-3), laid at interval of c. 3 days; incubation c. 41-45 days per egg, almost exclusively by female; hatching asynchronous; chicks have first and second down white or whitish; younger chick often dies due to older sibling's attacks; fledging 65-80 days; young can be dependent on adults and fed by them for some months, and sometimes tolerated in adults' home range until following season. 1-3 chicks fledge, normally 1, very rarely 3; one case of bigamy with 4 chicks raised; mean 0.4-1.3 per breeding pair, and 1.0-1.6 per successful pair, but wide range. Failure or non-breeding are common, sometimes occurring in 50% or more of pairs; success influenced by food supply and weather; sometimes declines if reaches very high densities. Possibly only 25% of chicks reach maturity, due to starvation, accidents with powerlines, shooting, etc. Birds live up to 38 years in wild, and up to 50 years in captivity.

Movements. Generally sedentary; mainly migratory in northernmost parts of range, both in North America and in Asia, where in winter prey may be scarce or inaccessible, e.g. hibernating ground squirrels. In North America, migrants leave breeding grounds from Sept; most winter in W USA, but S to Mexico, some in areas with resident populations too; return starts Feb, and lasts months, with juveniles returning latest. Sedentary adult pairs normally stay in approximately same home range throughout year. Juveniles markedly more dispersive and travel further.

Status and Conservation. Not globally threatened. CITES II. Heavily persecuted in past, with declines in range and numbers in Europe and much of North America, often from 19th century, and mainly due to direct persecution and poisoned baits (see page 92). Banning of poisons and protection have permitted increase or at least stabilization in many countries, but recolonization has not yet reached all of original range, e.g. still very localized in C Europe and E USA. In Europe at end of 1980's, total population c. 4500-5000 pairs; main populations in Spain with 1192-1265 pairs, and Scotland with 425 pairs; sizeable populations (of 100 to 100's of pairs) in Norway, Sweden, Finland, France, Italy, Switzerland, Austria, Greece, former Yugoslavia, Bulgaria and European Russia. At least 100 pairs in Morocco and in Turkey; 21 pairs in Israel in 1984. Little information about status in Asia; in Japan no more than 370-500 birds in 1980's. Various estimates of North American population, possibly with maximum of 70,000 birds in 1980's, with highest densities in in Wyoming, Colorado and Montana. Throughout much of range, historical causes of decline have diminished by late 20th century; limiting factors now are food supply and

215. Wedge-tailed Eagle

Aquila audax

French: Aigle d'Australie

German: Keilschwanzadler

Spanish: Aguila Audaz

Taxonomy. *Vultur audax* Latham, 1801, New South Wales.

Formerly placed in monospecific genus *Uroaetus*, but clearly related to other *Aquila*. Has been considered to form superspecies with *A. chrysaetos*, and possibly also with *A. gurneyi*. Two subspecies recognized.

Subspecies and Distribution.

A. a. audax (Latham, 1801) - Australia, S New Guinea.

A. a. fleayi Condon & Amadon, 1954 - Tasmania.

Descriptive notes. 81-104 cm; male 2025-4000 g, larger female 3180-5300 g; wingspan 186-227 cm. Large *Aquila*; tail shape unique within genus. Distinguished from *A. gurneyi* by rufous nape, tail shape and cream-coloured to pale yellowish feet. Juvenile extensively brown and gold on upperparts; distinguished from juvenile *A. gurneyi* by dark underparts and tail shape. Race *fleayi* has heavier feet and claws; adults have pale nape, and lack rufous in plumage.

Habitat. Over most terrestrial habitats, from sea-level up to 2000 m, but avoids areas of dense human population, e.g. cities, intensive

agriculture. Occupies open forest, woodland, scrub, savanna, plains and deserts, typically in rough or remote country; avoids dense rain forest. Nests in all wooded habitats distant from human activity.

Food and Feeding. Mammals, birds, reptiles and carrion. In S prefers rabbits and hares, in N young kangaroos and wallabies (*Macropus*); other mammals more rarely captured include lamb, goat kid, cat, fox, young dog and spiny echidna (*Tachyglossus*). Birds commonly include *Corvus*, cockatoos (*Cacatua*) and waterfowl, rarely up to size of crane and bustard. Reptiles commonly include dragons (Agamidae) and monitors (*Varanus*), rarely snakes. Forages by low, slow quartering, high soaring or still-hunting from perch. Seizes prey on ground or sometimes in tree canopy, after swift, stealthy glide or dive which may become short chase; rarely takes prey in flight. Occasionally removes mammals such as possums (*Trichosurus*) from tree hollows. Pairs or groups attack large prey co-operatively. Gathers at carcasses of large animals, where dominates smaller scavengers; occasionally robs other predators.

Breeding. Apr-Sept; sometimes earlier (Jan-Feb) in tropical N of range. Solitary. Large platform of sticks typically 70-90 cm wide, 30-80 cm deep, lined with green leaves; may become 180 cm wide, 300 cm deep with repeated use. Usually built in live or dead tree with commanding view, 2-73 m above ground in tallest available tree, though often near ground in remote deserts; typically on rise or hillside. Also occasionally on cliff ledges, or among rocks, and even on ground on islands, in areas inaccessible to humans. Usually 2 eggs (1-3), rarely 4; usually 1 in Tasmania. Incubation 42-48 days in wild (slightly less in captivity); chicks have white down; fledging 79-95 days; post-fledging dependence of up to 6 months. Sexual maturity at 3 years; will pair in immature plumage though seldom breeds before adult plumage at 6 years. Oldest ringed bird 9 years; longevity 40 years in captivity. Success varies regionally: in SW Australia, 0.7-1.2 young fledged per clutch laid, 0.19-0.46 young per pair per year; in SE Australia, 0.9-1.5 young per clutch laid, 0.6-1.0 young per pair per year; in Tasmania, 0.8 young per clutch laid, 1.07 per successful nest.

Movements. Breeding adults sedentary, except in arid zone when forced to move by severe drought. Juveniles dispersive, commonly wandering off 200 km and up to 800 km, but some remain, or return to nest area; movement often follows ridges or valleys.

Status and Conservation. Not globally threatened. CITES II. Widespread and common on Australian mainland, despite formerly intense persecution for supposed impact on domestic stock (now shown to be negligible). Local declines in S through habitat disturbance in heavily settled and farmed areas, because intolerance to human activity leads to nest abandonment; has benefited elsewhere from thinning of tree cover, introduction of rabbit and provision of abundant carrion. Eggshell thickness not significantly reduced by DDT; still subject to illegal shooting and poisoning. Isolated Tasmanian race endangered, because range and population small (60-80 breeding pairs) and has more specific habitat requirements; less tolerant of habitat alteration around nest-site.

Bibliography. Bockel (1984b), Beecher *et al.* (1956), Brooker (1974, 1983), Brooker & Ridpath (1980), Brown, L.H. (1976b), Coates (1985), Copper & Copper (1981), Eddy (1959), Flay (1952), Garnett (1992), Hollands (1984), Hughes & Hughes (1984), Hull (1986), Leopold & Wolfe (1970), Marchant & Higgins (1993), Meredith (1990a, 1990b), Morris (1976b), Olsen & Marples (1992, 1993), Olsen, Crome & Olsen (1993), Pizey (1958), Price-Jones (1983), Ridpath & Brooker (1986a, 1986b, 1987), Robertson, G. (1987), Schodde & Tidemann (1988), Young, H. (1973).

216. Verreaux's Eagle

Aquila verreauxii

French: Aigle de Verreaux

German: Kaffernadler

Spanish: Aguila Caffre

Other common names: (African) Black Eagle

Taxonomy. *Aquila Verreauxii* Lesson, 1830, Cape of Good Hope, South Africa.

Monotypic.

Distribution. S Chad and W Sudan; from Israel, Egypt (Sinai) and SE Arabian Peninsula; Ethiopia to Somalia and thence S, with main range Kenya S to South Africa.

Descriptive notes. 80-90 cm; male 3000-4150 g, female 3100-5800 g; wingspan 199 cm. White back and white patches in primaries notable against black plumage in flight, together with narrow black to wing. Juvenile mixed rufous, brown and black; larger and less streaked than *A. rapax*.

Habitat. River gorges and rocky outcrops, kopjes, hills and mountains, from sea-level to over 5000 m, wherever hyrax prey occurs.

Food and Feeding. In most areas, hyraxes (*Procavia*, *Heterohyrax*) form at least 90% of diet, supplemented with various medium-sized mammals, birds and reptiles; rarely

small livestock. Hunts mainly on the wing, stooping from a height or swooping rapidly around a hillside to surprise prey. Less often strikes from a perch, and only rarely pirates other raptors or comes to carrion. Pairs often hunt in tandem.

Breeding. Laying in Jan in Arabia; Oct-Dec in NE Africa; Feb-Sept in E Africa (peak Jun-Jul); Apr-Aug in S and C Africa (peak May-Jul). Builds a massive nest of sticks, lined with sprays of green leaves, on a cliff ledge, rarely in a hillside tree or on a radio tower. Usually 2 eggs (1-3); incubation 43-46 days; chicks have white down; elder chick almost invariably kills younger sibling soon after hatching; fledging 90-98 days.

Movements. Resident throughout its range, although some movement between patches of hilly habitat must occur.

Status and Conservation. Not globally threatened. CITES II. Common in suitable habitat, especially in S Africa where reported mean inter-nest densities of 9 km in Natal, 7-13 km in Transvaal and 4 km in Zimbabwe and Cape Province. Estimated 240 pairs breeding in Transvaal, South Africa. More local and uncommon in C and E Africa; sparse on Arabian Peninsula; in Israel, 2 single birds recorded in 1993. Rugged terrain often last to be modified, but species declines where drought, overgrazing and hunting combine to reduce hyrax prey. Persecuted heavily in some areas of small-stock farming, and eliminated from parts of S Africa. Not known to be affected by pesticides. The most studied eagle in Africa.

Bibliography. Allan (1988a), Benson & Benson (1975), Boshoff & Palmer (1988), Boshoff *et al.* (1991), Brown, C.J. (1988a), Brown, C.J. & Cooper (1987), Brown, L.H. Genus *HIERAAETUS* Kaup, 1844

217. Bonelli's Eagle

Hieraaetus fasciatus

French: Aigle de Bonelli

German: Habichtsadler

Spanish: Aguila-azor Perdicera

Taxonomy. *Aquila fasciata* Vieillot, 1822, Fontainebleau, France, and Sardinia.

Forms superspecies with *H. spilogaster*, with which has often been considered conspecific. Race *renschii* may constitute separate species. Two subspecies normally recognized.

Subspecies and Distribution.

H. f. fasciatus (Vieillot, 1822) - NW Africa and Iberian Peninsula E through Mediterranean, SW Asia and Arabia to Afghanistan, Pakistan and India, and on through N Indochina to S China.

H. f. renschii Stresemann, 1932 - Sumbawa, Timor, Wetar, Luang and probably Flores (Lesser Sunda Is).

wing and tail feathers.

Habitat. Mainly warm, sunny mountainous or broken terrain, normally with crags and cliffs. Vegetation cover variable: normally zones with extensive growth of bushes and shrubs, e.g. maquis, garrigue; sometimes with forest, but also barren slopes with virtually no vegetation. Sometimes visits flatish open areas, with pastures, cultivation or wetlands (mostly juveniles, or outside breeding season). Generally rather retiring, although relatively adaptable to fairly humanized zones. Mainly at low or medium altitudes, but occurs up to 2000 m and above in NW Africa and Asia.

Food and Feeding. Normally medium-sized birds and mammals; adaptable, eating most readily available prey. Diet well known in SW Europe: prefers rabbits and partridges; if these are scarce, will switch to other, normally secondary, prey, e.g. pigeons, corvids, gulls, squirrels and other rodents, or lizards. In Israel takes mainly partridges and pigeons, with few mammals or reptiles. Large prey unusual, although Houbara Bustards (*Chamaeydotis undulata*), storks, herons, buzzards and foxes reported. Very agile flight, capturing most of prey on ground, but also birds in flight; sometimes pairs hunt together.

Breeding. Laying mainly from Feb to mid-Mar in Mediterranean region; Dec throughout much of Indian Subcontinent. Nests on cliff ledges, or less often in trees, habit varying with region. Nest bulky, up to 200 cm wide, 100 cm deep; built of sticks and lined with green leaves. Normally various nests per pair, often close together and even on same cliff face; used alternately. 1-2 eggs, rarely 3, laid at intervals of 2-3 days; incubation 37-41 days, mainly by female; chicks brooded and fed by female; at first only male brings prey to nest; chicks have first and second down white; fledging c. 60-70 days; juveniles may stay in territory several months more. 1-2 chicks fledge; averages in Mediterranean 1-1.5 chicks per clutch, 1-4-1.6 per successful breeding attempt. Sexual maturity possible before adult plumage acquired, very occasionally in second year. High juvenile mortality, sometimes of over 50% in first year. Recorded up to 20 years old in captivity.

Movements. Sedentary and dispersive. Breeding pairs closely tied to home range, although somewhat less outside breeding season. Juveniles disperse once independent; in SW Europe, at least, tend to move to areas not occupied by adults, often agricultural zones, with fairly gentle relief, especially rich in prey; may travel hundreds of kilometres from natal areas.

Status and Conservation. Not globally threatened, CITES II. In decline in Europe, with some regional stabilization, but in 1980's, in Spain, home to bulk of European population, perhaps up to 116 pairs disappeared; this contrasts with stability or recovery of Spanish populations of other eagles, especially *Aquila chrysaetos* and *A. adalberti*, which presumably face similar difficulties and threats; in areas of high density of *A. chrysaetos*, present species suffers somewhat, as a result of competition. Trends unknown in Africa and Asia. In early 1990's, c. 900 pairs in Europe: 679-755 in Spain, c. 75-90 in Portugal, 29 in France, c. 15 in Italy, 50-70 in Greece, and less than 60 in rest of Balkans. Estimates in N Africa of 500-1000 pairs in Morocco, perhaps 200 pairs in Algeria, and c. 100 pairs in Tunisia. In Turkey c. 50 pairs; in Israel, after slight recovery, 19 pairs in 1980's. Almost extinct in former USSR: widely distributed but rare or uncommon in Indian Subcontinent. Race *renschii* very poorly known and rarely recorded. Causes of decline not wholly understood, but species obviously affected by direct persecution and accidents with powerlines, which cause much mortality, particularly amongst juveniles; also important are degradation and transformation of habitat, reduction in numbers of prey species, and a large increase in human interference and disturbance in breeding areas.

218. African Hawk-eagle

Hieraaetus spilogaster

French: Aigle fascié **German:** Afrikanischer Habichtsadler **Spanish:** Aguila-azor Africana
Other common names: African Eagle

Taxonomy. *Spizaetus spilogaster* Bonaparte, 1850, Ethiopia.

Forms superspecies with *H. fasciatus*, and sometimes considered conspecific. Monotypic.

Distribution. Senegambia E to Ethiopia and Somalia, and S to NE South Africa.

Descriptive notes. 60-70 cm; male 1150-1300 g, female 1444-1750 g; wingspan 142 cm. Distinctive pale area in primaries in flight. Recalls *H. ayresii*, but larger, usually not as heavily marked, and without pure white patch at base of forewing. Female larger and more heavily streaked below than male. Juvenile with variable amount of streaking on underparts.

Habitat. Woodland and tree savanna, extending along riverine trees, or using exotic plantations in drier habitats.

Food and Feeding. Mainly takes francolins, guinea fowl and other birds, augmented by

small mammals, such as hares and mongooses, and some reptiles. A dashing hunter, stooping from soaring flight or a perch, less often making fast prospecting flights among trees. Members of pair often hunt together and follow prey into dense vegetation. Spends long periods perched within cover or soaring high above territory.

Breeding. Laying mainly in dry season: Feb in Gambia; Jan in Somalia; Oct-Nov in NE Zaire, Uganda and W Kenya; Apr-Sept in S and C Africa (peak Jun). Builds a substantial stick nest in a prominent upper fork of a large tree, often along a watercourse, rarely on a power pylon. Usually 2 eggs (1-3); incubation 42-44 days; chicks have first down dark grey with white belly and legs, second down white; elder chick usually kills younger sibling within few days of hatching; fledging 61-71 days.

Movements. Resident and sedentary with no movements reported.

Status and Conservation. Not globally threatened, CITES II. Widespread and common through most woodland and tree savanna areas of E, C and S Africa at densities of 1 pair/30-110 km², with estimated 200 pairs in Hwange National Park, Zimbabwe, and 1600 pairs in Transvaal, South Africa. Less common in Sahel and Guinea savanna of W Africa, and steppes of SW Africa. Vulnerable to cutting of woodland, and persecuted in many areas for attacks on poultry. Not known to be affected by pesticides.

Bibliography. Allan (1988b), Benson & Benson (1975), Brown, L.H. (1952, 1953, 1955, 1976b), Brown *et al.* (1982), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Howells & Hustler (1984), Hustler & Howells (1988c), Lewis & Pomerooy (1989), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Smeenk (1974), Steyn (1975b, 1982), Tarboton & Allan (1984), Tuer (1973).

219. Booted Eagle

Hieraaetus pennatus

French: Aigle botté **German:** Zwergadler **Spanish:** Aguililla Calzada

Taxonomy. *Falco pennatus* Gmelin, 1788, no locality = France.

Birds of C Asia sometimes classified as race *milvoides*, or alternatively *harterti*, but variation very slight and clinal. Monotypic.

Distribution. SW Europe and NW Africa through E Europe, Asia Minor and Caucasus to C Asia, NE to Mongolia and L Baikal area, and SE to N India; also Cape Province (S South Africa), and perhaps Namibia. Winters mostly in Africa S of Sahara, and in S Asia, especially India.

Descriptive notes. 45-55 cm; male 709 g, female 975 g; wingspan 110-132 cm. Two distinct colour morphs, with several intermediate plumages; both have broad pale band across upperwing, and pale uppertail-coverts. More frequent pale morph shows whitish underparts and underwing-coverts, contrasting markedly with flight-feathers, which are very dark, apart from paler, slightly translucent innermost primaries. Dark morph rather similar to *A. wahlbergi* and *Milvus migrans*. Juvenile also polymorphic, and very similar to adult, especially in dark morph; pale morph with more streaking and reddish brown tint below. Cline

in size from W to E, with larger birds in E.

Habitat. Forests and woods mixed with open areas, often in open woodland. Type of wood varies, including broad-leaved, coniferous, mixed woods and olive and palm groves in Morocco. Flat land, low hills and mountain slopes; up to 3000 m in India, 2700 m in N Africa, and 2000 m in Bulgaria. In Cape Province (South Africa) occurs in mountainous terrain, with cliffs, low bushes and karoo scrub.

Food and Feeding. Small and medium-sized birds, from small passerines to pigeons, gamebirds and corvids; also mammals, including mice, susliks, squirrels, pikas, rabbits; reptiles, e.g. ocellated lizard (*Lacerta lepida*) important in Spain, *Agama caucasia* in parts of Pakistan; some insects, such as locusts and termite alates in S Africa. Hunts in open or wooded areas; captures prey mainly on ground, stooping from air or after spotting prey from vantage perch; sometimes pair may hunt together.

Breeding. Lays Apr-May in N of range; second half of Sept in Cape Province. Nests in trees in woods, or sometimes solitary trees; in various regions, particularly Africa, also (or exclusively) on ledges, in clefts and on small trees on cliff faces. Nest large, of sticks and twigs, lined with fresh leaves; often reused. Normally 2 eggs (1-3), laid at interval of 2-3 days; incubation 37-40 days, by female; male brings all food during incubation and beginning of fledging period; chicks have first and second down white, grey or brown (uncertain if corresponds to subsequent colour morph of individual); fledging 50-54 days; juveniles may stay with adults for another 47+ days. 1-2 chicks fledge, average c. 1.5 chicks per pair.

Movements. Mainly migratory; very scarce in winter in parts of S Europe, N Africa and Middle East; resident populations in N Pakistan and India and Balearic Is. Bulk of W population winters in sub-Saharan Africa, crossing via Gibraltar and Suez, with E populations moving to Indian Subcontinent. Leaves Eurasian breeding grounds in Sept, and returns in Mar-Apr. Breeding population of Cape Province (South Africa) moves N to NW Cape and Namibia, leaving in Mar and returning in Aug.

Status and Conservation. Not globally threatened, CITES II. Population sizes not well known, and only fairly approximate estimates available; little information on trends, although apparently stable in general. In 1980's: perhaps 3000 pairs in Spain; c. 130-150 pairs in Portugal; minimum of 500 pairs in France; c. 50 pairs in Bulgaria; 4-5 pairs in Hungary; perhaps over 200 pairs in Greece; and c. 50 pairs in Yugoslavia. In 1990's: c. 10 pairs in Poland; perhaps 600 pairs in European sector of former USSR, with c. 300 pairs in Russia, and c. 80-100 pairs in Azerbaijan; possibly c. 100-500 pairs in Turkey. In Africa, in 1980's, estimated c. 500-1000 pairs in Morocco; common in Algeria and Tunisia; over 100 pairs estimated in South Africa. Numbers on post-breeding migration over Gibraltar estimated at 10,000-19,000 birds, corresponding to French and Iberian populations; autumn maximum in Suez of 12,000 birds, which would refer to populations of SE & E Europe, Asia Minor and Caucasus. Some negative factors affecting species are habitat degradation, decline in prey species, and human persecution; declining in Ukraine due to deforestation.

Bibliography. Ali & Ripley (1978), Bergier (1987), Brooke *et al.* (1980), Brown, L.H. (1976b), Brown *et al.* (1982), Carlon (1984), Chancellor (1991), Cheng Tso-hin (1987), Clark, W.S. (1987), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Donnelly (1966), Efimenko (1989), Etchécopar & Húe (1978), Flint *et al.* (1984), Génsbol (1986), Ginn *et al.* (1989), Goodman *et al.* (1989), Handrinos & Demetropoulos (1983), Holmeren (1984), Iribarren & Rodríguez Arbeloa (1988), Knystautas (1993), Król (1983), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Medway & Wells (1976), van der Merwe (1992), Paz (1987), Pickford *et al.* (1989), Richardson (1990), Roberts (1991), Rogacheva (1992), Shirihai & Christie (1992), Simeonov *et al.* (1990), Smythies (1986), Steyn & Grobler (1981), Suetens & van Groenendael (1969), Thiollay (1989c), Tribarren (1975).

220. Little Eagle

Hieraaetus morphnoides

French: Aigle nain **German:** Kaninchenadler **Spanish:** Aguililla Australiana

Taxonomy. *Aquila morphnoides* Gould, 1841, Hunter River, New South Wales.

Genus sometimes merged with *Aquila*, but kept separate by most modern authorities. Two subspecies recognized.

Subspecies and Distribution.

H. m. weiskei (Reichenow, 1900) - New Guinea.

H. m. morphnoides (Gould, 1841) - Australia.

Descriptive notes. Nominate race: 45-55 cm; male 530-810 g, larger female 745-1250 g; wingspan 110-136 cm. Race *weiskei* smaller: 38-48 cm; male 483 g. Small, polymorphic *Hieraaetus*: pale morph has characteristic underwing pattern, with markedly contrasted white greater coverts; dark morph generally duskier, with brown underparts and underwing, but rather variable, ranging from sandy to smoky chestnut on underparts; distinguished from closely similar *H. pennatus* by underwing pattern (pale morph), lack of white patch near shoulder, and pale cere and feet. Juveniles of both morphs more rufous. Race

weiskei shows more streaking on breast.

Habitat. Open forest, woodland, scrub and savanna, from sea-level to 1500 m in Australia, to 1950 m in New Guinea. Typically in rough, hilly country; avoids treeless areas and dense forest in Australia, but occurs over rain forest in New Guinea. Nests in forest and woodland, often riparian *Estuaries and mangroves*.

Food and Feeding. Mammals, birds, reptiles, occasionally large insects and carrion; rarely fish (possibly stolen from *Haliastur*). In S prefers young rabbits, in N birds. Takes mammals of up to 1500 g; birds commonly include parrots and passerines, rarely up to 1000 g (ducks, *Corvus*); reptiles commonly dragons (Agamidae) and large skinks, rarely snakes. Forages by quartering and high soaring; uses low flights between perches, or still-hunting from perch. Seizes prey on ground by glide or dive, sometimes by rapid stoop to tree canopy; rarely takes prey in flight.

Breeding. Season varies with latitude; longer in tropical N, occupying dry season, Mar-Sept; shorter in S, usually Aug-Oct, but rarely starting May, or extending to Dec for replacement clutches. Solitary, but sometimes near raptors of other species, though not *Aquila*. Platform of sticks 60-75 cm wide, c. 30 cm deep, lined with green leaves; placed 5-45 m above ground in fork of living tree. Usually 2 eggs (1-3); incubation c. 36-41 days; chicks have white down; fledging c. 54-66 days; post-fledging dependence c. 2 months. Sexual maturity apparently at 2 years or older. Oldest ringed bird 26 years. Success varies regionally and according to weather, being lower in very wet or drought years; in SE Australia, 0.5-1.0 young per pair per year, 0.8-0.9 young per clutch laid, and 1-1 young per successful nest.

Movements. Resident and partly migratory populations. Some breeding adults sedentary; at high latitudes and altitudes in SE of range, some birds, particularly females, spend winter in coastal or lowland areas, where they defend non-breeding territories. Juveniles dispersive. Vagrant to Halmahera (N Moluccas).

Status and Conservation. Not globally threatened. CITES II. Common and widespread in Australia; has benefited from thinning of tree cover and introduction of rabbit; has increased in range and numbers in coastal SE Australia. Eggshell thickness not significantly reduced by DDT; not easily disturbed at nest; seldom persecuted. Possibly affected locally, to minor degree, by extensive habitat clearance or by excessive loss of trees.

Bibliography. Baker-Gabb (1984b, 1985d), Beecher *et al.* (1986), Bollen (1989, 1991a), Brown, L.H. (1976b), Calaby (1951), Coates (1985), Cupper & Cupper (1981), Debus (1983b, 1984a, 1984b, 1989, 1990, 1991d), Garstone (1986), Hollands (1984), King (1990), Mallinson *et al.* (1990), Marchant & Higgins (1993), Meadrell (1990), Newgrain *et al.* (1993a), Olsen & Marples (1992, 1993), Olsen & Olsen (1987a), Olsen, Crome & Olsen (1993), Schodde & Tidemann (1988).

221. Ayres's Hawk-eagle

Hieraaetus ayresii

French: Aigle d'Ayres

German: Fleckenadler

Spanish: Aguila-azor de Ayres

Other common names: Ayres's Eagle

Taxonomy. *Spizaetus ayresii* Gurney, 1862, Natal, South Africa.

May form superspecies with *H. pennatus*, and possibly even *H. morphnoides*. Until recently, frequently called *H. dubius*, but this name apparently refers to *H. pennatus*. Monotypic.

Distribution. Sierra Leone E to Ethiopia and Somalia, then S to N Namibia, N Botswana and NE South Africa.

(Sierra Leone).

Food and Feeding. Mainly birds of 40-200 g, especially doves and pigeons; also a few mammals, such as squirrels or fruit bats. Hunts mostly by fast stoop from high soaring flight, wings held in typical heart-shaped conformation, dashing through the canopy in pursuit and taking most prey in flight. Sits unobtrusively for long periods and may strike from a perch.

Breeding. Laying Nov in NE Zaire, and Feb in SE Zaire; Mar, May-Sept in Kenya; Apr-May in C Africa. Builds a large stick nest lined with green leaves, in a high fork of a large tree. Single egg; incubation 43-45 days; chick has white down with dark grey spot in front of eye; fledging 73-75 days.

Movements. In the rainy season (Nov-Apr) moves out of denser and taller deciduous woodlands of C Africa into more open tree savanna further S, and probably into coastal E Africa; spring foliage turns woodland into forest and tree savanna into woodland. May then enter towns in S Africa to prey mainly on doves and feral pigeons. Similar N-S movements expected in W Africa, where species recorded (uncertainly) W to Senegambia.

Status and Conservation. Not globally threatened. CITES II. Generally considered rare and sparsely distributed; apparently only reasonably common in woodlands of C Africa. Vulnerable to clearing of woodland. Not known to be affected by pesticides but persecuted in parts of S non-breeding range for preying on racing pigeons. Naturally low breeding success reported from E Africa, but unstudied elsewhere.

Bibliography. Benson & Benson (1975), Brown, L.H. (1952, 1953, 1955, 1966, 1974b, 1976b), Brown & Davey (1978), Brown *et al.* (1982), Dewhurst *et al.* (1988), Ginn *et al.* (1989), Grimes (1987), Hartley (1982), Lendrum (1982), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pickford *et al.* (1989), Pinto (1983), Snow (1978), Steyn (1982), Tarboton & Allan (1984), Wolf (1984).

222. Rufous-bellied Eagle

Hieraaetus kienerii

French: Aigle à ventre roux

German: Rothbauchadler

Spanish: Aguila-azor Ventrirroja

Other common names: Chestnut-bellied/Rufous-bellied Hawk-eagle

Taxonomy. *Asur kienerii* Geoffroy Saint-Hilaire, 1835, Himalayas.

Two subspecies recognized.

Subspecies and Distribution.

H. k. kienerii (Geoffroy Saint-Hilaire, 1835) - NE India and Nepal; SW India (W Ghats) and Sri Lanka.

H. k. formosus Stresemann, 1924 - Burma and Hainan through W. S. & EC Indochina and Malay Peninsula to Greater Sundas, Bali, Philippines and Sulawesi.

Descriptive notes. 42-60 cm; male 732 g; wingspan 90-127 cm. Small, dark, aerial eagle with short bushy crest. Bright rufous underparts and underwing-coverts only noticeable at close range, appearing dark greyish from afar. Wing shape and underwing pattern in flight similar to those found in buzzards. Juvenile strikingly different, with completely white underparts and underwing. Race *formosus* smaller, with darker upperparts.

Habitat. Heavy evergreen and moist deciduous forest from foothills up to 1500 m, and perhaps higher.

Food and Feeding. Feeds on birds and mammals, e.g. squirrels; some rather large birds taken, including pheasants, junglefowl and pigeons. Very aerial hunter; captures prey on or near ground or treetops after spectacular stoops, reminiscent of Peregrine Falcon (*Falco peregrinus*).

Breeding. Season: Dec-Mar in Sri Lanka and S India; Feb in Philippines; somewhat later in N India. Large nest built by pair in crown of large tree in dense forest; lined with green leaves. Display flight involves repeated dives with wings closed, and also shivering of wings. 1 egg; incubation by both sexes. Pair vigorous in defence of nest against humans. No further information available.

Movements. Mainly sedentary, but migrants reported on Malay Peninsula. Status on Bali uncertain, possibly only uncommon migrant or vagrant; recently seen on Flores; also recorded on Ternate (N Moluccas).

Status and Conservation. Not globally threatened. CITES II. Widespread, but status variable: rare in Java and Burma; scarce in Nepal; uncommon in Philippines; moderately common in Sulawesi. During recent raptor survey in Java only rarely recorded, invariably in forest fragments. Recently found to be common in forested areas of NE India and SW India (W Ghats). Has undoubtedly suffered as result of extensive deforestation that still continues throughout most of range.

Bibliography. Ali & Ripley (1978), Bishop *et al.* (1994), Brown, L.H. (1976b), Cheng Tso-hin (1987), Clark & Schmitt (1993), Deignan (1945), Dickinson *et al.* (1991), Henry (1971), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Smythies (1981, 1986), Stresemann (1940a), Thiollay & Meyburg (1988), White & Bruce (1986).

Genus POLEMAETUS Heine, 1890

223. Martial Eagle

Polemaetus bellicosus

French: Aigle martial

German: Kampfadler

Spanish: Aguila Marcial

Other common names: Martial Hawk-eagle

Taxonomy. *Falco bellicosus* Daudin, 1800, Great Namaqualand, South Africa.

Monotypic genus, but may be better placed in genus *Hieraaetus*, on grounds of strong skeletal evidence. Monotypic.

Distribution. Senegambia E to Ethiopia and S to South Africa.

Descriptive notes. 78-86 cm; 3012-6200 g; wingspan 212 cm. Large head and long broad blackish wings notable. Resembles *Circus pectoralis*, but larger, with black spots on lower breast and dark underwing. Grey and white juvenile resembles that of *Stephanoaetus coronatus*, but for short tail, long wings and pure white underparts.

Habitat. Any areas of open habitat from desert and steppe to grassland and woodland.

Food and Feeding. Mainly vertebrates weighing 1-5 kg, with large birds (e.g. gamebirds and waterfowl), monitor lizards, or mammals (e.g. hares, hyraxes, mongooses and

small antelopes) predominating as prey in different habitats. Takes some small livestock and poultry. Hunts for long periods on the wing, soaring high overhead in search of prey and striking after a long shallow dive, sometimes concealed behind cover. May also strike from a prominent perch.

Breeding. Laying mainly in dry season: Nov in W Africa; Aug-Jan in NE Africa; Feb-Nov in E. C and S Africa (peak Apr-Jun). Builds a large structure of sticks in a main fork of an emergent tree, or even on a power pylon, cliff or boulder in open areas. Nest often visible from far off, and well lined with green leaves when active. Single egg (rarely 2); incubation 47-51 days; chick has down dark grey above and white below; fledging 96-99 days; may remain dependent on parents for 8-12 months after fledging. Usually breeds annually in some areas (South Africa), biennially in others (Zimbabwe).

Movements. No regular movements reported, but juveniles range widely.

Status and Conservation. Not globally threatened. CITES II. Widespread and common in E and S Africa, less so in W Africa. Occupies many types of savanna and steppe, but occurs at low densities with home ranges of 108-302 km². Estimated 110 pairs for Hwange National Park (Zimbabwe), and 100-120 for Kruger National Park and 500 pairs for whole of Transvaal (South Africa). Occurs in many large national parks, reserves and extensive ranching areas, spreading range into treeless areas by use of power pylons. Heavily persecuted in some small-stock and free-range poultry farming areas, and extirpated from parts of South Africa, Namibia and Zimbabwe. Breeding in immature plumage might indicate population decline, e.g. in Transvaal. Not known to be affected by pesticides.

Bibliography. Allan (1988b), Benson & Benson (1975), Boshoff (1993), Boshoff & Palmer (1980), Boshoff & Vernon (1980a), Boshoff *et al.* (1990), Brown, C.J. (1991b), Brown, L.H. (1952, 1953, 1955, 1966, 1976b), Brown, L.H. *et al.* (1982), Ginn *et al.* (1989), Gore (1990), Grimes (1987), Howells & Huxler (1984), Huxler & Howells (1987), Kemp & Kemp (1974), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Marx & van Staden (1989).

Pickford *et al.* (1989), Pinto (1983), Smeenk (1974), Steyn (1980a, 1982), Tarboton (1976), Tarboton & Allan (1984), Thiollay (1978c).

Genus *SPIZASTUR* G. R. Gray, 1841

224. Black-and-white Hawk-eagle

Spizastur melanoleucus

French: Aigle noir et blanc **German:** Elsteradler **Spanish:** Aguila-azor Blanquinegra

Taxonomy. *Buteo melanoleucus* Vieillot, 1816, Guiana.

Monotypic genus, very similar to Old World *Hieraetus*. Monotypic.

Distribution. E & S Mexico (Veracruz, Oaxaca) through Central America to Colombia, whence S on Pacific slope to W Ecuador, and E through N Venezuela to the Guianas, then S through E & S Brazil to NE Argentina and Paraguay; E Peru (Loreto) and N & E Bolivia (Beni to Santa Cruz).

Descriptive notes. 51-61 cm; 850 g. Head, neck and underparts, including underwing-coverts, immaculate white; crown and short, bushy occipital crest black; above black; tail brownish with narrow white tip and four black bands. Iris pale orangish yellow, cere orange, feet bright yellow. Differs from immature *Spizaetus ornatus* in much darker upperparts and black lores. Female similar, but larger. Immature has some white edging to upperwing-coverts, and brownish grey admixture on back.

Habitat. Very catholic in habitat requirements: variety of forested areas in tropical and

subtropical zones, but seems to prefer areas with some open country or rivers. Savanna and gallery forest in Mato Grosso, SW Brazil.

Food and Feeding. Prey recorded includes mammals, reptiles, toads and many birds, e.g. caciues (*Psarocolius*), araçaris (*Pteroglossus*), tinamous and chachalacas (*Ortalis*); tanagers and cotingas attacked on fruiting trees; cormorants and (threatened) Brazilian Mergansers (*Mergus octosetaceus*) in Misiones, NE Argentina. Monkeys have not been recorded as prey, but attacks on troops of small monkeys have been witnessed. Stoops from a high soar, at c. 200 m, into forest canopy; seems to prefer forest edge and ridges for foraging, perhaps to facilitate hunting technique of soar and stoop.

Breeding. Only one nest recorded, in Panama: construction initiated in Sept, during very dry period in midst of rainy season, but abandoned when heavy rains recommenced. Male in breeding condition in Mar, Belize; dates on eggs collected in Guyana suggest laying in dry season (Mar-Apr). Stick nest 40 m high in tall tree, on ridge overlooking a mosaic of forest and open country.

Movements. No information available.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Extensive range, but spotty distribution. Rare in most areas, but relatively common at one forest site in French Guiana, with estimated average density of at least 7 individuals/10,000 ha; rare and very local in Colombia; sparsely distributed throughout Brazil. Tolerance of diverse habitat types suggests species should not be too seriously affected by transformation of habitat.

Genus *LOPHAETUS* Kaup, 1847

225. Long-crested Eagle

Lophaelus occipitalis

French: Aigle huppard **German:** Schopfädel **Spanish:** Aguila Crestilarga

Taxonomy. *Falco occipitalis* Daudin, 1800, Knysna district, South Africa.

Monotypic genus, but may belong within genus *Spizaetus*. Monotypic.

Distribution. Senegambia E to Ethiopia and S to N Namibia, N Botswana and E South Africa.

Descriptive notes. 53-58 cm; male 912-1363 g, female 1367-1523 g. Broad, rounded wings with white carpal patches distinctive in flight. Long crest present at all ages. Female larger than male. Juvenile similar to adult; fresh male and juvenile plumage accompanied by pure white legs, adult female often has off-white to brown legs.

Habitat. Edges of forest and woodland bordering on patches of marsh and long grass. Moves readily into exotic pine and eucalypt plantations and small-scale cultivation.

Food and Feeding. Mainly rodents and shrews, especially *Otomys* in S Africa; also

some birds, up to size of francolin, reptiles, arthropods, and rarely fish or fruit. Perches in prominent position for long periods, swooping down to take prey on the ground below. Usually swallows prey whole via its wide gape.

Breeding. Laying generally in wet season, but erratic and may breed successfully more than once in a year: Jan/Mar-Apr in W Africa; Jun-Aug in NE Africa; all months in E Africa; Apr-Jan in S and C Africa. Builds a relatively small platform of sticks in an upper fork of a tall tree on the edge of forest or woodland. 1-2 eggs; incubation 42 days; chick has first down pale grey, second down grey above and white below; fledging 53-58 days; two chicks may be raised quite regularly and sometimes a second brood.

Movements. No regular movements reported but renowned in S, E and NE Africa for turning up, and sometimes even breeding, in temporarily wet areas after good rainy seasons.

Status and Conservation. Not globally threatened. CITES II. Common, especially in E Africa, but often locally distributed where and when suitable moist habitat occurs. Estimated 200 pairs in Transvaal, South Africa. Conspicuous, but not usually persecuted, due to recognition of primarily rodent diet. Vulnerable to degradation of woodland and drainage of wetlands, but compensates to some extent by using exotic plantations, small agricultural clearings and other secondary forest habitats. Not known to be affected by pesticides.

Bibliography. Benson & Benson (1975), Brown, L.H. Genus *SPIZAETUS* Vieillot, 1816

226. Cassin's Hawk-eagle

Spizaetus africanus

French: Aigle de Cassin German: Schwarzsachseladler Spanish: Aguila-azor Congoleña

Taxonomy. *Limnaetus africanus* Cassin, 1865, Ogabi River, Gabon.

The only African member of the genus (as presently defined); previously placed in *Hieraetus*, or more often in its own genus *Cassiniaetus*. Monotypic.

Distribution. Sierra Leone and Liberia E to W Uganda and E Zaire; also NW Angola.

Descriptive notes. 50-61 cm; male 938-1049 g, female 1153 g. Slight crest, short rounded wings, black underwing coverts and long tail; lightly spotted below. Most like *Hieraetus ayresii*, but plainer white below; generally whiter below than *Accipiter melanoleucus*. Female has less black on flanks. Juvenile pale rufous, with underparts spotted darker.

Habitat. Lowland tropical evergreen forest and adjacent secondary and gallery forest, even entering plantations with large trees.

Food and Feeding. Poorly known. Mainly birds, also squirrels, recorded from stomach contents. Probably hunts mostly by perch-hunt-

ing in forest canopy, or soars low over forest in search of prey, so difficult to observe.

Breeding. Laying in Oct-Dec in Ghana and Gabon; Dec in Uganda. Sometimes soars calling loudly above forest canopy. Builds large stick nest high in forest tree; used in successive seasons. Only a single chick ever recorded, with white down, still present in the nest area 6 months after fledging.

Movements. None recorded. Probably resident and sedentary.

Status and Conservation. Not globally threatened. CITES II. Recorded infrequently, but probably commoner than supposed, and large tracts of forest habitat still exist in Congo Basin. Angolan specimen suggests species may be more widespread than so far recorded. Vulnerable to deforestation, but uses many secondary habitats; numbers probably reduced in many areas of W Africa. Not known to be affected by pesticides.

Bibliography. Brosset (1971), Brown *et al.* (1982), Chapin (1932), Grimes (1987), Macdonald (1980a), Macdonald & Taylor (1977), Mackworth-Præd & Grant (1957-1973), Pinto (1983), Serle *et al.* (1977), Skorupa (1981), Snow (1978), Thiollay (1985d).

227. Changeable Hawk-eagle

Spizaetus cirrhatus

French: Aigle huppé German: Haubenadler Spanish: Aguila-azor Variable
Other common names: Crested Hawk-eagle (*cirrhatus*); Sunda Hawk-eagle (*floris*)

Taxonomy. *Falco cirrhatus* Gmelin, 1788, India.

Races *limnaetus* (incorporating *andamanensis* and *vanheurni*) and *floris* sometimes considered two separate species on grounds of plumage and lack of crest, but behaviour appears to be identical. Six subspecies normally recognized.

Subspecies and Distribution.

S. c. cirrhatus (Gmelin, 1788) - India S of Rajasthan and Gangetic Plain.

S. c. ceylanensis Gmelin, 1788 - Sri Lanka.

S. c. andamanensis Tytler, 1865 - Andaman Is.

S. c. limnaetus Horsfield, 1821 - N India and Nepal through Burma, W & S Indochina and Malay Peninsula to Greater Sundas and W & SE Philippines (Palawan, Mindoro, Mindanao).

S. c. vanheurni Junge, 1936 - Simeulue I (off W Sumatra).

S. c. floris Hartert, 1898 - mountains of Sumbawa and Flores.

Descriptive notes. 57-79 cm; 1300-1900 g; wingspan 127-138 cm. Typical hawk-eagle occurring in two forms, crested and crestless. Dark brown above, and heavily streaked dark on whitish underparts. Differs from other Asiatic *Spizaetus* in that leg feathering does not extend down between toes. Juvenile similar, but with pale head and less heavily marked underparts. Race *ceylanensis*, with long crest, similar to nominate but smaller; other races crestless, but otherwise fairly similar to nominate; *floris* all white below, virtually unmarked; *limnaetus* has dark morph, not recorded in N India.

Habitat. Deciduous and evergreen forest, as well as secondary forest and tea and teak plantations, in lowlands and foothills up to 1500 m. Mainly at forest edge and in open woodland, but usually not inside dense forest, where replaced by *S. nannus* or *S. alboniger*.

Food and Feeding. Small and large birds, snakes, frogs, lizards and mammals. Hunts like large goshawk, from concealed perch inside forest, or along forest edge. Prey captured after short rapid stoop.

Breeding. Season varies: usually Dec-Jan in Borneo, Sumatra, Sri Lanka and Malay Peninsula; mainly Jan-Feb (Nov-Apr) throughout India; Apr-Aug in Java; downy young in Oct in Sumatra. Large stick nest built by pair 10-30 m up, in crown or high fork of large tree; usually in forest, but alternatively in isolated tree. Display probably consists of pair soaring over territory, constantly calling, 1 egg; incubation by female, estimated to take over 40 days, one bird fledged after 68 days; period of dependency unknown.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Widespread and apparently common to uncommon throughout extensive range; scarce in Java, due to deforestation.

Bibliography. Ali & Ripley (1978), Allen (1949), Amadon (1953, 1982a), Bishop *et al.* (1994), Brown, L.H. (1976b), Clark & Schmitt (1992), Dickinson *et al.* (1991), Henry (1971), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), MacKinnon & Phillips (1993), van Marle & Voous (1988), Medway & Wells (1976), Smythies (1981), Stresemann (1938), Wilkinson *et al.* (1991a, 1991b).

Round (1991), MacKinnon (1988), van Marle & Voous (1988), Medway & Wells (1976), Naomiji (1985), Riley (1938), Schmutz, E. (1977), Smythies (1981, 1986), Thiollay & Meyburg (1988), Tikader (1988), White & Bruce (1986)

228. Mountain Hawk-eagle

Spizaetus nipalensis

French: Aigle montagnard German: Bergadler Spanish: Aguila-azor Montañesa
Other common names: Hodgson's/Feather-toed Hawk-eagle

Taxonomy. *Nisaetus Nipalensis* Hodgson, 1836, Nepal.

Forms superspecies with *S. alboniger*, *S. bartelsi*, *S. lanceolatus*, and *S. philippensis*. Proposed races *fokiensis* and *whiteheadi* of S China not valid. Three subspecies recognized.

Subspecies and Distribution.

S. n. orientalis Temminck & Schlegel, 1844 - Japan.

S. n. nipalensis (Hodgson, 1836) - Himalayas of India and Nepal E through S China and Hainan to E China and Taiwan, and S to N Indochina and N Malay Peninsula; recently Vietnam.

S. n. kelaarti Legge, 1878 - SW India (W Ghats) and Sri Lanka.

Descriptive notes. 67-86 cm; 1800-3500 g; wingspan 130-165 cm. Large, powerful hawk-eagle with dark and light tail banding of even width. Juvenile generally paler, and almost entirely whitish below. Japanese race *orientalis* largest, with short crest; *kelaarti* differs from nominate only in smaller size.

Habitat. Montane forest from 600 m to 4000 m.

Food and Feeding. Mostly small to medium-sized mammals, especially hares, and game birds, e.g. pheasants and quails; occasionally lizards and snakes, and even one report of a fish; will readily take domestic fowl. Typical hawk-eagle, hunting from cover inside forest and

along forest edge. Prey captured, usually on ground, after short, rapid stoop from concealed perch.

Breeding. Season usually Dec-Mar in Sri Lanka; Jan-Apr in Japan; and Feb-June in Himalayas. Large nest built by pair 12-25 m up large tree, often conifer in N India and Japan. Display flight probably consists of pair soaring over territory while calling; also undulating flight. Usually 1 egg, rarely 2 (reports of 3 from Japan require verification); incubation perhaps only by female; incubation and nestling periods unknown, but estimated to total c. 80 days; dependency period may be long, as young birds seen with parents long after nesting period. Pair vigorous in defence of nest against humans.

Movements. Mainly sedentary; however, fairly common in lowlands of Thailand in winter, and a few individuals, possibly juveniles, have been recorded in Malay Peninsula and in lowlands of Japan. Erroneously recorded on spring passage at Beidaihe (NE China), probably due to confusion with *Pernis ptilorhynchus*. Many birds claimed to move S onto Gangetic Plain.

Status and Conservation. Not globally threatened. CITES II. Uncommon to rare; has undoubtedly suffered as result of extensive deforestation that still continues throughout most of range.

Bibliography. Ali & Ripley (1978), Amadon (1953, 1982a), Brazil (1991), Brown, L.H. (1976b), Cheng Tso-hin (1987), Deignan (1945, 1963), Etchécopar & Hùe (1978), Henry (1971), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), Medway & Wells (1976), Meyer de Schauensee (1984), Roberts (1991), Smythies (1986).

229. Blyth's Hawk-eagle

Spizaetus alboniger

French: Aigle de Blyth German: Traueradler Spanish: Aguila-azor Indonesia
Other common names: Mountain Hawk-eagle(!), Black-and-white Hawk-eagle(!)

Taxonomy. *Nisaetus alboniger* Blyth, 1845, Malacca, Malay Peninsula.

Forms superspecies with *S. nipalensis*, *S. bartelsi*, *S. lanceolatus* and *S. philippensis*. Monotypic.

Distribution. S Burma (Tenasserim) and S Thailand through Malay Peninsula to Sumatra and off-lying islands; N Borneo.

Descriptive notes. 52-58 cm; 830 g. Typical hawk-eagle with fairly long crest, but blacker above than most of congeners. Juvenile has brown head and pale underparts; similar to smaller, sympatric juvenile *S. nannus*; subadult of present species almost identical to adult *S. nannus*.

Habitat. Hill and montane evergreen forest from 200 to 1700 m.

Food and Feeding. Arboreal mammals, birds, lizards and sometimes bats; will take domestic fowl. Captures prey in trees after agile flight; hunts in upper storeys of forest, presumably from concealed perch in typical manner of genus.

Breeding. One nest with incubation in Nov, fledging in Feb; one nest in Sumatra, with incubating female in Jul. Large nest built by pair in crown of emergent tree in forest. Noisy aerial display over forest; possible display involves undulating flights of pair; may also include soaring. At one nest, only 1 young fledged. No further information available.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Generally appears to be uncommon. Long term threat is loss of habitat, with extensive deforestation throughout much of range.

Bibliography. Amadon (1953, 1982a), Brown, L.H. (1976b), Deignan (1963), King *et al.* (1975), Lekagul & Round (1991), MacKinnon & Phillips (1993), van Marle & Voous (1988), Medway & Wells (1976), Smythies (1981), Stresemann (1938), Wilkinson *et al.* (1991a, 1991b).

230. Javan Hawk-eagle

Spizaetus bartelsi

French: Aigle de Java German: Javaadler Spanish: Aguila-azor de Java

Taxonomy. *Spizaetus nipalensis bartelsi* Stresemann, 1924, western Java. Forms superspecies with *S. nipalensis*, *S. alboniger*, *S. lanceolatus* and *S. philippensis*. Sometimes considered to be race of *S. nipalensis*, but clearly distinct. Monotypic.

Distribution. Java.

Descriptive notes. 56-61 cm. Typical hawk-eagle, with long crest. Heavily barred below, recalling considerably larger *S. nipalensis* and smaller *S. nanus*; much deeper rufous on head and neck. Juvenile has rufous buff head and underparts; underparts unmarked, as is typical for genus.

Habitat. Humid tropical forest; mainly in primary forest, but also to lesser extent in secondary forest; typically found at 200-1200 m, but recorded up to 3000 m.

Food and Feeding. Preys on large birds, including junglefowl (*Gallus*); mammals, e.g. stink badgers (*Mydaus*) and fruit bats; also li-

zards. Hunting methods not recorded.

Breeding. Season May-Aug. Nest built by pair in tall tree in forest. 1 egg. No further information available.

Movements. Apparently sedentary.

Status and Conservation. VULNERABLE. CITES II. One of rarest of all raptors. Population estimate, based on recent surveys, suggests that 52-61 pairs remain, although c. 15-20 more pairs might be found in as yet unsurveyed areas. Most of these occur in small forest reserves, which urgently require far more rigorous protection measures. Chronic loss of forest is major factor in decline of species, along with exponential growth of human population in Java. Other threats include (illegal) bird trade: species regularly seen in Jakarta bird markets; dispersing immatures are particularly vulnerable, as they tend to wander into areas with denser human population. Shooting also seems to have accounted for fair numbers.

Bibliography. Amadon (1953, 1982), Andrew (1985), van Balen (1991), van Balen & Meyburg (1994), Brown, L.H. (1976b), Collar & Andrew (1988), Kuroda (1933-1936), MacKinnon (1988), MacKinnon & Philipps (1993), Meyburg (1986), Meyburg *et al.* (1989), Thiollay & Meyburg (1988).

231. Sulawesi Hawk-eagle

Spizaetus lanceolatus

French: Aigle des Célèbes **German:** Celebesadler **Spanish:** Aguila-azor de Célebes
Other common names: Celebes Hawk-eagle

Taxonomy. *Spizaetus* [sic] *lanceolatus* Temminck and Schlegel, 1844, Sulawesi.

Forms superspecies with *S. nipalensis*, *S. alboniger*, *S. bartelsi* and *S. philippensis*. Monotypic.

Distribution. Sulawesi and off-lying islands of Muna and Butung; Banggai Is (Peleng) and Sula Is.

Descriptive notes. 56-64 cm. Boldly marked hawk-eagle, without crest. Striking similarity in plumage to that of sympatric *Pernis celebensis*. Juvenile has white head and unmarked white underparts.

Habitat. Primary and old secondary forest with open areas, from 250 to over 2000 m.

Food and Feeding. Few data available. Probably takes small to medium-sized birds and mammals, with some snakes and lizards; also said to take domestic fowl. Apparently hunts from concealed perches like congeners; preys to hunt over grassy clearings in forest.

Breeding. One nest in Aug. Nest was on large

horizontal limb of huge tree in forest; cradled in epiphytes c. 20 m above forest floor. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Generally uncommon and local; status very poorly known. Common in Dumoga-Bone National Park (N Sulawesi).

Bibliography. Amadon (1953), Andrew (1992), van Bemmelen & Voous (1951), Bishop *et al.* (1994), Brown, L.H. (1976b), Brown & Amadon (1968), Stresemann (1940a), White & Bruce (1986).

232. Philippine Hawk-eagle

Spizaetus philippensis

French: Aigle des Philippines **German:** Philippinenadler **Spanish:** Aguila-azor Filipina

Taxonomy. *Spizaetus philippensis* Gould, 1863, Philippines.

Forms superspecies with *S. nipalensis*, *S. alboniger*, *S. bartelsi* and *S. lanceolatus*. Monotypic.

Distribution. Philippine Is.

Descriptive notes. 64-69 cm; 1168 g (1 bird). Typical hawk-eagle with long crest. Somewhat similar in plumage to smaller sympatric *Pernis celebensis*. Juvenile has pale head, as is typical for genus; also pale underparts, with some barring on belly and flanks.

Habitat. Forest in lowlands and foothills.

Food and Feeding. No information available. Presumably similar to other members of genus, taking large birds and some mammals.

Breeding. No information available.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-

threatened. Generally considered to be uncommon, but may be commoner than thought, with few reports because of retiring habits and dearth of ornithological research. Overall status very poorly known; fairly common at Mt Katanglad (N Mindanao).

Bibliography. Amadon (1953), Brown, L.H. (1976b), Brown & Amadon (1968), Dickinson *et al.* (1991), DuPont (1971), Ferguson-Lees & Faull (1992), Gilliard (1950), McGregor (1909-1910), Parkes (1970), Rand & Rabor (1960).

233. Wallace's Hawk-eagle

Spizaetus nanus

French: Aigle de Wallace **German:** Dschungeladler **Spanish:** Aguila-azor de Wallace
Other common names: Small Hawk-eagle

Taxonomy. *Spizaetus nanus* Wallace, 1868, Sarawak.

Long considered synonymous with *S. alboniger*, due to confusion with immature plumages of latter. Two subspecies recognized.

Subspecies and Distribution.

S. n. nanus Wallace, 1868 - S Burma (Tennasserim) and S Thailand through Malay Peninsula to Sumatra and Borneo.

S. n. stresemanni Amadon, 1953 - Nias I (off W Sumatra).

Descriptive notes. 43-58 cm; 500-610 g. Small, typical hawk-eagle with crest. Adult similar in plumage to subadult of sympatric *S. alboniger*; but present species smaller and paler, with more pale bands in tail. Juvenile likewise very similar to that of *S. alboniger*, with buffy head and underparts. Adult of race *stresemanni* as nominate, but juvenile has head and underparts white.

Food and Feeding. Prey includes birds, bats, lizards and skinks. Hunting methods not recorded, but probably similar to those of congeners.

Breeding. Only nest known contained large chick in Feb. Nest was c. 35 m up, in lowest

fork of huge tree in forest.

Movements. Apparently sedentary.

Status and Conservation. RARE. CITES II. Uncommon to rare. Increasingly threatened by loss of lowland rain forest throughout range; rarely seen, but may be commoner than hitherto suspected. Race *stresemanni* of Nias I currently reckoned to be endangered.

Bibliography. Amadon (1953, 1982a), Brown, L.H. (1976b), Brown & Amadon (1968), Collar & Andrew (1988), Deignan (1963), Humphrey & Bain (1990), King *et al.* (1975), Lekagul & Round (1991), van Marle & Voous (1988), Medway & Wells (1976), Smythies (1981, 1986), Stresemann (1938), Wells (1985).

234. Black Hawk-eagle

Spizaetus tyrannus

French: Aigle tyran **German:** Tyrannenadler **Spanish:** Aguila-azor Negra

Taxonomy. *Falco tyrannus* Wied, 1820, Bahia, Brazil.

Like *S. ornatus*, not clearly related to Old World species of the genus. Two subspecies recognized.

Subspecies and Distribution.

S. t. serus Friedmann, 1950 - C Mexico S to Colombia, whence E of Andes to the Guianas, Trinidad and Brazil, and S to Paraguay and NE Argentina; recent records W of Andes in Ecuador and Peru (but not Colombia).

S. t. tyrannus (Wied, 1820) - E & S Brazil and extreme NE Argentina (Misiones).

Descriptive notes. 58-71 cm; male c. 950 g, female 1120 g; wingspan 140 cm. Glossy black overall; rather bushy occipital crest has feathers basally white; very broad wings; long, rounded tail with brownish grey tip and three broad grey bands; thighs, feathered tarsi, undertail- and underwing-coverts narrowly barred white. Iris bright orange, cere slate, feet yellow. Female similar to male, but larger. Juvenile unique in genus: has throat, forehead, supercilium and tips of crest feathers white, head mixed white and buff; browner above than adult; breast streaked brown and black, belly mottled blackish and white. Race *serus* smaller and less

heavily marked on underwing-coverts; flanks, thighs and legs with more distinct white barring.

Habitat. Tropical forests, generally in lowlands, but up to 2000 m, and even to 3000 m in Guatemala. Prefers semi-open habitat, second growth forest, forest edge or vicinity of rivers, but also occurs in extensive forests. While purportedly prefers more open forest than *S. ornatus*, occurs in dense forest both at Tikal National Park (Guatemala) and in forests N of Manaus (NC Brazil); present species recorded more frequently than *S. ornatus*, possibly reflecting a preference for more open, disturbed habitats, but perhaps related with more frequent and higher soaring.

Food and Feeding. Birds, mammals, iguanas and snakes. Mammals mostly arboreal, e.g. squirrels, small monkeys and bats, and nocturnal marsupials, which are delivered in broad daylight. In Yucatán (SE Mexico), toucans and araçaris (Ramphastidae) made up over 50% of prey items; all birds 82% of prey, rest being small to medium-sized mammals. In Belize reported to feed more heavily on small mammals. In the Petén (Guatemala), mammals made up 96% of identified prey items, with bats 31% of recorded prey items. Apparently takes most of prey by perch-hunting; regularly soars high.

Breeding. In Panama, chicks recorded in Feb, feathered young in Jul, fledglings in Aug. Stick nest c. 110 cm wide; one placed 17 m up a 23 m mahogany tree in Yucatán; in crown of royal palm (*Roystonea*) in Panama; in the Petén, nests in tall trees, supported by dense tangles of vines, rather than crotch of large branch. Fresh boughs delivered to nest during nesting period. Courtship entails display flight with contact and roll-overs; in Petén, birds quiet around nest, not vociferous as reported elsewhere. 1 egg. At one nest in Petén: hatching in May (late dry season); female abandoned nest 63 days later, leaving male to provision the young for remaining of nestling and fledgling dependency periods; fledgling 71 days. Young probably have long dependency period, permitting adults to nest only every third year, as in *S. ornatus* and other large tropical forest raptors. Normally, both parents feed the young.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Fairly common in suitable habitat, but not in areas that have been heavily disturbed by agriculture. Locally fairly common in Colombia. Declining in Mexico, due to habitat loss caused by cattle ranching, the timber industry and tourism.

Bibliography. Amadon (1982a), Belton (1984), Blake (1977), Cheber (1989), Clinton-Elliott (1986), Funes *et al.* (1992), Gail & Brown (1986), *Mexico de Schmittsen & Pielou* (1978), Moine (1968), Ornat *et al.* (1989), Ortiz (1986), de la Peña (1992), Pinto (1964), Rangel-Salazar & Enriquez-Rocha (1993), Ridgely (1980), Ridgely & Gwynne (1989), Robbins & Ridgely (1990), Ruschi (1979), Russell (1964), Sick (1985a, 1993), Slud (1964), Smith

(1970), Süles & Skutch (1989), Terborgh (1983), Terborgh & Weske (1975), Thiollay (1985a, 1989a, 1989b, 1989), Wetmore (1965), Wiedenfeld *et al.* (1985).

235. Ornate Hawk-eagle

Spizaetus ornatus

French: Aigle orné

German: Prachtadler

Spanish: Aguila-azor Galana

Taxonomy. *Falco ornatus* Daudin, 1800, Cayenne.

As with *S. tyrannus*, relationship to Old World species of genus unclear. Two subspecies recognized.

Subspecies and Distribution.

S. o. vicarius Friedmann, 1935 - SE Mexico through Central America to W Colombia and W Ecuador.
S. o. ornatus (Daudin, 1800) - E Colombia E to the Guianas and Trinidad, and S through E Ecuador, NE Peru, N & E Bolivia and Brazil to Paraguay and N Argentina (Jujuy to Misiones).

Descriptive notes. 58-67 cm; male c. 1000 g, female c. 1450 g. A large, powerful, strikingly coloured hawk-eagle: black crown and occipital crest set off by chestnut on sides of head and hindneck, extending to sides of breast; otherwise white below, boldly barred black below breast; tarsi feathered; above blackish; tail has three greyish brown bars. Iris orange, cere and legs yellow. Much larger than very similarly plumaged immature of *Accipiter poliogaster*. Female similar to male, but larger. Immature extensively white below, recalling adult and immature of *Spizastur melanoleucus*, but lacks black mask and has more black on

flanks and underwings; iris pale yellow; progression to adult plumage gradual, apparently taking more than one year; occipital crest becomes black, and black barring on flanks and thighs becomes more prominent. Race *vicarius* much brighter and deeper chestnut on head and neck.

Habitat. Humid forest in tropical and subtropical zones, in Colombia usually up to 1200 m, but occasionally up to 1800 m; elsewhere reported rarely up to 3000 m. Inhabits denser, more extensive tracts of primary forest than *S. tyrannus*. Sometimes near open areas in *llanos* of Venezuela; in the Petén (Guatemala), occurs in low swamp forest, as well as high primary forest. Nest trees often at forest ecotones, frequently close to base of low hills, or near area of low trees or agricultural clearings. Frequently soars over nesting territory.

Food and Feeding. A powerful raptor that mainly hunts large prey: especially birds, including macaws, parrots, toucans, pigeons, cocks-of-the-rock, cracids (*Penelope*, *Crax rubra*), tinamous, Little Blue Heron (*Egretta caerulea*) and chickens; mammals, including kinkajou, agoutis, squirrels, rats and 1 bat; occasionally reptiles, e.g. iguanids, teids, snakes; one seen feeding on American Black Vulture (*Coragyps atratus*) which it had presumably killed, at a monkey carcass. In Petén, 55% of prey items were birds, 31% mammals, and 14% unidentified vertebrates. Agoutis were an important part of the food delivered to a nest in Manaus, Brazil. One male delivered mostly squirrels to nest; females take larger prey; avian prey weighs 160-3800 g. No reports of monkeys as prey, but recorded attacking troops of small monkeys. Usually hunts from perch in middle storey, often along forest edge, but also in forest itself; moves about inconspicuously from perch to perch. Prey caught on ground or in trees; sometimes stoops on prey in canopy.

Breeding. In Petén (Guatemala), rather extended season, with laying in Jan-May (dry season); fledging at beginning of rainy season in Panama; in Manaus, NC Brazil, copulation in June, laying in Aug (peak dry season). Stick nest 100-125 cm wide, in tall tree, e.g. silk cottonwood (*Ceciba penandra*); often on large lateral branch some metres from main trunk of tree; often somewhat isolated from other tall trees, with easy access for adults to the nest but reduced access to nest for potential terrestrial predators; one pair usurped nest of *Buteogallus urubitinga*. Courtship begins a month or two before egg-laying. Flight display entails calling and diving c. 10 m with folded wings, and pitching back up from bottom of dive. 1 egg; incubation c. 48 days, almost entirely by female; fledging 66-93 days; young remain near nest, being fed by adult (usually the male), for up to 1 year after fledging. Adults can probably breed only every third year, when successful. Female aggressively defends 50 m around nest from other birds and mammals (coati, tayras). Male rarely delivers food to nest, transferring it to female c. 100 m from nest; does not feed young, but will incubate while female feeds. Female begins hunting when young c. 3 weeks old, initiating attacks from nest tree itself (one captured a coati 15 m from the nest), but hunting actively farther from nest only late in nestling period. Female ignores young after fledging, expanding home range, from c. 640 ha prior to laying, to 1970 ha after fledging, moving 5-6 km from nest; male stays closer, usually c. 1 km from nest, but expands home range to 1090 ha, when young fledged.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Relatively common, although apparently outnumbered by *S. tyrannus*, where the two co-exist. Has decreased at S limit of range in Argentina, and in areas of heavy deforestation in S Brazil; very few records from W Ecuador. Average density of at least c. 13 individuals/10,000 ha estimated at one forest site in French Guiana; in Petén, density estimated at 1 nest/787 ha.

Genus STEPHANOAEETUS W. L. Sclater, 1922

236. Crowned Hawk-eagle

Stephanoaetus coronatus

French: Aigle couronné

German: Kronenadler

Spanish: Aguila Coronada

Other common names: (African) Crowned Eagle(!)

Taxonomy. *Falco coronatus* Linnaeus, 1766, coast of Guinea.

Monotypic genus; sometimes merged with *Spizaetus*, but skeletal anatomy recalls *Harpia*. Monotypic.

Distribution. Senegambia E to S Kenya and C Ethiopia, and S to Angola, NE Botswana and E South Africa.

Descriptive notes. 80-99 cm; male 2700-4120 g, female 3175-3853 g; wingspan of male 163 cm, female 180 cm. Long tail and short, rounded wings like a giant goshawk. Small face and voluminous crest notable at all ages. Female larger, more heavily marked below, with one less black wingbar than male. Juvenile similar grey and white to that of *Polemaetus bellicosus*, but different proportions and habitat, and rufous wash below.

Habitat. Forest and dense woodland, from extensive lowland rain forest to small patches of montane and riverine forest, and even stands of mature exotic plantations. When foraging,

moves into surrounding secondary forest or dry savanna where necessary.

Food and Feeding. Mainly mammals, especially monkeys and small antelopes in lowland rain forest, or hyraxes and viverrids in drier forests. Will also take other vertebrates such as pangolins, porcupines, squirrels, gamebirds, pigeons and large lizards; rarely small livestock or carrion. An extremely powerful eagle, dropping onto prey from a perch or stooping from soaring flight. Mates may combine in various aerial attack strategies and usually share prey. Often kills prey in excess of own body weight; large prey, up to 20 kg, is dismembered and the pieces cached in tree forks. Adults, but not juveniles with white plumage, are taunted and threatened by monkeys.

Breeding. Laying Oct-Dec in W Africa and Zaire; all months in Gabon and E Africa (peak Jun-Aug); Feb-Nov in S Africa. Each pair may have own preferred laying cycle. Performs a regular aerial display with loud calling high above territory. Builds a massive structure of sticks lined with sprays of green leaves, in the main fork of a large forest tree; often used over many years. Usually 2 eggs (1-2); incubation 49-51 days; chick has white down; elder chick always kills younger sibling within a few days of hatching; fledging 90-115 days; post-fledging dependence 90-350 days, so may only breed in alternate years in some areas.

Movements. Resident and sedentary.

Status and Conservation. Not globally threatened. CITES II. Common and widespread within extensive lowland forest habitats of W and E Africa; 1 pair/20 km on river transects; small home range of 10 km²; and nests 2.5-12 km apart. Common in other forest types, but habitat often patchy, as in Kenya, Malawi or South Africa (only 100 pairs estimated for Transvaal). Vulnerable to deforestation and overhunting of prey animals, so now rare in many parts of W Africa. Persecuted in some areas of S Africa for small-stock losses. Not known to be affected by pesticides.

Bibliography. Bataamba (1989), Benson & Benson (1975), Brosset & Erard (1986), Brown, L.H. (1952, 1953, 1955, 1966, 1971, 1972b, 1976b, 1982), Brown, L.H. *et al.* (1978, 1982), Ginn *et al.* (1989), Grimes (1987), Holdaway (1994), Jarvis *et al.* (1980), Leland & MacLachy (1937), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Msuya (1993), Pickford *et al.* (1989), Pinto (1983), Steyn (1982), Struhsaker & Leakey (1990), Tarboton & Allan (1984), Thiollay (1978c, 1985d), Thomsett (1988), Tuer & Tuer (1974), Vernon (1984).

Genus OROAETUS Ridgway, 1920

237. Black-and-chestnut Eagle

Oroaetus isidori

French: Aigle d'Isidore

German: Isidoradler

Spanish: Aguila Poma

Other common names: Isidor's Eagle

Taxonomy. *Falco Isidori* Des Murs, 1845, Santa Fé de Bogotá, Colombia.

Monotypic genus closely related to *Spizaetus*, in which sometimes included. Monotypic.

Distribution. Coastal ranges of NW Venezuela (Carabobo) and NE Colombia (Santa Marta Mts), and S on subtropical slopes of Andes from Venezuela (Mérida) through Colombia, Ecuador and Peru to WC Bolivia and (formerly?) NW Argentina.

Descriptive notes. 60-80 cm, wingspan c. 175 cm. Large, stocky eagle with relatively short tail. Head, crest, neck and upperparts black, below chestnut streaked with black; thighs black, feathered tarsi chestnut; tail greyish, with thick black subterminal band; underside of primaries whitish with black tips, contrasting sharply with chestnut secondaries and underwing-coverts. Crest seems to be erected when "relaxed"; held erect even in flight, and lowered in stressful situations. Female similar to male, but significantly larger. Iris orange-yellow, cere yellowish horn, feet yellow. Immature fuscous brown above; head, neck and

underparts white; tail with two visible blackish bands above broader subterminal band; hindneck and mantle streaked dusky, crest tipped black. Gradual transition to adult plumage, with progressive darkening over four years; underparts become streaked with chestnut and dusky brown; iris blue-grey in juvenile, becoming yellowish in older immature birds.

Habitat. Heavily forested mountain slopes in subtropical zone, probably occurring mostly in large valleys; usually at 1500-2800 m, but recorded from sea-level up to 3500 m.

Food and Feeding. Large birds (e.g. guans) and arboreal mammals, from squirrels (frequently delivered to young) to monkeys (*Lagothrix*). Powerful legs and talons specialized for taking large prey. Hunts primarily in the canopy; soars frequently and is rarely seen perched.

Breeding. Few nests found. In Venezuela, nest building Feb-Mar, hatching May, fledging probably Aug; in Bolivia, nesting in Aug. Very large stick nest, up to 2 m wide; built in emergent tree, or in tree on side of ravine; in Venezuela, prefers oaks, and perhaps east-facing valley slopes; greenery brought to nest from time to time. Probably only 1 egg; chick has white down; fledging estimated at 4 months. Male provides most of food until young well developed; noisily announces arrival at nest; will feed young if female away from nest.

Movements. Presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Rare and patchily distributed; status very poorly known. Probably susceptible to loss of continuous forest habitat; observed in some partially logged tracts of forest, but perhaps as direct result of loss of extensive primary forest in subtropical zone. No records in NW Argentina since 1957.

Bibliography. Amadon (1950), Blake (1977), Eijlsd & Krabbe (1990), Hilty & Brown (1986), Lehman (1959), Meyer de Schauensee & Phelps (1978), Olog (1985), Parker *et al.* (1992), de la Peña (1992), Thiollay (1991a).

Class AVES

Order FALCONIFORMES

Suborder SAGITTARII

Family SAGITTARIIDAE (SECRETARYBIRD)

- Large raptorial birds with hooked bill, long stork-like legs, loose crest of long feathers and long central tail feathers.
- 125-150 cm.

- Afrotropical Region.
- Woodland, savanna and steppe.
- 1 genus, 1 species, 1 taxon.
- No species threatened; none extinct since 1600.

Systematics

The Secretarybird (*Sagittarius serpentarius*) has always been placed in its own monospecific family, usually in its own suborder, Sagittarii, and sometimes even elevated to the rank of its own order, Sagittariiformes. It has usually been placed adjacent to other diurnal birds of prey in the order Falconiformes and family Accipitridae, although relationships with seriernas (Cariamidae), bustards (Otididae) or cranes (Gruidae) in the order Gruiformes have also been proposed.

It has a number of distinctive anatomical features, especially in the skeleton and musculature of the skull, legs and toes, which preclude its inclusion in any other families of diurnal birds of prey. Its karyotype is also quite different from other birds of prey and certainly not like the distinct arrangement of the Accipitridae, nor is it like that of the seriernas. Superficially, the Secretarybird appears and acts like a "long-legged marching" or "pedestrian" eagle, and indeed with eagles it shares similar anatomy of the skull and head, except for the long upper eyelashes, while it also has related feather lice. However, aspects of its breeding habits are most similar to those of storks in the order Ciconiiformes and it is notable that recent anatomical interpretations, comparisons of behaviour and studies of DNA-DNA hybridization indicate a close affinity between storks and birds of prey.

The family is now confined to Africa, but fossil remains of two other species in the genus *Pelargopappus*, with a stork-like and relatively shorter tarsometatarsus, exist from the Middle and Upper Oligocene and early Miocene of France. A smaller true hawk (Accipitridae) of convergent leg morphology has also been described from the Miocene of North America.

Morphological Aspects

The Secretarybird stands about 1.2 m tall, and its most notable features are the long legs, the elongated, spatulate nape feathers and the long central tail feathers. The legs and elongated central tail feathers extend well behind the bird in flight and the neck is also extended, like a stork. When the bird is on the ground, the crest feathers form a distinctive coronet if raised or lie along the nape like a ponytail.

The head is decidedly aquiline, with its hooked blue-grey bill, the yellow cere around the elongate, vertical, oval nostrils,

the bright orange bare facial skin and the long crest. The neck is not especially long, and the bill can only reach to the intertarsal joint, which means that the bird must stoop or kneel to pick up any object from the ground or to drink. However, the gape is wide, allowing large food items to be swallowed whole, so that only very large prey or morsels for the chicks need be torn apart with the bill while being held down with the feet, in the style of an eagle, though often more clumsily.

The long legs are clothed in black feathered breeches down to the intertarsal or "knee" joint. The bare tarsus and feet are a deep pink, with heavy scaling, especially down the front, which may protect them when walking or attacking prey. Animals of whatever size are disabled by being kicked with the stout toes and short curved claws, but the feet lack any significant grasping ability. The three anterior toes are interconnected by a strong web at the base, and the inner and

The long, broad wings of the Secretarybird render it capable of efficient soaring flight, although it actually moves about most of the time on foot. Its flight silhouette is quite distinctive, with the long legs and greatly elongated central tail feathers projecting beyond the rest of the tail, the long neck, and the contrast between the gray body plumage and the black flight-feathers.

The Secretarybird spends much of the day walking about over grassland or bare ground in search of food. Rain does not necessarily put a halt to this activity, although during particularly wet spells, when the grass is soaked, birds tend to spend more time at their roosting sites and commence their foraging activity later in the day. The length of the grass is decisive in terms of suitable feeding habitat, for birds tend to avoid areas where it grows one metre tall or more, as this prevents them from moving about comfortably and easily.

Martínez]

outer toes are equally developed, possibly to increase the strike area of the foot, whereas the hind toe is much smaller, probably to improve the stride.

The toes are about one fifth, and the legs about three times, the length of those of an eagle of equivalent body size. The length of the legs, aided by balance and lift from the opened wings, allows considerable speed, dexterity and manoeuvrability when attacking prey. The head is kept well clear until the prey is immobilized, whereafter the bird stoops to pick up the food in the bill. Only small or harmless prey may be picked up directly and despatched with the bill.

On average the wings span 2.12 m. They are broad and are used mainly in soaring flight, with the upturned primary feathers held well apart to provide deep slotting for control of turbulence. Flapping flight is heavy, slow, and can not be maintained for long without assistance from some form of rising air, which means that under certain conditions birds may be chased to exhaustion. However, once aloft, they are capable of performing spectacular display or attack flights with great agility and speed.

The plumage is pale grey above, offset by the white upper-tail-coverts, and white below, with the black abdomen and thighs standing out. The primary, secondary and tertial flight-feathers in the wing are also black, looking like coat-tails when folded, and in flight contrasting with the grey upperwing- and white underwing-coverts. The tail feathers are marbled at the base with black and grey, have a broad black sub-terminal band

and end in a white tip. The five outer feathers on each side are graduated in size, but the long central pair still project some 20 cm past the longest of them. The long crest feathers are black, and when folded form a dark patch down the back of the neck.

The sexes are identical, except that males probably average slightly smaller than females, and are a bluer shade of grey. They tend to have a longer tail, a shorter, more rounded head, with slightly less bare facial skin, and more crest feathers, some of which may be grey. Immature birds are similar to adults but can be distinguished by the paler orange colour of the facial skin, the black, as opposed to pale blue-grey, bill and the fine grey barring on the underwing- and undertail-coverts. The eye is dark brown in young chicks, pale grey in juveniles and subsequently hazel brown in adults. Juveniles fledge in either grey or grey-brown plumage, and young females probably have the grey areas of the flight-feathers and coverts tipped with brown.

Habitat

It is only the areas of forest and dense woodland within sub-Saharan Africa that are not utilized by Secretarybirds. They occur in all types of grassland and savanna, from the driest steppes bordering the Namib and Sahara Deserts to the high moist grasslands of South Africa and Ethiopia. They are most

common in areas of short open grassland with scattered low thorn trees, especially in eastern and southern Africa, habitats which also support the abundance of arthropods and other small animals that form the bulk of their diet. However, food supplies fluctuate in many parts of their range during alternating periods of drought and rainfall, making them nomadic over much of their range, but resulting in their abundance in a variety of habitats over time.

Secretarybirds generally avoid patches of dense bushes and trees, due to the problem of taking off in such confined places. However, if pressed, they can take to the air in a single bound, rather than running the few initial steps as they prefer, and they can use this technique to clear the livestock fences that now span their habitat in many areas. They also avoid hilly and rocky areas, or areas of dense, tangled grass, over which they have trouble walking with their long stilt-like legs.

Within their home range they require at least one tree with a flat and robust canopy, on top of which they can roost and build their nest, although they will occasionally roost and breed on the ground. Normally, they prefer a low thorny *Acacia* tree, and the flat tops of many African species provide ideal platforms, but when necessary their choice may range from a low bush to the top of a tall introduced pine or indigenous forest tree, at heights of 1.8-36 m. Ideally, their territory will include several suitable trees that can provide alternate roost- and nest-sites. Although one site may be used for many years, the large nests tend to tilt or collapse into the crown with time, and in most cases a new nest-site is used each year, where feasible.

General Habits

Secretarybirds are usually encountered in pairs, the birds walking some distance apart across the savanna and hunting independently for any prey they may find or flush. They do not seem to wander independently through their territory, except when one bird is confined to the nest, and part of their daily movements may involve patrolling the area against neighbours and other intruders.

Single birds are mostly found in less suitable areas and apparently are usually adult males, occupying territories until conditions improve sufficiently for them to attract potential mates to the area. Young birds of both sexes also roam widely before maturity and often turn up in areas unoccupied by resident adults, such as fields within woodland or around airports. In such unfamiliar and marginal habitat they seem more prone to accidents, including predation or collisions with wires and vehicles; on top of this, they are regularly evicted from occupied areas by resident adults. Rarely, as many as 50 birds may gather in an area with special resources, for instance during plagues of locusts or rodents, around a pool of water in more arid environments, or where insects are flushed before a bush

fire. It is not known if these concentrations comprise breeding residents or non-breeding nomads.

Pairs may spend an hour or more at their roosts after first light, preening and warming in the sun, or descend to do the same on the ground nearby. Hunting then starts in earnest and may continue for much of the rest of the day, during which a distance of up to 20 km may be walked, the head nodding to and fro with each step. Occasional breaks are taken to preen, rest in the shade or squat down on the "knees". Sometimes birds even lie down, to sleep, to dust-bathe or to stretch out in the sun with the wings wide open. Where available, they may even seek out water to bathe or drink.

Secretarybirds usually take off and land with considerable grace, running a few paces with the wings outstretched when not airborne, but they can also run, jump and leap into the air with great agility. They often take to the wing in the middle of the day, to take advantage of thermals to cool off or soar from one area to another, rising as high as 3800 m over their territory. Soaring may also stimulate neighbours to take off, besides giving a good overview of the area, and encounters with intruders often lead to territorial disputes, involving either aerial pendulum displays (see Breeding) or pursuits that end on the ground with several birds involved in energetic bouts of leaping, kicking, running and chasing. Such encounters may be mistaken for courtship dances and are also shown as play behaviour between recently fledged chicks.

In the late afternoon, pairs make their way back to the roost area and fly up onto the roost tree at dusk. They sleep crouched down on the canopy or on an old nest, usually with the head tucked back under the wing.

A territory may extend over 20 km² in mixed tree and grass savanna, 45 km² on dry grassland, or 70 km² on montane grassland within South Africa. Densities of 50 km²/pair have been reported for parts of the Transvaal and Zimbabwe, but densities may be as low as 100-500 km²/pair during years of low rainfall or in more arid areas of the continent.

Voice

Secretarybirds are generally silent, except when aggressively proclaiming their presence. The main call is a deep guttural croak that becomes a loud roaring groan at high intensity, sometimes uttered with the head thrown back. It is uttered in flight during pendulum displays, on the ground during fights and at the nest by mates during bowing greeting displays, or by large chicks in response to a predator.

A single high croak indicates alarm, while deeper croaks are used in threat. Softer clucking calls and low whistles are also given by mates at the nest. Small chicks beg with soft cheeping calls that become insistent clucking, mewling, squealing and then braying notes, as the birds become older and hungrier, and calling can even continue at night.

Mobile prey, as in this case a grasshopper, is immobilized with the short, thick toes by means of powerful, well directed stamps. Because the bird's neck is very short in comparison with its lanky legs, it must then bend forward, flexing its legs, in order to pick up the prey item in its bill.

[*Sagittarius serpentarius*.
Photos: Clem Haagner/
Ardea]

The Secretarybird's short toes, well adapted for walking long distances, are quite unsuited for grasping and carrying prey, so these actions must be performed with the bill. Prey varies considerably in size, ranging from fairly large insects to sizeable snakes and fully-grown hares, but even the largest prey items are normally swallowed whole. This bird has drawn the nictitating membrane, or third lid, over its eye, a practice that in many species seems to be linked with rapid head movements, for instance when the bird is manipulating prey. It is thought that the function might be to block out the blurred images caused by such movements.

Planet Earth]

Food and Feeding

The prey of Secretarybirds consists of any small animals that can be overcome by the fast hard kicks rained down with the long legs and stout toes. The same technique is applied across the whole size spectrum, from small moths to full-grown hares. The bulk of the diet by number is comprised of arthropods, in particular grasshoppers or locusts and sometimes large beetles, although small vertebrates often form the main biomass. The fast movements of rodents and lizards are no match for this dexterous hunting technique, which can also be used to surprise birds such as warblers, larks, doves and small hornbills. Larger prey and snakes are dispatched by blows directed mainly at the head, but there is no evidence of the wings being used in attacks other than for balance and lift.

The most rewarding kinds of prey are such large items as frogs, snakes, including poisonous adders and cobras, lizards, chameleons, gamebirds or plovers and their chicks, rats, shrews, hedgehogs, small felids, mongooses and meerkats. All but the largest prey is swallowed whole, including small tortoises and hares. Large prey may also be cached under a bush and collected later, especially when the birds are breeding. Careful searching also reveals birds' nests, the eggs or chicks of which are picked up and swallowed whole without any kicking, as is the case with other very small or immobile types of prey, such as termites or carrion found lying around after a fire. Even golf balls, lost in the rough, are also mistaken for eggs and swallowed at times. Rarely, prey such as wasps and their nests may be picked directly from vegetation with the bill.

Hunting birds appear to view only a fairly narrow field as they stalk across the veld, moving more slowly and deliberately the taller and denser the ground cover. They walk with a stride of about 40 cm, at about 120 paces/minute and an average of 3 km/h, but they sometimes accelerate or break into a run if

the presence of prey is suspected ahead. They may also stop to kick repeatedly at grass tufts or piles of dung in an attempt to flush prey. The long crest feathers are often raised during hunting, forming a halo around the bird's head that may assist in scaring out prey and shading the face. The exact stimuli for crest erection at other times are not consistent, for example during social encounters or changes in activity.

Indigestible food remains are regurgitated as large pellets, 40-45 mm in diameter and 30-100 mm long. These are often dropped on or in the vicinity of the roost and nest trees, but they may be cast at any time of day, even while the bird is incubating. Analysis of fragments and hair found in pellets is an important indicator of the prey taken. Pellets also often include quantities of grass or small stones, of uncertain dietary significance. Chicks begin to produce pellets from about one week of age, usually once a day in the early morning.

Encounters with other predators are rare except for piracy by Tawny Eagles (*Aquila rapax*), which may attack singly or in pairs. The eagles often steal larger prey from the Secretarybird, such as snakes or mongooses, although sometimes they are beaten off by combined attacks from a pair, or are even bettered and pinned down on the ground. A *Circaetus* snake-eagle was also seen to take a snake which a Secretarybird had dropped while in flight, but there are also questionable reports of Secretarybirds dropping snakes to kill them. One attacked a young Jackal Buzzard (*Buteo rufofuscus*) but was driven off and possibly mortally wounded by the parents.

Breeding

Much of the range of the Secretarybird experiences alternating wet and dry seasons, and chicks are most often reared during the wet season when the savanna is most productive of small animals. However, when food supplies are extended, during

In addition to the typical undulating aerial displays, courtship also includes displays on the ground. These consist of one bird chasing the other, twisting and turning, with its wings raised up over its back. A similar form of behaviour often occurs in territorial defence, with the defender often leaping at the intruder and kicking out at it. Such situations can develop into real kicking fights, and both members of the pair sometimes join in to repel an intruder.

seasons of above average rainfall, or when rodent or locust numbers are high, successive breeding attempts may occur, with intervals of as little as three weeks between broods. Hence egg-laying may be expected at any time of the year with chicks sometimes being raised well into the dry season. Furthermore, pairs in the same area may have different breeding schedules with some being regular and seasonal and others more erratic and aseasonal.

An increase in soaring and calling high above the nest area heralds the onset of breeding. One or both members of a pair may also perform pendulum displays for as long as 15 minutes, stalling and then swooping down with wings closed, only to swing up again and repeat the whole performance. Alternatively, they may swoop at one another and roll over to present the feet, even when one bird is on the ground near the nest.

Back to earth, usually in the morning after leaving the roost, the canopy of a tree is trampled flat, and then sticks and weed stems are collected in the bill before being carried to form the nest. This develops into a platform 1-2.5 m in diameter and 30-50 cm deep, and grass tufts, picked up or ripped out with the bill, form the main lining, together with some small sticks, wool, animal dung, leaves and other debris collected nearby. Both sexes build, although the male brings more material and the female spends more time arranging this on the nest.

Display, building and even sitting for extended periods may proceed at the nest-site for up to six months before egg-laying, if suitable conditions are delayed. The same site may be used in successive seasons but an alternative site may be used, especially since the bulky structure often either collapses in the centre or tilts to one side. Nests are sometimes taken over by other raptors such as Lappet-faced Vultures (*Torgos tracheliotus*) or Greater Kestrels (*Falco rupicoloides*). Copulation is

reported to take place on the ground or a tree, but it has not yet been described.

One to three eggs are laid, with two the most common clutch size; the eggs are smaller and more numerous than would be expected for a bird of prey of similar size. Both the eggs themselves and the clutch size are more like those found in storks, being chalky in texture, plain white or pale blue-green, rather pointed at one end and only rarely blotched or streaked with pale brown and rufous.

The parents usually share incubation, and later brooding of the chicks, one bird sitting on the nest while the other is away foraging. This may vary between pairs, since in some cases the male regurgitates food at the nest, whereupon the female eats this and then continues with the incubation. At the changeover, the returning bird usually picks up some lining as it approaches the nest, before flying on to it, at which point the sitting bird rises and usually performs a bowing display before departing, raising and lowering the head, in a manner similar to the "Up-down" display of many storks. The display, at highest intensity, includes the croaking call, fanning of the tail almost vertically above the back and exposure of the voluminous white undertail-coverts at each bow. It is performed most commonly during nest building and the early stages of incubation.

Incubating birds sit very tight, lying flat in the nest if approached, with only the long tail protruding over the nest rim, but if accosted, they sometimes stand and threaten with wings raised. Some chicks also threaten intruders by puffing out the neck, tossing back the head, opening the wings, croaking loudly and sometimes even throwing up their food.

The eggs measure 68-92 x 51-65 mm, with an average of 78 x 56 mm; they often become deeply stained during incubation. They hatch after a period of 42-46 days, having started to

pip about two days earlier. They are laid two to four days apart and retain that interval for hatching, since incubation begins with the first egg. The chick is covered in pale grey down at hatching, darkest on the dorsal surface and palest below. The head appears large, and the large brown eyes open within hours. The cere, gape and skin around the eyes are pale orange while the legs are pale grey. The bill is black with a pale orange tip and there is already a protuberance at the back of the head from which the crest feathers will sprout.

A second coat of pale grey down appears by the time the chick is about two weeks old, and at this stage the pale yellow facial skin is prominent. When it is about three weeks old the crest feathers appear, and by five weeks old the upperparts are largely feathered. The chick can stand at four to six weeks old, and by seven weeks old it is fully-feathered and starts flapping exercises. Thereafter, feather growth proceeds only in the flight-feathers and the tail, until the bird is ready for fledging.

A parent remains in attendance at the nest throughout the first two or three weeks after hatching, whereafter the chicks are able to thermoregulate and are left for extended periods during the day, but are still brooded at night and during bad weather. However, one parent usually remains in the nest area until the chicks are four to six weeks old, rushing to their defence if a falcon or crow passes nearby, but later on chicks are usually left alone, even at night, except for brief visits with food.

The parents take turns to feed the chicks. They return to the nest with the crop full of food, either after walking back to the nest or after descending from a high soar, which is the quickest and most economical way to return from the borders of the territory during the heat of the day. Rarely a large food item, such as a snake or a mongoose, is carried in the bill, although this renders the Secretarybird vulnerable to piratical attacks by Tawny Eagles, in areas where both species occur.

The first visit with food is usually in the late morning, followed by others at mid-afternoon and in the evening. This gives the parent several hours to find food for itself and then

fill its well developed crop before returning to the nest. Food may be brought at any time, depending on what is available and how close it is found to the nest, but usually only three to five feeds are delivered daily. Sometimes, later in the nestling period, both parents will return together with food.

The food is regurgitated onto the nest floor, from where the parents pick up or tear off scraps to feed small chicks. Within two or three weeks of hatching, the chicks are able to pick up and swallow some of their own food, and by six weeks old they gobble down most prey into their wide gapes, so that feeding visits become brief, but hectic, scrimmages of only two to five minutes. One adult, usually the female, may sometimes swallow food delivered by the other, which it later regurgitates to the chicks at intervals, or from which it produces some liquid. Tearing of prey by the chicks does not begin until they are about 40 days old, as they need to be able to stand and balance well on their long, rather brittle legs.

The adults also trickle a liquid, probably mainly water, directly into the chicks' bills. This may include partly digested food, which is possibly of some importance in the diet of small chicks, although even day-old chicks are fed directly on whole food items, and they may not receive liquid for days, yet they continue to receive fluid almost until fledging. The chicks take the parent's bill inside their own when drinking, swallow repeatedly, as shown by the pumping action of the tongue, and maintain a fast, steady patter with the lower mandible against the adult's bill, which may stimulate the release of fluid. This pattering with the bill may even lead to stork-like bill-clapping in hungry fledglings. Food has to be torn up while standing, but fluids may be dribbled to the chicks while the adult kneels in the nest.

Later in the nesting cycle, water is often specially drunk near the nest and dribbled into the chick's bill, especially on hot, dry and windy days. Sometimes the chicks refuse to feed until supplied with water and, if they have water readily available, hand-reared nestlings drink regularly. No observations at nests in waterless areas are documented. Some food items are

Both sexes take part in the building of the nest. The necessary sticks and stems are collected within the immediate vicinity of the nest, and are invariably transported in the bill, as the feet are useless for this purpose. The nest is typically sited on the top of a thorny tree, very often a dense, flat-topped Acacia. The sexes are very similar or perhaps even identical in terms of plumage, but there appears to be a slight degree of size dimorphism. Recent prolonged observations of several pairs at their nests suggest that, contrary to the traditional view, it is, in fact, the females that tend to average a little larger.

[*Sagittarius serpentarius*,
Etosha National Park,

Survival]

The Secretarybird's nest tends to be sited in a fairly low tree, and is usually only about three to seven metres above the ground. For security against predators, it appears that the height of the tree is less important than is the presence of a thick, impenetrable layer of thorns, which provides effective protection from below. However, this is not sufficient protection against human ingenuity, and birds can hardly ever breed successfully near areas of dense human population, where the nests are commonly disturbed and eventually destroyed by children. The species is normally found in open country, typically grassy plains, semi-arid savanna, Karoo scrub and sub-deserts; it also frequents open woodland, but avoids closed habitats, such as forest.

[*Sagittarius serpentarius*,
Masai Mara National
Park, Kenya.
Photo: Günter Ziesler]

Incubation lasts about 45 days and, as far as is known, is performed entirely by the female; during this period the male frequently brings food to her at the nest. This bird is panting, a mechanism that Secretarybirds use for keeping cool when they are exposed to high temperatures. The species may actually be rather sensitive to heat, which might explain its absence from certain hot lowland areas, which in other respects appear to be ideal for it. Note the characteristic brightly coloured bare facial skin, which tends to be slightly more extensive in females than in males.

repeatedly reswallowed and regurgitated by the parents during feeds, probably in order to clean the nest, nourish the parent or control the flow of liquid. The roles of the sexes, regurgitation of food and transport of water are all forms of behaviour that are more reminiscent of storks than of other birds of prey.

The nestling period is variable, even within the same brood, with a range of 65-106 days, but it usually lasts 75-85 days. Its duration probably depends on the food supply available and can end prematurely at 47-54 days, if a chick is blown off the nest when feeding or exercising. Often one or more of the younger chicks in a brood develops more slowly, or starves, even after surviving long into the nestling period, and on rare occasions even cannibalism of deceased chicks has been recorded. Well nourished chicks grow from about 56-83 g at hatching to the adult weight of about 2.3-4.3 kg by eight weeks old. Three chicks are rarely reared, and the third egg often fails to hatch and may even be carried some distance from the nest by the parents.

The fledgling remains in the nest area, being fed by the parents, either on the nest or while crouching on the ground nearby. It usually also returns to roost on or below the nest tree. It soon begins to practise kicking and hunting, and can even catch its first prey within a fortnight. However, it has first to learn to fly back onto the nest, walk without tripping all the time, avoid walking into thorns and fly over rather than squeeze through fences. After about four to eight weeks it joins its parents on feeding forays, until leaving the area and becoming independent a few weeks later. Some juveniles may still return to roost in the nest area three months after fledging, lying on the nest with the head tucked under the wing as they did when still chicks. The age at first breeding remains to be discovered.

Breeding frequency and success are highly variable. On one territory in natural habitat in Kenya, only one attempt was successful, with two chicks fledging, over a period of six years. In another area of Kenya, three out of five pairs bred one year,

but only fledged two chicks from one nest; the next year only one pair was present and this did not breed; and in the third year no pairs were present. On three territories on farmland in the Transvaal, South Africa, at least 14 chicks were fledged in 26 pair-years between 1974 and 1988. Most failures in each study were due to adult or nestling persecution. Crows, ravens, Verreaux's Eagle owls (*Bubo lacteus*) and Southern Ground-hornbills (*Bucorvus leadbeateri*) have all been implicated in predation of nestlings, but despite all this, broods of three chicks are sometimes raised. Adults have perished from collisions with motor vehicles, utility lines and aircraft, by being bitten on the wing by a poisonous snake, from eating poisoned carrion, by becoming entangled with large snakes, by being stoned on the nest and from infection with the protozoan *Trichomonas gallinae*.

Movements

No regular migratory movements are described. However, much of the range of the species experiences ephemeral conditions based on the timing, extent and quantity of rainfall, grazing and fires.

In the most stable habitats, pairs may reside on the same territory and breed regularly for many years in succession. In less mesic areas, pairs may form and breed for only a season or two and then be absent for several years. In the most arid areas, nomads may only stay for a brief temporary visit or for a single breeding attempt.

Relationship with Man

Traditionally, the Secretarybird has not been molested by African peoples. Its distinctive appearance is striking, and its

When the chicks are small, the adults feed them on a liquid diet that is thought to be composed mainly of partially digested insects. Often, as in this case, and especially in clutches of three, one of the eggs turns out to be infertile. In fact, there is no record of three chicks at a nest ever having been reared to fledging, and it is only rarely that two young are fledged, even though there is no aggression between siblings. This chick is clothed in its first coat of down, which can be white or pale grey; two weeks after hatching this will be replaced by a second coat of thicker, darker down.

[*Sagittarius serpentarius*, South Africa.
Photo: Ardea]

ability to deal with large poisonous snakes and other vermin has been admired by many peoples, including European settlers who introduced fines designed to encourage its protection. It is now protected by law in many African states, but at the same time traditional observances are declining and cases of interference are increasing, especially at roost- and nest-sites. Its preference for running to safety unless there is thermal lift to assist flight makes it vulnerable to hunters using packs of dogs or motor vehicles.

The common name was originally thought to refer to the long crest feathers which can appear like quill pens stuck behind the ear of a medieval scribe. However, a recent proposal suggests that it is a Francophone corruption of the Arabic *sagret-tair* or "hunter-bird".

The species adapts well to captivity and has been bred repeatedly by several avicultural institutions, since the last century. It is also reported to make good eating.

Status and Conservation

The Secretarybird is widespread and common over much of its range. Importantly, this is the case in a number of the larger game reserves and national parks. It is also common in many inhabited areas and under various agricultural regimes. In some areas of Kenya, it has even been found to be commoner around

cereal croplands, where rodents abound, than in adjacent livestock areas or game reserves where arthropods alone formed the bulk of the prey. Exotic trees planted on open grasslands have also provided suitable sites for nesting and roosting, where none existed previously.

However, it has also declined in some areas, as human population densities and nest interference increase, and as excess livestock lower the productivity of some savanna regions. Clearing of areas of dense bush, woodland and forest for agriculture may have opened up some new areas for occupation, but at the same time afforestation of grasslands has decreased habitat, especially in South Africa. However, the nomadic nature of the species makes it difficult to assess long term population trends in any given area.

The total population in Africa has never been estimated but is expected to be in the tens of thousands, with 1068 breeding pairs estimated for the 286,000 km² Transvaal Province of South Africa alone. Fluctuations in population size are expected, given the cyclical nature of the climate over much of its range, but the species must be considered capable of rapid recovery, given the large clutches, abbreviated nestling periods and propensity for raising multiple broods which it exhibits under ideal conditions. Such flexible and productive breeding biology is unusual for such a large bird of prey, but is ideally suited to the variable climate of the African savanna, and is similar to that of several African stork species.

Genus *SAGITTARIUS* Herman, 1783

Secretarybird

Sagittarius serpentarius

French: Messenger serpenteaire

German: Sekretär

Spanish: Secretario

Taxonomy. *Falco serpentarius* J. F. Miller 1779, Cape of Good Hope.

Shows most morphological, behavioural and molecular affinities with Falconiformes, especially Accipitridae. Also some behavioural affinities with Ciconiidae. Proposed relationships to Cariamidae and other Gruiformes unsubstantiated. Birds of W Africa have occasionally been awarded separate race, *gambiensis*. Monotypic.

Distribution. Senegambia E to Ethiopia and Somalia, and S to South Africa.

Descriptive notes. 125-150 cm; c. 2300-4270 g; wingspan 212 cm. Unmistakable, with long pink legs, long black crest feathers, bare orange face, hooked aquiline bill and long central tail feathers. Grey above, white below with black flight feathers, abdomen and thighs. Female probably slightly larger. Juvenile similar to adult with grey barring on white underwing- and undertail-coverts; also paler face; brown edges to grey dorsal feathers, especially in juvenile female. Eye changes from grey to brown and bill from black to blue-grey when adult.

Habitat. Steppe or tree and grass savanna, favouring short grass with scattered *Acacia* thorn trees to provide sites for roosting and nesting. Rarely visits clearings in woodland or forest.

Food and Feeding. Mostly arthropods, especially grasshoppers and beetles, but devours most small animals including frogs, lizards, tortoises, snakes, rodents, hedgehogs, mongooses, squirrels and hares. Usually kills prey by fast kicks with the long legs and stout toes, swallows it whole with the wide gape and only tears larger prey while holding it down with the inner toes. Usually hunts alone or with mate in close proximity.

Breeding. Nests at any time of year when food abundant, usually to fledge chicks in period of summer rainy season abundance. Territory of 25-45 km², each pair placing large nest platform of sticks and grass on top of low tree. Normally 2 eggs (1-3); incubation 42-46 days; chicks hatch in pale grey down with short straight bill, second dark grey down by 3 weeks, well feathered by 6 weeks; nestling period variable at 65-106 days. Only rarely 3 chicks raised, but pair may have successive broods with intervals of less than a month between them.

Movements. Sedentary with regular seasonal breeding in some areas, but nomadic in most areas in response to changes in rainfall, grazing and fires. Adult males usually last to forsake territories; juveniles wander widely in search of areas unoccupied by mated pairs. May enter and breed regularly in an area for several years and then be absent, or only prevent in much reduced numbers.

Status and Conservation. Not globally threatened, CITES II. Widespread and often locally common, both in protected natural areas and in various forms of extensive agriculture. Often protected in recognition of snake and rodent killing abilities, but sometimes persecuted at low accessible nest-sites. Afforestation of grasslands and intensive land use have eliminated habitat, with some compensation where bush has been cleared for grazing or croplands. No total population estimates but over 1000 breeding pairs thought to occur in Transvaal Province of South Africa alone. Protected under CITES, due to pressure of live animal trade. Has been bred several times in captivity.

Class AVES

Order FALCONIFORMES

Suborder FALCONES

Family FALCONIDAE (FALCONS AND CARACARAS)

- Small to medium-sized predatory birds with hooked bill and usually raptorial talons.
- 14-65 cm.

- All regions except Antarctic.
- All habitats, from tundra to desert to tropical forest.
- 10 genera, 61 species, 149 taxa.
- 5 species threatened; 1 subspecies extinct since 1600.

Systematics

On first inspection, the 59-63 species of Falconidae do not appear to be a well defined family, because of their great diversity of lifestyles. They range from long-winged falcons (*Falco*) of open country to scavenging, ground-dwelling caracaras (*Polyborus*) reminiscent of vultures; from arboreal, almost chicken-like caracaras (*Daptrius*) to forest-falcons (*Micrastur*) of tropical forests that resemble true hawks (*Accipiter*) with their short wings; and tiny falconets (*Microhierax*), which are only the size of a thrush or even a finch. They are, however, all united taxonomically by at least six or more distinctive morphological characteristics, including, for example, a characteristic flight-feather moult pattern (starting with primary 4), a bony tubercle developed to one degree or another in the nostril (except in forest-falcons), the same *Mallophaga* feather lice, and eggshells of the same chemical composition. In addition, except in the case of the pygmy-falcons that have white eggs, their eggs are all blotched and spotted reddish brown, and, rather than the greenish internal tint of accipitrid eggs, the shells have a reddish yellow translucence.

Since the time of Linnaeus, the Falconidae have generally been placed alongside the other diurnal raptors, including hawks, eagles, kites and other groups now included in the order Falconiformes. This approach has been supported by diverse pieces of evidence from traditional studies of external morphology, internal anatomy, behaviour, feather parasites, and moult patterns, as well as more recent molecular evidence based on comparisons of feather proteins, allozymes and DNA. However, M. Jollie made detailed studies of the morphology of families traditionally included in Falconiformes, and he concluded that the order is polyphyletic. Reviving an old notion, he suggested that falconids were not related to accipitrids, but were actually closer to owls, parrots, cuckoos and plantain-eaters. Most modern authorities, however, regard the shared features of falcons and owls to be convergent, and virtually all recent comprehensive avian family classifications have retained the place of Falconidae within the order Falconiformes.

On very fragmentary evidence, a tiny fossil, smaller than contemporary falconets (*Microhierax*), was reported as a new genus of falconid from the lower Eocene of England, about 55 million years ago. The first well documented falconids, however, were described from the Eo-Oligocene in France, and date to about 36 million years ago. From North and South America

the group shows up in the Miocene, about 23 million years ago. Such early representatives included *Badiostes*, a group with characteristics of caracaras, and early examples of the contemporary genus *Falco*. Several other extinct genera and species have been described. While not extensive, the family has a fossil history as old as divers (loons) and tinamous, which are generally regarded as more "primitive" groups.

There are no good clues to indicate where the family might have originated geographically. Because of their molecular traits, the contemporary species of falcons (*Falco*) are thought to have had a rather recent, explosive and rapid radiation, probably in the late Pliocene and Pleistocene, and all are closely related. At least 20 living falconid species are known from the Pleistocene, which lasted from approximately 1.85 million to 10,000 years ago. The fossil record does not contain contemporary species back beyond about 2 million years. Nor does

Subdivision of the
Falconidae.

[Figure: Ian Willis &
Hilary Burn]

the existing record provide evidence for contemporary species being united in some fashion as Gondwanan groups, although the basic stocks that gave rise to subfamilies, clades and genera certainly could have been Gondwanan.

Most of the diversity within the family is concentrated in the Neotropics among genera of caracaras, forest-falcons, the Laughing Falcon (*Herpetotheres cachinnans*), the Spot-winged Falconet (*Spizapteryx circumcinctus*) and the true falcons; here are found eight of the ten falconid genera, with seven of them endemic. Of the 39 or so species of *Falco*, 17 breed in Africa and associated islands, with ten of these endemic, while another six boreal species winter there. Of the aforementioned 17 species, 10 are kestrels (comprising 76% of all kestrel species), and these include the species that are thought to be the most primitive kestrels. Thus, Africa and its satellite islands form a centre of diversity for the kestrels and perhaps for the entire genus *Falco*.

Concerning the systematics of the family, there are four main issues that dominate discussions and investigation: how many subfamilies should be recognized within the family, and the composition of each of these; the relationships between the various different genera, and how these relationships should be reflected in a linear sequence; how many species there are, and the relationships of the different species within various genera; and, finally, what name should be used for particular species or genera. In themselves, names are, of course, not of great importance, but the information they convey suggests evolutionary and systematic relationships.

At the subfamily level, two, three or four groups are variously identified. Most modern classifications (as here) recognize two subfamilies, with the falcons and falconets forming a single subfamily, although the Spot-winged Falconet is sometimes placed in the other subfamily, alongside the caracaras. A typical treatment with three subfamilies has the caracaras

in one subfamily, the Laughing Falcon and the forest-falcons together in another, and all other species in a third subfamily. A variation of this is to place caracaras in one subfamily, forest-falcons in another, and all other species in a third. Finally, a few authorities have recognized four subfamilies by separating falconets from *Falco*. There is general agreement that the caracaras are more closely allied to the forest-falcons than to the clade or clades containing the falconets and *Falco*. Beyond these broad details, most of the recently suggested schemes based on data from the analysis of DNA, allozymes and morphology present some major differences. In several major contemporary classifications, the monotypic genus *Herpetotheres* is placed near either forest-falcons or true falcons, or it is placed together with another monotypic genus, *Spizapteryx*, of South America, in an entirely separate clade. The overall situation is made all the more confusing by the lack of agreement thus far between various molecular and morphological data sets. It appears that a universally acceptable arrangement of the groups of species within Falconidae must await the refinement of current quantitative methods and systematic techniques, or the development of better ones.

Within the large genus *Falco*, there is such an array of falcon types, ranging from largely insect-eating kestrels to the almost exclusively bird-eating Peregrine Falcon (*Falco peregrinus*), that little agreement has emerged on the internal arrangement and relationships of the species. Regardless of the analysis technique applied, the correct arrangement should be consistent within historical and biogeographical contexts. The linear sequence followed here is a compromise between several arrangements and is based on the most recent and convincing data.

There are several groups that fit together nicely. A notable example is supplied by the large Arctic or desert falcons with soft, lax plumage, the Gyrfalcon (*Falco rusticolus*), the Saker

The systematic position of the Spot-winged Falconet is much disputed, and it is variously associated with different genera.

At present, many authorities consider it closest to the Old World genus *Polihierax*, and thus include it in the subfamily Falconinae, alongside the falconets and true falcons. However, some authors feel that it is more likely to be related to other Neotropical genera, especially *Herpetotheres* or *Micrastur*, and thus place it in Polyborinae. It might represent some form of link between the two subfamilies, or perhaps even merit isolation in a third subfamily; for the moment, nobody can be sure.

[*Spizapteryx circumcinctus*.

Photo: H. Rivarola/
Bruce Coleman]

The Brown Falcon has been separated from other falcons in the genus *Falco* (Falconidae), either alone or along with its closest ally, the New Zealand Falcon (*Falco novaeseelandiae*). However, in spite of the Brown Falcon's very long legs and its rather terrestrial hunting habits, it appears to be a true Falcon in most respects. Seven different subspecies have been described, but recent study suggests that some of these have been erected due to confusion with the strikingly different colour morphs, and at present only three races are considered valid.

[*Falco berigora*, Australia. Photo: J. J. Brooks/Aquila]

Falcon (*Falco cherrug*), the Lanner Falcon (*Falco biarmicus*) and the Laggar Falcon (*Falco jugger*). The hobby group, of four to six species, contains the Eurasian Hobby (*Falco subbuteo*), the African Hobby (*Falco cuvierii*), the Oriental Hobby (*Falco severus*) and the Australian Hobby (*Falco longipennis*); also included sometimes are Eleonora's Falcon (*Falco eleonora*) and the Sooty Falcon (*Falco concolor*), both of which breed from late summer to early autumn around the Mediterranean and North Africa, and migrate to winter mainly in Madagascar. Another well defined group comprises the kestrels, except the three grey species of Africa and Madagascar, Dickinson's Kestrel (*Falco dickinsoni*), the Grey Kestrel (*Falco ardosiaceus*) and the Banded Kestrel (*Falco zoniventris*). The latter are considered to form a discrete group in several analyses, and they have been regarded as aberrant kestrels; too much weight may have been given to their distinctive grey colour, but even feather protein has shown them to be distinct from other kestrels.

Some recent data concerning chromosomes, DNA sequences and behaviour suggest that the Prairie Falcon (*Falco mexicanus*), most frequently allied with large desert falcons, a relationship supported by feather protein data, may actually be more closely related to the Peregrine Falcon. The courtship vocalizations of these two species share some of the same sequence, repertoire and types, and these differ from those found in desert falcons; also, both have 48 chromosomes, rather than the 52 of the desert falcons. The Red-footed Falcon (*Falco vespertinus*) and the Amur Falcon (*Falco amurensis*) have alternatively been treated as races of the same species, as separate species, or as a species pair; they are reckoned to be allied to either kestrels or hobbies. As yet, there are no complete molecular data to shed light on the taxonomic status of these two forms.

Feather protein data indicate that the Black Falcon (*Falco subniger*) and the Grey Falcon (*Falco hypoleucos*), both Aus-

tralian endemics, might be closer to one another and allied to the hobbies, rather than belonging in different subgenera, as proposed in some schemes; the same may also be true for two other Australasian endemics, the Brown Falcon (*Falco berigora*) and the New Zealand Falcon (*Falco novaeseelandiae*). Lastly, the Aplomado Falcon (*Falco femoralis*), the Bat Falcon (*Falco rufigularis*), and the Orange-breasted Falcon (*Falco deiroleucus*) are more closely related to one another than to other groups, as suggested by shared endemic Neotropical distribution and behavioural traits, including courtship, vocalization, and sun-bathing postures, yet all three have at times been assigned to different subgenera, with the Orange-breasted Falcon placed near the Peregrine Falcon. Where these species fit in a linear arrangement within *Falco* is uncertain.

At the level of species, disputes revolve around several taxa, and there seems to be no pending resolution to these questions, since even available molecular analyses are at variance and are not definitive. For example, the Mountain Caracara (*Phalcoboenus megalopterus*) is a species of the puna and high Andes of western South America, south to at least Bolivia and north-west Argentina. Another similar species, the White-throated Caracara (*Phalcoboenus albogularis*) appears in northern Chile, south of the range of the former and extending southward to Tierra del Fuego. It differs from the Mountain Caracara by having entirely white underparts, whereas the former has only the lower third of the underparts white. Because some specimens appear to be intermediate between them, suggesting intergradation, *albogularis* is often treated as a subspecies of *megalopterus*, yet it is seemingly a good species, and these two probably form a superspecies, along with the Carunculated Caracara (*Phalcoboenus carunculatus*). The extinct Guadalupe Caracara (*Polyborus plancus lutosus*) has endured, albeit posthumously, considerable taxonomic debate over its taxonomic status. Perhaps DNA from the feather quill pulp of a study skin might show whether it was merely a

subspecies of the Crested Caracara (*Polyborus plancus*) or a full species, although the question is, lamentably, now one mainly of academic interest.

The secretive forest-falcons are hard to study in their tropical forest habitat, since they tend to frequent the canopy of forest interiors. Some species are rare in museum collections and so presumed to be rare in the field. The first study on the breeding biology of the genus was only completed in 1992, and thus it is not surprising that their taxonomic status is muddled. The Barred Forest-falcon (*Micrastur ruficollis*) and the Lined Forest-falcon (*Micrastur gilvicolis*) were both described in 1817, only a single page apart in Vieillot's treatise on new Neotropical birds. Some authorities consider them conspecific, with *gilvicolis* a subspecies of *ruficollis*, but they are sympatric in Venezuela and the Guianas without interbreeding, have different numbers of pale bars on the tail, and have different calls, all characters suggesting they are good phylogenetic species. In 1918, the Plumbeous Forest-falcon (*Micrastur plumbeus*), another species similar to the Lined Forest-falcon, was described from populations in north-west Ecuador and adjacent Colombia. It is often considered conspecific with the latter, but its isolation and certain morphological differences, including a shorter tail with a single pale bar, suggest that it is indeed a valid species. As with caracaras, there is no consensus on the nature or degree of character differences that should be regarded as indicators of full species status.

In 1891, a dark brown to bluish falcon from the Altai Mountains that mark the joint borders of Russia, Mongolia and China, was named as "*Falco altaicus*", the Altai Falcon. The original species description was based on an adult male collected at the eyrie, one of its young in juvenile plumage and four other siblings that were kept alive until they died at various ages in different plumages. In combination, a few traits from these specimens, especially the bluish cast to the adult's upperparts, are somewhat intermediate between those found in the Saker Falcon and the Gyrfalcon. These characters were explained as indicating hybridization between these two species, with the Altai Falcon thus regarded as a hybrid form, or grounds for considering it a subspecies of either of them or a full species in its own right. It is now known that dark "Altai-type" nestlings from the south flank of the Altai Mountains in Kazakhstan

may have pale, typical Saker-like siblings. DNA fingerprinting analysis of one "*altaicus*" individual by J. Longmire showed that its mother, at least, was a Saker Falcon; it was not intermediate, nor a different species. As yet, insufficient specimens of "true *altaicus*" are available from the breeding grounds of this enigmatic form to yield enough molecular data to answer this intriguing problem. If not a phylogenetic species, and thus a close allospecies of the Saker, then "*altaicus*" may well be a subspecies of it. Could it therefore be a form in the process of speciation?

Among Peregrine-like falcons, there are those with a dark bluish or black head and neck, and those with a rufous nuchal collar and head and a proportionally shorter tail. The rufous-headed form *pelegrinoides*, the Barbary Falcon, is often regarded as a species separate from the Peregrine Falcon. Full species status is supported by skeletal and feather protein characters. However, because of its distribution relative to dark-headed Peregrines in North Africa, some contact zones with hybridization, the impossibility of distinguishing the two forms using DNA from cytochrome *b* genes, a lack of distinctive behavioural differences, and complete interfertility in mixed pairs in captivity, the Barbary Falcon seems actually to be a subspecies of the Peregrine Falcon, or at least a very close allospecies. Again, some authorities regard it as a full phylogenetic species, or another form that is in the process of speciation.

The classification of the caracaras has undergone several proposed but disputed changes. Traditionally, most authorities have recognized four genera (*Daptrius*, *Phalcoboenus*, *Polyborus*, *Milvago*) containing 9-11 species. A major study of caracaras in the 1970's by F. Vuilleumier analysed six aspects, namely size, proportions, plumage colour and pattern, bare facial skin, nostril shape, and habitat preference. The study suggested that all of the species, except *Daptrius*, be lumped into a single genus, *Polyborus*. This lumping resulted in the arrangement of two groups, the "forest caracaras", comprising the two species of *Daptrius*, and the "non-forest caracaras", with the remaining five species joined in *Polyborus*. Several later studies, using DNA-DNA hybridization, an analysis of 37 characters (including behaviour, genetics and morphology), and features of syringeal morphology, however, supported the no-

Amongst the most characteristic features of falcons (lacking in the *Polyborinae*) are the tomial teeth on the upper mandible, which are thought to serve mainly in the process of killing prey by breaking the victim's neck, although they may be equally important for dismembering tough parts of prey. Other specialities visible in this immature Laggar Falcon include the bony tubercle in the nostrils, the bare orbital skin and the dark moustachial streak, which may be connected with reducing glare.

[*Falco jugger*.

Bruce Coleman]

tion of keeping separate the genera lumped by Vuilleumier into *Polyborus*. In addition to this *Polyborus* question, the two species in *Daptrius*, the Black Caracara (*Daptrius ater*) and the Red-throated Caracara (*Daptrius americanus*), are quite different in behaviour, habitat and syringeal morphology, so an earlier name, *Ibycter*, may be appropriately revived for the latter species; this question awaits further study and interpretation. Recently, it has been shown that the time-honoured generic name *Polyborus* was originally applied to a form of uncertain identity. As a result, it has been proposed that *Caracara* should therefore substitute it as the name for this genus. However, not only has *Polyborus* been used almost universally for over 150 years, but it is also the basis of the subfamily name Polyborinae. In the interests of stability, one of the overriding principles in zoological nomenclature, it seems likely that *Polyborus* will be retained.

In addition to caracaras, at least three other taxa have had their generic situation disputed, reflecting uncertainty about their affinities. Among the Old World pygmy-falcons currently placed in the genus *Polihierax*, one occurs in Africa, while a larger species with different morphology and a different colour pattern occurs in Asia. Recent studies on syringeal morphology by C. Griffiths indicate that the African Pygmy-falcon (*Polihierax semitorquatus*) clearly is related to other falconets, such as those from Indonesia and South America, but the White-rumped Pygmy-falcon (*Polihierax insignis*) of Asia is quite separate from them. The latter species is not a sister taxon of the African species, and is even placed in a different clade. Because of these differences, an earlier generic name, *Neohierax*, may be applied to the Asian species. Lastly, the Brown Falcon of Australia and the New Zealand Falcon constitute departures in morphology or behaviour from the *Falco* norm. They are closely related to each other, although some phylogenetic schemes separate them. Their differences from other *Falco* are great enough that the name *Ieracidea* (or *Hieracidea*) has been applied to the Brown Falcon and *Nesierax* to the New Zealand Falcon, or both species have been placed in *Ieracidea*. This issue certainly merits more study, but DNA-DNA hybridization data from both species indicate that there is no difference between them and other *Falco* species, so for the moment they are retained within *Falco*.

hierax semitorquatus) clearly is related to other falconets, such as those from Indonesia and South America, but the White-rumped Pygmy-falcon (*Polihierax insignis*) of Asia is quite separate from them. Their differences from other *Falco* are great enough that the name *Ieracidea* (or *Hieracidea*) has been applied to the Brown Falcon and *Nesierax* to the New Zealand Falcon, or both species have been placed in *Ieracidea*. This issue certainly merits more study, but DNA-DNA hybridization data from both species indicate that there is no difference between them and other *Falco* species, so for the moment they are retained within *Falco*.

Morphological Aspects

The popular image of the family is probably that of the typical falcons which have long pointed wings, strong hooked bills, sharp curved talons and great powers of flight and sight. Certainly, falconids are readily identified as birds of prey but perhaps not as easily distinguished from some of the hawks and kites of the family Accipitridae.

The smallest family members are the dashing Black-thighed Falconet (*Microhierax fringillarius*) and White-fronted Falconet (*Microhierax latifrons*), with a wing length of about 89-105 millimetres and weight sometimes as low as about 35 grams. The largest is the mighty Gyrfalcon, with an average wing length of about 369 mm for males and 406 mm for females, and average weights of about 1115 g and 1735 g respectively. Larger species and subspecies tend to be found nearer the poles, and there are greater numbers of smaller species closer to the equator.

The falconids have relatively small, light bodies with great power for their size. Ankylosed thoracic vertebrae make their bodies strong and rigid, and, except in the caracaras, the neck is short, making the birds appear blunt-headed in flight. Particularly in the faster fliers, the pectoral muscles are large and powerful; few measurements have been made, but those available show that the percentage of the total body weight taken up by these muscles ranges from 12% in kestrels to 20% in the Peregrine Falcon.

The *Microhierax* falconets are the smallest of all birds of prey. The Collared Falconet, for example, can measure as little as 15 cm in total length. Like the true falcons, these species have a "toothed" bill, but the body is relatively chunkier and the wings somewhat more rounded, in connection with a rather less active hunting technique.

[*Microhierax caerulescens*. Photo: Frank W. Lane/FLPA]

The falcons present a highly distinctive flight silhouette, with each wing tapering to a point. Tail length is more variable, and the species with the longest tails tend to be those that hover, such as the Common Kestrel. All members of the Falconidae are powerful fliers. They regularly use a dashing flight style that contrasts markedly with the seemingly rather relaxed soaring and gliding flight that typifies the medium-sized and large members of other raptor families.

[*Falco tinnunculus*. Photo: A. Limbrunner]

Whilst some falcons are ranked amongst the fastest fliers in the bird world, others are noted for their expertise in different aspects of flight, such as hovering. The Lanner Falcon does not often perform the spectacular stoops of some species, but it is a most versatile hunter, and as such is much prized by falconers. It tends to capture its prey after a very rapid pursuit flight, and is even known to attack prey that is flying towards it, a process that requires incredibly fast reflexes. The heavily streaked underparts of this bird indicate that it is an immature.

[*Falco biarmicus*.

Plumage in falconids consists of combinations of brown to chestnut, grey, black or white, often mottled, barred or streaked on the underside. Mostly, the feathers are waxy, but in a few caracaras, for instance the Black Caracara, they are glossy black with a green sheen. Tropical species tend to be more strikingly plumaged, as do species or forms from humid areas. For example, the Brown Falcon has several colour morphs which vary in prevalence from region to region, the species tending to be paler in more arid areas. Some forest-falcons have rufous and melanistic morphs.

The immature plumage of several species is distinct from that of the adult, though it is more distinctive in some species than in others. Immatures tend to be browner, with pale edges to their feathers, and have less bright or less strikingly patterned plumage than adults, generally with more streaking rather than barring. The plumage of the male tends to be somewhat bolder than that of the female in many species, and in a few species sexual dichromatism is marked. For example, in most kestrels the adult male is greyer than the female and immatures, and in *Polyborus* the adult female has a chestnut cape or crown, unlike the male and immatures. Falconids with distinctive adult plumage usually acquire it mainly during their first annual moult, beginning towards the end of their first year.

A few New World falconids have specialized plumage: forest-falcons have narrow, curved, stiff feathers that form a small ear ruff; some caracaras have the feathers of the occiput lengthened to form a flat crest (*Polyborus*), or curled to form a cap (*Phalcoboenus*), which is wavier in adults than in immatures; and the Laughing Falcon sports a bushy crest and collar.

Typically, falconids undergo a full moult annually, commencing during the breeding season. In the better studied species, the female drops her first flight-feathers soon after incubation commences, followed within a few weeks by the male, and both have dropped all their old remiges in about three (to four) months. The sequence of moult of flight-feathers is a characteristic of the family: flight-feathers are dropped sequentially, in pairs, beginning at the fourth primary from the inside and proceeding both inwards and outwards from this centre; moult of secondaries is also ascendent and descendent, and begins at secondary number five. The tail moult begins with the central pair of rectrices and proceeds outwards except for

the outermost rectrice (t6), which can be moulted anywhere between t1 and t5.

Apart from the caracaras, falconids have a shortened face, and most members of the family have brown eyes. With the exception of the white-eyed Greater Kestrel (*Falco rupicoloides*), all falcons and falconets have deep brown eyes. The eyes of caracaras are brown or hazel, and those of some forest-falcons are orange-brown. Generally, there is little age difference in eye colour, but in Black Caracaras the irides are brown in immatures and reddish brown in adults. The more crepuscular species, for example hobbies, have relatively large eyes.

Most species have bright yellow soft parts, comprising the orbital ring, cere and legs. However, in some these parts are grey, for example Black Falcons and most Brown Falcons, or orange, as in the Red-footed Falcon. In others they are grey in immatures, changing to yellow in adults, for instance in *Phalcoboenus* and some subspecies of the Peregrine Falcon. Their nostrils are oval, circular or slit-like (caracaras) and set in a fleshy cere. Some caracaras have unfeathered sides to the face, throat and crop, with brightly coloured bare skin. All members of *Falco*, except dark-cheeked species, have a dark malar stripe or stripes extending down from the anterior corner of the eye; these are thought to reduce glare reaching the eye.

Variations in the basic falconid form are closely linked to function, particularly to prey type, hunting habitat and hunting technique. For example, the robust bill of the Peregrine enables it to kill and dismantle relatively large prey, but with some loss of bill kinesis; it is less dextrous and has a smaller gape than the Brown Falcon, which has a narrower, less arched bill, eats smaller prey and swallows some prey whole. Short bills and jaw muscles modified to deliver a powerful bite, to kill and dismember prey, are typical of falcons and falconets. Some of the less predatory caracaras have relatively unhooked, weak, chicken-like bills, notably *Daptrius* and *Phalcoboenus*. By contrast, that of the Crested Caracara is large, laterally compressed and strongly hooked. *Herpetotheres* has a stout bill, rather like that of *Falco*, but it is untoothed.

Falcons' characteristic tomial teeth, projections on the cutting edge of the upper mandible with corresponding notches in the lower mandible, are thought to facilitate the killing of prey

At first sight, the caracaras do not look at all similar to the true falcons. The larger, bulkier body, the more rounded wings and the blunt, rather chunky bill combine to make these birds appear far less elegant, and their tendency towards terrestrial scavenging, as opposed to aerial predation, heightens the contrast. However, in the air the relationship between the two is apparent, due to their rather similar styles of flight.

[*Polyborus plancus plancus*, Falkland Islands. Photo: Annie Price/Survival]

and prevent slippage during dismantling; these are absent in the caracaras, Laughing Falcon and forest-falcons.

There are intraspecific and intersexual differences in bill morphology. For example, compared with many other subspecies, the Australian races of the Peregrine Falcon have a relatively large bill which may aid in the killing and dismantling of relatively stout-necked or difficult prey. Also, compared with males, female Peregrine Falcons have relatively larger bills.

A falconid grasps its prey using the talons of its sturdy hind toe and elongated middle toe. Mammal- or insect-catching species have fleshier, shorter toes, and a shorter middle toe, compared with falcons that more often catch birds. The talons are thin and only slightly curved in the terrestrial caracaras, sharp in *Daptrius*, and blunt in *Phalcoboenus* and *Polyborus*. They are highly curved and sharp in the other species, and can be quite massive, especially the hind "killer" talon of the larger *Falco* species. The length and thickness of the tarsus is also related to hunting mode. Peregrine and Black Falcons both have short, thick tarsi and hit relatively large prey with great force. More terrestrial species, such as kestrels and the Brown Falcon, have long legs and large, scute-like scales on the toes and tarsi. The Laughing Falcon has rough, hexagonal scales that are thought to withstand the bites of the venomous snakes on which it preys; bird-catching species tend to have fine, reticulate scales.

Falcons are renowned for their supposedly remarkable powers of sight. Head bobbing, while perched, is a typical falcon characteristic that makes the object of interest move in relation to the horizon and the background and thus aids in the perception of distance. Typically, falconids have two foveae, a nasally-placed monocular fovea which projects into the area of no visual overlap with the field of the other eye, and a temporally-placed binocular fovea. The Chimango Caracara (*Milvago chimango*) lacks the binocular fovea, perhaps because its scavenging habits reduce the need for detection and fixation of rapidly moving prey. However, the monofoveate condition may

prove to be primitive, rather than having a strong functional basis.

Falconids that hunt in dim light have relatively large eyes, for example pygmy-falcons, some hobbies, and the Brown Falcon. The diurnal and crepuscular Brown Falcon has been estimated to have about the same visual acuity as humans, the result of trade-off between resolving power and sensitivity, because of a need for resolution over a wide range of luminances. Falcons' supposed visual superiority over humans is thought to be primarily in the detection of movement rather than purely in exceptional acuity.

In general, falconids hunt from height and use mainly visual clues to locate prey. Thus it is not unexpected that they are unable to capture prey using auditory clues alone. In *Falco* species studied to date, the minimum audible angle (the angular margin of error in determining the direction of sound) is about 10°, compared with 1°-2° for their nocturnal counterparts, the owls. Although most species locate prey primarily by sight, some use sound on occasion, for example Brown Falcons, which listen and wait at the nest holes of passerines. More than any other falconids, forest-falcons use sound to locate prey; they have upward-curved ear feathers that form a slight ruff, designed for collecting sound, and also large asymmetric ear openings.

Falcons are credited with extraordinary powers of flight. The Peregrine is probably the fastest of all birds. It has a powerful direct flight with strong wingbeats and may reach 180km/h in a stoop; although greater speeds are claimed, there are no accurate estimates. Kestrels have been clocked flying steadily in light wind at 32 km/h; hobbies and falconets are energetic fliers and appear to reach high speeds over short distances. Caracaras tend to be slow, rather mechanical fliers.

While falcons are typically fast fliers, they also soar with ease, while some, particularly kestrels, regularly hover into the wind. Their wings are long and pointed, as are those of some

The Red-throated Caracara is one of the few falconids that occurs in dense forest. Indeed, it appears to be largely confined to areas of undisturbed forest, and, although also recorded in selectively logged forest, it does not appear able to adapt to heavily disturbed secondary growth.

caracaras, with a low camber and quite high wing aspect ratio (length:breadth); these are essentially adaptations for life in open country, for powered flight, speed or hovering. The falconets have short, usually pointed wings and make brief flights to catch insects. The wings of forest-dwelling species, for example the Mauritius Kestrel (*Falco punctatus*) and the New Zealand Falcon, are shorter and quite rounded, particularly so in the forest-falcons and Laughing Falcon, allowing short, buoyant flight through the trees. Those falconids with greatest need for manoeuvrability tend to have relatively long tails. The forest-falcons, with short, rounded wings, a long tail, long legs and an ear ruff, superficially resemble an accipitrid, but the similarity is convergent, their forms reflecting similar lifestyles.

Most falconids are found in open habitats, ranging from savanna and steppe to desert and semi-desert. Like its three congeners, the Carunculated Caracara is a species of the temperate zone in South America. It occurs above the tree-line in the Andes of Ecuador and south-west Colombia, where it is one of the most conspicuous inhabitants of the páramo.

[*Phalcoboenus carunculatus*,

E. Parer-Cook/Ardea]

Thermal and wind currents are utilized by many falconids for foraging and display flights, and also for migration. A few species hover, notably most species of true kestrel, which hover into the prevailing breeze with ease; from this "aerial perch" the bird's body takes the buffets of the wind while its head remains stationary relative to any point of interest below.

The typical falconids have 10 functional primary remiges, with a vestigial eleventh, 11 secondary remiges, and 12 retrices. The Crested Caracara is said to differ, with its 10 primaries and 13-14 secondaries. Faster-flying falconids have tighter plumage, stiffer primaries and more pointed wings than slower species. The second outermost primary is usually the longest, but wing shape varies with lifestyle, particularly in relation to hunting habitat and technique. For example, the Brown Falcon of open woodland has long, broad wings, which are relatively rounded at the tip for a falcon; its wing formula is the same as that of the New Zealand Falcon, which has similarly shaped, but shorter, wings for life amongst denser vegetation.

Longer-legged falconids can walk or run along the ground, or the branches of trees, with ease. Some scratch at, or stamp on, the soil to disturb invertebrates or worms; this is typical of several caracaras, but also occurs, occasionally, in a few falcons. Most falcons, however, are rather short-legged and slightly awkward on the ground, although they can lean forward and run surprisingly fast. Rarely, a falcon may be pulled into the water during an attack on prey, but it is usually able to "row" overarm, with its wings, to the shore.

Habitat

Falconids are found throughout the world, with the exception of the Antarctic and the high Arctic. They occur in most habitats from rain forest to desert, from wilderness to city centre. Although members of the family are encountered in nearly every climatic zone, the greatest number of species is found close to the tropics and only two species breed far north in the Arctic tundra. Diversity also tends to be poorest at high altitudes, and richest in lowlands.

Because the structure of the habitat is more important to them than any particular plant types, most falconids are quite adaptable. Nevertheless, several species have quite specific nest-site requirements, and so are limited by habitat suitable for breeding. For example, many species need tree cavities, and colonially nesting Eleonora's Falcons prefer remote islets and rocky sea cliffs pocked with hundreds of sheltered holes and ledges.

Long periods are spent preening. Diligent feather care is essential, because the condition of the plumage obviously has most important effects on flight performance and hunting success, and ultimately on the bird's long-term survival. Some species have been recorded allopreening, whereby partners preen each other; this probably serves mainly to strengthen the pair-bond. Other common forms of comfort behaviour include bathing in water and dust-bathing.

[*Falco vespertinus*.
Photo: P. Bracht]

Most falconids have a fairly wide distribution, but, with notable exceptions, typically occur at fairly low densities with somewhat scattered distribution. Nevertheless, certain species may be the most successful of raptors. For instance, the Common Kestrel (*Falco tinnunculus*) breeds over large areas of Eurasia and Africa, in a wide variety of habitats and under a number of climatic conditions, and it is often common. In Australia, Australian Kestrels (*Falco cenchroides*) and Brown Falcons occur almost throughout the continent, and during a national survey these two falconids were the most widely encountered of any bird species. The cosmopolitan Peregrine Falcon may have the widest breeding distribution of any bird. At the other extreme are falconids greatly restricted in distribution or numbers: the naturally rare Taita Falcon (*Falco fasciinucha*) is found only in dry country at scattered gorges and mountainous locations in East and Central Africa; Eleonora's Falcon breeds in fewer than 100 more or less dense nest colonies almost all in the Mediterranean; the semi-deserts of northern Argentina are the very limited range of the Spot-winged Falconet; and the highly endangered Mauritius Kestrel is found only on the isolated island of Mauritius, where it has been driven to the brink of extinction by destruction of its forest habitat.

Typically, the falconids are thought of as birds of open country. Most of the falcons and caracaras conform to this

image, and frequent open or semi-open areas, normally of woodland or scrub. Even the forest-dwelling falconets and Bat Falcon are found near forest edges and clearings, and New Zealand Falcons favour broken forest. As a group, the forest-falcons may be the most dependent on continuous forested habitat. Other forest species, for example the Black and Red-throated Caracaras, although able to survive in semi-cleared areas, apparently are less successful there than in undisturbed habitat.

Fifteen species occur exclusively in Central and South America, including all the species of caracara and forest-falcon, the Spot-winged Falconet and two members of *Falco*. Only the Prairie Falcon is exclusive to North America, and a further two falcons, the American Kestrel (*Falco sparverius*) and the Aplomado Falcon, are found only in the Americas. Six of the seven species of falconet are found in Asia. Six *Falco*, five of which are kestrels, are confined to islands or island groups where they are often the sole falconid species. Seven *Falco* are Eurasian, with two extending to Africa and one to North America. Six *Falco* are solely Australasian in distribution and another six are restricted to Africa. A further five falcons have a breeding distribution that includes Africa, and seven more species winter on that continent.

According to the categorization developed by L. H. Brown, there are twelve main raptor habitats, each with its own typical

Many falconids are fairly vocal, and this is particularly true of the caracaras and the suitably named Laughing Falcon (*Herpetotheres cachinnans*). The caracaras of the genera *Phalcoboenus* and *Polyborus*, and to a lesser degree *Milvago*, have loud, normally rather raucous calls, which are used for proclaiming occupation of a territory. When calling, these birds adopt a characteristic posture, with the head thrown right back, as illustrated by this Striated Caracara.

[*Phalcoboenus australis*.
Photo: Fritz Polking/FLPA]

The Prairie Falcon feeds mainly on fairly small mammals and birds, and amongst the former ground squirrels are particularly favoured, as in this case. This species usually forages by flying along at medium height, diving in a fairly shallow stoop at prey. It typically captures a great deal of its prey, including birds, either on or close to the ground.

[*Falco mexicanus*, Idaho, USA.

mix of falconids. In the four richest habitats: about 30 species breed regularly in tropical savannas; and around 20 species each in temperate to subtropical steppe and grassland, subtropical semi-arid woodlands and mountains, and tropical forests. Temperate moorlands and mountains provide regular breeding habitat for 10 species, and deserts and semi-deserts for 12 or so species. The Gyrfalcon and the Peregrine Falcon breed in the northern tundra and are joined by the Merlin (*Falco columbarius*) in the taiga. Another three habitats are frequented by two to three species each: aquatic (coastal) habitats by Eleonora's and the Sooty Falcons; tropical montane moorlands and mountains by Peregrine and Lanner Falcons and the Mountain Caracara; and temperate deciduous woodlands by the White-throated Caracara and the Eurasian Hobby. Lastly, at least 15 species find that the establishment of cities creates breeding sites and attracts a regular supply of prey.

After breeding, many species shift to a different habitat. Resident species may make a local movement to an area with more abundant food than is found around the nest-site. For example, some Australian Peregrines shift with their fledglings from sub-coastal cliffs (some over temperate forest) a short distance to coastal lowlands, over farmlands and towns. Migrants may make more drastic changes in habitat. A good example is Eleonora's Falcon, which breeds in barren parts of the Mediterranean and nearby Atlantic coasts, and migrates to the humid forests and woodlands of Madagascar. Nevertheless, migrants are often found in habitats that are structurally similar to that in which they bred. Gyrfalcons breed in Arctic areas mainly above the tree-line, and migrate south to winter in moorland, steppe and other open areas with low vegetation.

Sometimes the sexes winter in different habitats: female American Kestrels tend to winter in more open country than do males. The immatures of many falconids may frequent habitats that are not well used by adults; often those with ample prey and suitable hunting habitat, but which are unsuitable for nesting.

General Habits

Typically, falconids are thought of as solitary predators that co-operate with conspecifics only to reproduce. Although most

species do live alone or as solitary pairs, it may come as a surprise that several species are highly gregarious. These social species tend to lead less predatory lifestyles than typical members of the family: Red-throated Caracaras forage in the forest for wasp nests; and Lesser Kestrels (*Falco naumanni*) specialize on insect swarms. Red-throated Caracaras may be unique among raptors. About six birds, in a group, defend a territory all year round and forage together through the forest, each member searching independently, as many pairs of eyes are better than one. Group cohesion is maintained by means of loud contact calls, sharing of large prey items and allofeeding, which involves one bird feeding another. Lesser Kestrels live in flocks, and, although each member appears to operate independently when hunting, some advantage may be gained through disruption of the insect swarms on which the birds prey.

Even the most predatory of species, for example some of the larger falcons, hunt in co-operative pairs at times and share prey. Fledglings are usually more gregarious than adults, and move in sibling groups, in family groups or occasionally with unrelated birds; they hunt and roost together. Even adults of some species may congregate in loose single- or mixed-species flocks, where food is temporarily plentiful. In Australia, occasional outbreaks of the house mouse (*Mus musculus*) may attract large gatherings of Brown Falcons and Australian Kestrels, sometimes peppered with Black Falcons and other raptors, all hunting independently. In a mixed-species foraging guild, other frugivorous species of bird join Red-throated Caracara groups to forage in the forest understorey, where they rarely venture otherwise. The Caracaras' efficient anti-predator warning and mobbing behaviour probably protects the whole foraging group.

Territoriality is typical for most falconids, which depend on prey that is at least seasonally predictable and reasonably widely available. Species that specialize on patchy or ephemeral prey tend to live in groups, as individual defence of such resources would be impractical and individual searching less likely to be successful than a joint effort.

Raptor pairs space themselves apart, particularly from conspecifics, and even those of colonial species defend a small area: a few square metres for pairs of Eleonora's Falcons; less

The Lesser Kestrel is a noted specialist on insects, which often make up over 90% of its prey. Crickets are very commonly taken, as are grasshoppers, locusts and beetles, while termites and ants are important in its African winter quarters. The widespread and often indiscriminate use of pesticides has caused a major decline of this species, mainly as a result of poisoning and reductions in the populations of its prey species.

[*Falco naumanni*.

Nature & Travel]

than 1 km² for each American Kestrel pair; and as much as 1000 km² for each Gyrfalcon. Groups of Red-throated Caracaras defend a shared territory all year round, but only one pair breeds. For some species the territory is permanent, for others it is occupied and defended only during the breeding season. Some territories with traditional nesting and roosting sites are occupied by successive pairs of raptors for centuries. Non-resident species, for example the American Kestrel, may defend winter territories.

Defence is not only against conspecifics but also against predators and other aggressive species. Colonial nesters and foragers perform collective defence against potential predators. For example, Eleonora's Falcons take to the air *en masse* to defend the colony area against potential predators, such as eagles, but on the ground they behave like solitary nesters, although with a markedly smaller space per individual. In a communal territorial display during the breeding season, between morning and evening feeding periods, adult Amur Falcons gather and soar in noisy, chattering flocks, gradually descending to fly in formation in a wave-like pattern just above the ground, and turning sharply in unison to flash their wings. Conspicuous, sometimes spectacular, aerobatics seem to serve as territorial displays for many species, but they are not often seen outside the breeding season. Forest-dwellers often rely on calls to advertise territoriality.

Some species hunt, nest and roost together year round. The Lesser Kestrel uses traditional roosts on migration, some in city centres, with up to 70,000 noisy birds crowded into a patch of eucalypts. Before roosting, they gather in wheeling flocks around dusk, and after dawn they leave in smaller groups to forage on the wing most of the day. Similarly, Amur Falcons number up to 5000 at favoured roosts, with as many as 100 in a tree. Other species, such as the Eurasian Hobby, flock on migration and roost gregariously with other small falcons, but disperse to individual territories on returning to their breeding grounds. Many falconids become more gregarious outside the breeding season. It has only been fairly recently that the communal roosting habits of Peregrine Falcons have been reported. Each autumn up to nine Peregrines, five Common Kestrels, six accipitrids and 17 corvids roost together in British conifer woodland surrounded by open country, and up to five adult

Peregrines have been seen sharing a traditional autumn roost in Czechoslovakia; around sunrise, the birds disperse to different feeding areas. The function of communal roosts is hotly debated. They are suggested to serve as centres for exchange of information about local prey, for protection, for thermoregulation or for social purposes, but none of these proposals has been investigated in falconids. On occasions, pairs and family groups of diminutive pygmy-falcons (*Polihierax*) huddle together at a roost, for warmth in the cold desert night.

Solitary species also use traditional roosts, as well as temporary ones. They are usually at sites sheltered from the prevailing weather, the heat of the day and so forth. Roost-sites can be quite varied, for instance the Red-necked Falcon (*Falco chicquera*) roosts in *Borassus* palms, pygmy-falcons roost in weaver nests, many species roost in clumps of *Eucalyptus*, and some caracaras roost on the ground.

Typically, falconids are active by day. Many leave their roosts around dawn to forage; on rainy or overcast days they delay their departure. In hotter climes, some species roost during the heat of the day. Eurasian Hobbies and Bat Falcons may roost by day and hunt moths and bats crepuscularly. Red-throated Caracaras are active from before sunrise to after sunset, with a rest of one to three hours at a roost around midday. They rest during heavy rain, but continue their foraging during showers, averaging about ten hours of activity per day, with little day to day variation. Several species normally active by day occasionally hunt nocturnally. For example, Australian and Common Kestrels have been observed hunting by moonlight, and Australian Peregrine Falcons catch petrels as they return to their burrows well after nightfall. Where several species occur in the same habitat they usually have different habits, including different activity patterns, that serve to separate them in space and time.

In common with most birds, falconids spend considerable time on feather maintenance. They have well developed oil glands, and many species bathe in water, others in dust (usually desert species). The aerial hobbies may "bathe" by flying through wet foliage. Many species also sunbathe, back to the sun, with the wings outstretched, although this may be for warmth as much as for feather care. Preening does not follow a sequence, but rather it seems to be carried out according to

need. Australian Kestrels spend about one third of their preening time, scattered throughout the day, on the wings, one fifth on the underparts, and one tenth each on the head, tail and back. Pairs of a very few species allopreen, for example occasionally a Brown Falcon will gently groom the cheek feathers of its mate, presumably to help maintain the pair-bond.

In many sexually dichromatic raptors the plumage of immatures of both sexes resembles that of the adult female. At least for the Common Kestrel, evidence suggests that in young males this serves to reduce competition with adult males by deception, through mimicry of females, rather than by signalling low status due to immaturity.

Other plumage differences may also function as social signals, for example the pronounced facial pattern of the Bat Falcon may serve as a territorial signal: a bird will perch prominently above the forest canopy and puff out its cheek and neck feathers. Similarly, to the human eye, the pale bib of a Peregrine Falcon is visible for some distance, particularly when the crop is full. In the caracaras, a bright face and a bright crop serve

as social signals. For example, the face of the Crested Caracara changes from orange to bright yellow in excitement. The bare crop in these species, so obviously displayed when full, may serve as a cue in scuffles over food, or to advertise hunting prowess to potential partners. Bright soft parts on any species may signal the good health of that individual, perhaps an aid to sexual selection. Another unusual feature of the caracara group, unprecedented among birds, is the ability of the Red-throated Caracara to emit a powerful insect repellent so that when the birds plunder insect nests the angry wasps and bees depart instead of attacking.

Voice

One of the distinguishing characteristics of the Falconidae is the structure of their syrinx, the organ of voice production. Thus it is not unexpected that members of this family have calls of different quality to those of other diurnal raptors belonging to the Accipitridae. Nevertheless, members of both families have rather unspecialized, simple calls.

Most falconid vocalizations consist of repeated monosyllables, varied in pitch and frequency of repetition to suit different situations. Both sexes use a similar range of calls, but the pitch is usually consistent with the bird's size, so that those of males are somewhat shriller. Falconids' voices tend to be rather harsh or strident, described by such terms as cackle, chatter or chitter, squawk, croak, wail and whine. The call of the Collared Forest-falcon (*Micrastur semitorquatus*) is said to sound like a person groaning in pain!

The birds' calls cover a variety of functions, including most social situations, threats, alarm, courtship, begging and so on. Group cohesion is probably the main function of the continual calling emitted by members of noisy groups of Red-throated Caracaras as they forage closely, but independently, through the forest. Similarly, Lined Forest-falcon pairs call to each other as they travel through the forest.

It is suggested that some forest-falcons use a certain call, which carries little directional information about the caller, to attract small birds on which they prey. The birds arrive to mob the calling, concealed predator, but are unable to discern its location, and thus are vulnerable to attack (see Food and Feeding).

Mostly before sunrise, pairs of all forest-falcon species duet in a brief, sonorous dawn chorus, which arguably qualifies as true song, although both sexes contribute. Laughing Falcon pairs often duet in the twilight as well as around dusk. Perched within metres of each other, they assume an erect posture and sing two far-carrying notes over and over again, the two birds varying the timing and pitch to produce a full, smooth, unhawk-like sound; the laugh-like call for which they are named is uttered when they are disturbed. As with most birds species, falconids that duet are tropical species frequenting dense vegetation, most likely with high mate and territory fidelity.

Forest-dwelling species are probably the most vocal, in order to maintain bonds in dense vegetation, whereas most falconids live in more open country, solitarily or as scattered pairs, and would have less need for contact calls or for song. Indeed, most species are fairly silent except during the breeding season when they make excited courtship calls and engage in spirited, raucous defence of the nest area. Colonies of Lesser Kestrels, Eleonora's Falcon, Red-footed Falcons and Amur Falcons are noisy places of low, chattering, sexual excitement interspersed with higher-pitched screeches. Resident species sometimes continue to defend the nest-site all year round. For example, at any time of year, if present, Orange-breasted and Bat Falcons are very vocal when their nest-sites are approached.

The caracaras are the only falconids with an onomatopoeic name, probably referring to the chattering, rattling call of the Crested Caracara. The Spot-winged Falconet and the forest-falcons also make loud, guttural calls or nasal, barking calls. Vocalizations are often associated with gestures. For instance,

Although it has been said to prey extensively on insects and rodents, the Aplomado Falcon is now known to feed mostly on birds. Members of a pair will frequently hunt in tandem, which can involve one of the birds moving into cover in order to flush prey out, so that the waiting partner can pounce on it. Research has shown that, when attempting to catch avian prey, pairs operating in tandem are more than twice as successful as solitary individuals.

[*Falco femoralis femoralis*,
Tierra del Fuego.
Photo: Günter Ziesler]

Once prey has been caught, it is often taken to a favoured perch to be eaten; birds are carefully plucked prior to consumption. The Eurasian Hobby is one of the most aerial of predators, feeding extensively on insects, but also on small birds, especially during the breeding season when fledglings of small passerines abound. This species regularly dismembers and eats insect prey while on the wing.

[*Falco subbuteo*.

NHPA]

when Black and Red-throated Caracaras utter calls likened to forced laughter, this is accompanied by nodding of the head. The members of *Polyborus* and *Phalcoboenus* throw the head back, often until it touches the shoulders, when they make their raucous territorial calls. At the nest they make short clicks, and grumbles when disturbed. For obvious reasons, the softer calls, made in more intimate situations, are less well known than the louder defensive or advertising calls.

It is not always possible to distinguish species by their calls. For example, the calls of the various different forest-falcon species are rather similar, as are those of several kestrel species. In fact all the falcons and falconets have very similar calls, based mainly on a multi-purpose "kek" or "kik", and their calls differ chiefly in that they are higher-pitched in the smaller species. In each species the basic call is adapted to a range of situations by varying its pitch, the number of repetitions, the frequency of repetition and so forth. The Australasian Brown Falcon may be the exception. As well as typical falcon calls, it makes a variety of atypical chatters, squawks, chuckles and clucks, some seemingly caracara-like, and it tends to be rather vocal.

Older nestlings call insistently when hungry or uncomfortable, including yelps in *Milvago*, and whines and wails in *Falco*. Adult females often use similar calls to solicit food from males. In *Falco*, at least, these are combined with a submissive, hunched posture or fluttering flight, as used by a soliciting fledgling.

Unlike the accipitrids, falconids sometimes hiss defensively when cornered, a form of behaviour that has occasionally been claimed to ally them to the owls.

Food and Feeding

Falconids usually evoke images of fast-flying, highly effective predators that catch birds on the wing, and, in fact, most large members of *Falco* and some falconets do so. Some tiny

family members, the dashing falconets of the genus *Microhierax*, catch large flying insects rather than birds in the air. There are others, however, primarily Neotropical caracaras, that walk on the ground, scratching the earth and scavenging. Some authors loosely clump falconids into two categories of hunters, the searchers and the attackers. Searchers spend considerable time searching, and usually hunt small, abundant prey that is relatively easy to catch. They usually have a high success rate. Attackers, on the other hand, put more effort into the actual capture, and usually hunt larger, less numerous and more agile prey types. They have lower success rates. Some searchers have relatively narrow wings and long tails, with light wing-loading, such as the Chimango Caracara. Others, like Crested Caracaras, have broader, more buzzard-like wings. Typical attackers, such as the African Hobby, have long, narrow wings with short tails. Some attackers that hunt in forests, like the Mauritius Kestrel and the New Zealand Falcon have wing and tail proportions somewhat like forest hawks, most notably in the case of the Collared Forest-falcon and its congeners.

Diet and foraging manner change somewhat from genus to genus within the family, and even considerably within true falcons. The diurnal schedule of hunting and also success rates vary considerably between groups and even within a single species. Although it is most informative to treat feeding by group, there are some interesting habits that are rather widespread within the family.

Kleptoparasitism is the stealing of food from another animal, in this case usually from a bird. The Crested Caracara is an accomplished kleptoparasite, taking food from other raptors, gulls and pelicans. The Aplomado Falcon steals from harriers (*Circus*) and kites (*Elanus*), and sometimes several falcons will even gang up on another raptor to take its food, a sort of social robbery. The list of falcons that are kleptoparasites is lengthy, and includes Common and Lesser Kestrels, the Merlin, the Eurasian Hobby, and Red-footed, Brown, Black, Lanner, Prairie and Peregrine Falcons. The Black Falcon even takes

Reptiles are taken by many falconid species, although they are not often the main source of food. The Australian Kestrel takes a fair variety of prey types, amongst which reptiles, especially skinks, are particularly important during the breeding season.

[*Falco cenchroides*, Australia.
Photo: Hans & Judy Beste/Ardea]

food from the Peregrine Falcon that is much faster, though smaller, than itself.

Caching, the putting away of food for later use, is another habit that, within *Falco* at least, is quite common. Such caches can be useful when hunting is made difficult during bad weather, and in Britain, for example, 39% of the food fed to young Peregrines at one eyrie was from a food cache. Caching occurs throughout the year and has been recorded in at least 21 species of falcons, ranging from the largest, the Gyrfalcon, to one of the smallest of the kestrels, the American Kestrel. It has accordingly occurred with species living in all habitats, from Arctic through temperate to tropical. It will probably be found to occur with most if not all falcon species. In Canada, a female Merlin was seen to cache food and immediately return to the business of hunting for other food, suggesting that she was hunting in the absence of immediate food needs. Another Merlin in Wyoming in mid-winter was seen to catch two House Sparrows (*Passer domesticus*) in succession and cache both of them, before flying off elsewhere to perch and loaf. A Peregrine Falcon, that had just eaten, cached the next two prey items caught; apparently hunting to cache rather than in response to hunger. A Gyrfalcon, feeding on a frozen ptarmigan (*Lagopus*) that had been retrieved from a cache in mid-winter in Alaska, seemed to be "shaving off" thin slivers from the frozen body with each bite. During the breeding season, the cache is usually not too far distant from the eyrie; the female can take a break from incubation, fly to the cache, and begin feeding, usually in less than a minute. In nearly all seasons, most caches are to be found in conspicuous locations, such as prominent clumps of grass in a field, unused nests or other obvious locations in trees, or conspicuous ledges or nooks on cliffs and buildings.

During the breeding season, even starting as early as the courtship period, the female falcon, in most species, is dependent on the male to provide food. In many species, nestlings are provisioned by the male for at least the first half of their nest life, after which time the female begins to hunt for food. Some falcons are principally insectivorous, but feed mainly mammals or birds to their nestlings, and the proportion of vertebrates increases as the young grow. Some species, such as Eleonora's Falcon, feed primarily on birds during breeding, but on insects during migration and on their non-breeding, wintering grounds.

Food requirements vary considerably depending on a bird's age, size, and activity, and also on the season. For example, an adult Peregrine Falcon in north temperate latitudes, requires about 15% of its body weight in winter and 11% in summer. Averaged for a year, a male Peregrine requires about 113 grams of food per day, a female roughly 141 grams. Soon after hatching, nestling Peregrines ate 80 grams per day; their peak food intake was at 33 days old, when each ate about 300 grams per day. Since the falcon wastes about 20%, by weight, of the kill, in feathers, bones and items not picked clean, on average it would take a total of about 22.4 kilograms a year for a pair of adults to raise a family of 2.5 young. In Australia, from the moment of hatching to that of fledging, young Peregrines each ate approximately 4000 grams of food.

While caracaras only make up about 7% of the falconid species, their food and feeding habits incorporate a spectrum and breadth perhaps exceeding the rest of the family. About the only thing they do not do with ease, nor frequently, is catch birds or insects on the wing. Much of the variety of their food fare arises because, in addition to killing food, they are omnivorous, and, for instance, regularly take carrion, even feeding in garbage dumps on discarded human waste, flies and other insects. The Crested Caracara and the Striated Caracara (*Phalacrocorax australis*) kill prey as large as lambs. The Crested Caracara adroitly takes nestling birds from nests, and in northern Mexico has been seen attempting to catch flying Cattle Egrets (*Bubulcus ibis*). In Argentina this species was seen to catch a domestic pigeon in flight. In Peru, when feeding at carrion, it clearly had the lowest rank in a dominance hierarchy with vultures and condors, arriving at the carcass after the vultures had gone, or prior to their morning arrival. Food of the Carunculated Caracara, of the high barren mountains of Ecuador, varies considerably from one mountain to another just 30 kilometres distant: earthworms made up 50% of the biomass at one location, but only 1.5% at the other; amphibians, lizards and other reptiles made up 62% of the biomass at one site, but only 1% at the other; other frequently eaten food items were beetle larvae, as large as a human thumb, and centipedes. On occasions, an adult Mountain Caracara will regurgitate a bolus of food, containing wheat, maggots and vegetable matter, for its young. In specific areas where local people engage in trap-

Caracaras regularly feed on carrion, and thus perform a similar role to vultures in disposing of rotting flesh and avoiding the spread of diseases. Inevitably, they also feed on the carcasses of domestic livestock, and this sometimes leads them into conflict with farmers, who accuse them of killing sheep. A dispute has broken out for dominance at this carcass between the two adults, as the duller, browner juveniles look on.

ping mammals, such as foxes, Mountain Caracaras are frequently seen with missing feet or toes. Locals concluded that perhaps the caracaras tried to take bait from their traps and were injured in the process. In the Falkland Islands, the Striated Caracara visits seabird colonies, especially those of penguins, to steal nestlings. The small *Milvago* caracaras frequent agricultural lands, and the Chimango Caracara follows ploughs, much in the manner of gulls, in order to glean worms, insects and other invertebrates that may be uncovered. The food fare of the Chimango is so extensive that it fills the roles of falcon, vulture, insectivore and herbivore. The Argentine observer Azara said that "all methods of subsistence are known to this bird; it pries into, understands, and takes advantage of everything." This description applies well to the Chimango: it has been seen trying to eat leather from discarded, crusty shoes; flying through fires on the *pampas* grabbing fleeing insects, mammals or birds; stealing nestling birds from concealed, domed ovenbird nests; and wading knee-deep in drying up pools looking for frogs, tadpoles and other aquatic prey. Charles Darwin watched it trying to pick flesh from saddle sores on the backs of horses. The Yellow-headed Caracara (*Milvago chimachima*) will take ticks from the backs of cattle, and eat eggs, fruit of oil palms, grain and horse dung. The deep forest caracaras (*Daptrius*) eat large numbers of wasps and a good deal of fruit. Red-throated Caracaras participate in food sharing and deliberately allofeed, which contributes to their social cohesion (see General Habits). In the mature primary forests in which they apparently evolved, they forage frequently in the understorey, where they have much higher success rates than do conspecifics foraging in secondary or disturbed forests.

The falconets comprise three distinctive and geographically disjunct genera: the Spot-winged Falconet of South America; the African and White-rumped Pygmy-falcons, of Africa and south-east Asia respectively; and the five species of "true" falconets (*Microhierax*) that range from India to the Philippines. The hunting habitat of the Spot-winged Falconet and the pygmy-falcons is similar, consisting of chaparral, open thorn-scrub and savanna, while that of the true falconets varies from deep forest to open forest along edges and clearings, frequently in agricultural areas. The five species of *Microhierax* hunt much like flycatchers, wood-swallows (*Artamus*) or

shrikes (*Lanius*), from a perch on a dead exposed branch, from which the bird makes rapid dashes at insects, the occasional bird, or lizards. They are birds with slightly rounded wings and high wing-loading, "hit-or-miss" attackers that never chase prey once it has been missed. H. Miranda describes the attack as usually proceeding with a relatively oblique flight on a downward slope of 30° or so. When prey is missed, the bird circles round and returns to an exposed perch, frequently the same one from which it launched forth. In India, small parties of Collared Falconets (*Microhierax caeruleus*) often launch out at prey from a huddle, one by one or several together, and, if the prey is missed, they circle back to the same perch to huddle again and wait for the next butterfly or flying insect to pass. A butterfly chase by the falconet is strongly reminiscent of the twirls and turns of the Merlin when pursuing a fast-flying songbird. Although these birds inhabit forests and especially forest edge, their hunting methods more clearly resemble those of typical falcons than those of forest hawks. This falcon-like hunting is reflected in the shape of the wing: while somewhat rounded, it is not nearly as reminiscent of the wings of *Accipiter*, as is the wing of the forest-hunting Mauritius Kestrel. Of 328 attacks by Philippine Falconets (*Microhierax erythrogenys*), 63% were successful with 70% of the prey being dragonflies, and 24% bees and butterflies. Birds as large as robins (*Erithacus*) and pipits (*Anthus*) are attacked. The most intense hunting in the Philippines took place in the morning, until about 10:00 hours, which coincided with peak activity of insects.

The African Pygmy-falcon also mainly takes large insects but it catches many more lizards and birds. While about 73% of a sample of regurgitated pellets contained insects, 37% also contained lizard remains, and 15% contained bits of birds and mammals. Birds as large as a Sociable Weaver (*Philetairus socius*), with which the species associates for breeding, have been caught on the wing; the weaver weighs about 35-45% of the falcon's weight. Pygmy-falcons often "hawk" their food from a perch, like a shrike (*Lanius*), but they do not hover like hunting kestrels.

The Spot-winged Falconet, the American counterpart of the African Pygmy-falcon, has been the subject of far less research to date. Its food consists of insects, arthropods and birds, but

its hunting techniques are not well documented. When hunting, it has been seen to fly from perch to perch with a low flight, fairly close to the ground, again much like a shrike as it swoops upward to the perch. An adult Monk Parakeet (*Myiopsitta monachus*), a species nearly equal in size to the falconet, is among the food fare recorded. Because the falconet frequently nests in parakeet colonies, perhaps an adult parakeet was unexpectedly caught while in its nest.

Laughing Falcons are snake specialists, the ecological equivalent in diet to the snake-eagles of Africa; the species might more appropriately have been named "Snake Falcon". Well over 90% of its diet is made up by snakes. In primary forest in Guatemala, 22 species of snakes are known in the diet; the percentage of arboreal to terrestrial snakes may change from year to year, with arboreal snakes more numerous, comprising up to 75% of all snakes taken. In modified habitats and near agricultural lands, the percentage of terrestrial snakes increases to 70%, and other reptiles, amphibians and an occasional bird are taken. A capture success rate has been given at 30%. A Laughing Falcon, in a crouched posture with its wings outspread, was seen walk up to a snake on the ground before catching and killing it. Snakes may be killed at the time of capture or brought to the nest alive; some, but not all, venomous snakes have their heads removed.

Diet among forest-falcons varies from species to species, with the percentage of different food types perhaps less important than the biomass they provide. R. Thorstrom reported that the diet of Barred Forest-falcons in Guatemala consisted of about 42% reptiles and 15% birds, while in the larger, perhaps more terrestrial, Collared Forest-falcon 35% of the food taken was made up of mammals, 27% of birds and 14% of reptiles. Birds as large as chachalacas (*Ortalis*), Keel-billed Toucans (*Ramphastos sulfuratus*) and aracaris (*Pteroglossus*) were caught. Barred Forest-falcons used various foraging techniques, including perch-hunting, nest robbing and still-hunting around ant swarms. This last technique consists of following army ants and capturing organisms that are flushed by the ants. At least two species use army ants as flushers, and it seems quite likely that all six species do so. Sometimes forest-falcons shake bran-

ches with their feet to flush prey. The Collared Forest-falcon has been seen on the ground running after prey, chachalacas in Guatemala and rabbits in Argentina. Perhaps the most unusual hunting technique of this group is the provoked mobbing of calling Slaty-backed Forest-falcons (*Micrastur mirandollei*) by small birds. Calls of the concealed forest-falcon attract birds within range, close enough for them to be caught. Apparently this works best on naive and inquisitive North American migrants that have no previous experience with the forest-falcon.

True falcons forage using an array of methods that are reflected in some anatomical adaptations. Grabbing prey in the air is facilitated by long toes, and an index of the feeding manner is reflected in the toe to tarsus ratios. Aerial bird specialists, such as the Peregrine Falcon and Orange-breasted Falcon, have long toes that are about 98% as long as the tarsi. The success rate of these species varies considerably, depending somewhat on the season and also on special circumstances. On migration, Peregrines have success rates reportedly as low as 7.5%. One unique male, in an area with abundant food in New Jersey, USA, had a reported success rate of 93% during the breeding season. A single hunting sortie in Peregrines can require as little as two minutes or as much as three hours, from the moment of leaving the perch through that of prey capture till that of returning to the perch. A male Peregrine in the Alaskan tundra was followed by helicopter, at sufficient distance not to cause the falcon any concern. On one hunt, he was followed for one hour, 20 minutes, during which time he made eleven stoops before catching prey. On another hunt, he travelled less than 30 m above the ground for 22 minutes, and achieved speeds of 112 km/h and 160 km/h in stoops. On yet another occasion, 23 minutes elapsed from his leaving the eyrie and returning with prey, which he caught on his second stoop.

With falcons generally, the time required for catching prey is related to: the age of the falcon; its experience and hunger level; prey density; the proximity and vulnerability of prey; time of day; and weather factors. Aerial insect- and bird-eating species, such as Sooty and Eleonora's Falcons and the Eurasian Hobby, are smaller than the aerial bird specialists and have relatively shorter toes, equivalent to 91% of the tarsi.

Caracaras are adaptable omnivores that are able to take advantage of whatever food source presents itself, and they often associate with man. The Mountain Caracara, for example, can regularly be seen at rubbish dumps, where it searches, mainly on foot, for scraps of carrion and waste, as well as small rodents and insects. This bird was feeding on excrements.

[*Phalcoboenus megalopterus*, Lake Poopó, Bolivia. Photo: X. Ferrer & A de Sostoa]

The Common Kestrel is an extremely efficient hunter, as is amply demonstrated by its abundance throughout much of its range, most notably in the heavily transformed habitats of Western Europe. Small mammals, such as voles and mice, can make up 90% of its prey, and these are often caught from hovering flight: the bird waits for the right moment, before swooping swiftly down on its prey. One of this bird's primaries has come adrift during this attack, but the kestrel has caught its mouse just the same.

[*Falco tinnunculus*,
Photo: A. Limbrunner]

Eleonora's Falcons sometimes pursue prey in groups, and J. Parrish and L. Clark recorded success rates of 71% thus, as compared with 68% for birds hunting singly. A pair of Bat Falcons caught 15 swallows in six hours. Ground-hunting kestrels, such as the Lesser and American Kestrels, have still shorter toes, equivalent to 65% of the tarsus. Their success rates vary somewhat, depending on whether or not they are perch-hunting, and whether they are feeding on insects or mammals. From a perch, success rate in American Kestrels is about 52%, but when they are hovering it is only about 14%; success rate on invertebrates is 85%, but on vertebrates only 23%. Lesser Kestrels are opportunistic feeders, and during the non-breeding season, when they are in Africa, they frequently hunt in small parties or large, disorganized groups. When insects are swarming, they hunt in flocks mixed with Red-footed Falcons and Eurasian Hobbies. They are particularly drawn to grass fires where insects are fleeing, and to areas where flying termites are emerging.

Ground-hunting generalists, such as the Brown Falcon, have long tarsi and short toes, with a ratio of 52%. This species has a very catholic diet consisting of grasshoppers, large frogs, lizards, snakes, beetles, rabbits and birds; they also feed on carrion. On Tasmania, about 80% of the diet in summer is made up of insects and reptiles, but in winter the main constituents are mammals and carrion, which contribute about 30% each.

Breeding

In details of breeding biology, the family Falconidae contains some of the best known, as well as some of the least known, of birds. Many falcons and their breeding habits have been studied for centuries, but, by contrast, the first forest-falcon nest was not discovered till the 1970's. Falconids are ostensibly monogamous and most nest as solitary pairs. They tend to be conservative breeders with rather stable breeding populations. A feature of their breeding is the division of duties between the sexes; the females brood, feed and defend the nestlings while the males do most of the hunting for the family.

The typical image of a falconid is as a solitary nester, yet more than 10% of the species nest in colonies, at least occa-

sionally, and many of these characteristically nest gregariously. These aggregations range from the dense colonies of Eleonora's Falcon to the loose, occasional colonies of the Striated Caracara. The former always nests colonially, with pairs as little as two metres apart, on rocky islands, preferring an array of sites whereby neighbouring pairs can not view each other from the nest. Where nest-sites are limited, caracara pairs sometimes nest less than ten metres apart, among grass tussocks or on rocky ledges. A colony of Lesser Kestrels, with birds nesting in the holes and ledges of a rockface, may number 100 pairs. Within all these colonies the birds breed as individual pairs. In contrast, communal nest guarding and brood care are reported for the group-living Red-throated Caracara, forms of behaviour that have not yet been observed in any other falconid. Such co-operative breeding may be related to the caracara's specialized foraging habits, as a lone pair may have difficulty sustaining a breeding attempt, although this can apparently happen on occasions; the subject warrants further study.

Odd instances of polygyny, a form of polygamy, have been recorded for the Common Kestrel, the Peregrine Falcon and the Merlin, usually involving a male attending females at two neighbouring sites. In other unusual threesomes, the extra bird was also a female, but did not breed: for example, 26 pairs of Peregrine Falcons in France were attended by an additional, generally first-year, female and achieved greater breeding success than lone pairs.

Most falcons are territorial breeders and, where food, habitat and nest-sites allow, spacing between breeding pairs is often fairly regular. Some species are resident in and around their nesting territory all year, whereas others migrate or wander, and return to re-establish territories just before the next breeding season. Larger species and bird-eaters tend to space themselves more widely than smaller species and eaters of mammals, reptiles or insects, but other factors are also involved. Communal nesters are usually dependent on prey that is abundant but transient, such as insect swarms or migrating passerine flocks, and around such prey sources nest-sites tend to be concentrated.

Even in the tropics, most falconids are seasonal breeders and breed annually. They often lay between late winter and

The Peregrine Falcon is one of the supreme predators. It takes mainly avian prey, which is habitually killed in mid-air, following a breathtaking stoop, in which the falcon may reach speeds of around 180 km/h. Note the elongated middle toe, typical of a bird-killer, which helps this immature bird to grip its prey, a Ring-necked Pheasant (*Phasianus colchicus*). As in the Accipitridae, falcons often perform a Mantling-display over their prey.

[*Falco peregrinus*.
Photo: A. & S. Carey/
Vireo]

early summer, but the timing ultimately depends on the seasonality of availability of the particular species' prey. Typically, the breeding season coincides with an influx of prey species, or an increase in their availability, or both, which continues or intensifies until after fledgling independence. Photoperiod and latitude have been shown to be related to the timing of breeding of some falcon species. Experienced birds tend to lay earlier in the season than inexperienced pairs. A few individuals of some kestrel species may breed twice in a good year, in spring and autumn. The falconets, at least the African Pygmy-falcon, sometimes produce a second brood, the same size as the first, as soon as two weeks after fledging the first.

Characteristically, members of the family do not build a nest, but simply rearrange the substrate of the nest-site to form a smooth depression to hold the eggs. This is achieved mainly by scraping with the feet and shuffling the body, with some moving of larger items with the bill. Some species, for example Australian Kestrels and Brown Falcons, may add a small amount of bark or leaves to line the nest cup. Although a few falcons are claimed to construct a nest, caracaras are the only substantiated exception; they often construct a nest of sticks from scratch, and line it with wool, dung and other matter. Many falconids are dependent on other species, including other raptors and corvids, to construct nests. In Southern Africa, the Lanner Falcon commonly breeds in raven nests on power pylons. In certain areas and for some species, breeding is constrained until a nest becomes available or can be appropriated.

The choice of nest-site can be flexible or fixed, both within and between species. Typically, the cosmopolitan Peregrine Falcon nests on cliffs. Where cliffs are scarce in areas of abundant prey and habitat, they may use other locally available sites: in Australia they commonly nest on cliffs, but also in large stick nests and large cavities in trees; in Finland they nest on the ground in bogs. The New Zealand Falcon nests on cliffs, in epiphytes, or on the ground under a log, rock or other object. Old rookeries are favoured by colonially-nesting Red-footed Falcon, whereas the *Microhierax* falconets usually breed in old barbet or woodpecker holes. Huge, active communal nests of sociable weavers, in open country, often provide nesting and roosting sites for a pair of African Pygmy-falcons. Likewise, the closely related Spot-winged Falconet uses the communal

nest of Monk Parakeets, but, unlike the African Pygmy-falcon, it sometimes supplants the parakeets. The crotch or cavity of a tree or a ledge on a power pylon have all provided a nest for the Laughing Falcon. Falconids nesting in stick nests may use an empty nest or evict the builder; for example, Grey Kestrels will evict Hamerkops (*Scopus umbretta*) from their domed nests. Increasingly, buildings and other imposing structures provide suitable sites for some cliff-nesting falcons. Preferred sites are usually sheltered from extreme conditions, such as prevailing winds and the heat of the day. Typically, falconids use a traditional nest-site, or an area with a few alternative sites, for generations.

The pair-bond lasts all year in resident species, but in those that spend the non-breeding season elsewhere the male tends to return to the nesting area first. The male appears to have greater attachment to the nest territory than the female and may perform spectacular, aerial territorial and courtship displays of his speed and agility, accompanied by excited chittering in at least some *Falco*. The pair may soar together, and one bird makes mock dives at the other, which rolls and presents talons. Pair-bonding in some forest-dwelling species, such as the forest-falcons, may involve spirited vocal performances. At dawn and dusk, the members of a nesting pair of Laughing Falcons join each other near the nest, to perch in an erect posture and perform a duet. Individual established pairs seem to display less vigorously than newly formed pairs. Females tend to prefer to pair with older males on the better quality territories and are more likely to change partners than are males, particularly after a breeding failure. Nevertheless, the majority stay with the same partner. During the pre-laying period, which may only cover three weeks in some migrants, conflict with an aspiring usurper or challenger sometimes occurs, usually involving an aerial chase and occasionally resulting in a fatality.

In many species the male escorts the female to potential nest-sites and sometimes displays at the site. Bowing, submissive crouching by the female, and whining and other calls, are components of a display at a perch, which may lead to copulation. However, copulation can occur without formality.

A remarkable aspect of copulation in falconids, and in raptors in general, is its frequency. For example, the Prairie Falcon

Many falcons are capable of catching prey considerably larger than themselves, although they normally seem to prefer prey species of more manageable sizes. The Red-necked Falcon habitually takes birds up to the size of doves. It is a dashing hunter that catches its prey after a rapid pursuit flight.

[*Falco chíchquera*.

Ardea]

copulates an estimated 194 times per clutch, spread over the pre-incubation period of 51 days, beginning weeks before the female's fertile period. Among the proposed explanations for such an apparent excess, the ideas of sperm competition and pair-bonding, which are not mutually exclusive, appear to have the most support. A male bird of prey provisions the female and is absent from his partner for relatively long periods, compared with birds that guard their partners, so the chance for extra-pair copulation and cuckoldry is high; frequent copulation enhances the chance of paternity. However, only three of 41 copulations were extra-pair in Merlins and none for a Prairie Falcon pair. This is not a high rate of cuckoldry, but, nevertheless, the cost of provisioning unrelated offspring is high and seemingly worth avoiding.

It might be expected that courtship feeding and copulation are connected. Although within pairs food does not appear to be traded for copulation, poorly fed females are likely to seek food from other males and copulate with them. Conscientious courtship feeding may therefore enhance mate fidelity.

Typically, the male hunts and brings food to the nest-site and the female flies out to meet him at a perch. He transfers the prey from his bill to his feet and offers it to her. When not hunting, and particularly during the female's fertile period, the male stays close to the nest. Courtship feeding appears to help the female lay down fat reserves for egg formation, and the few studies performed indicate that females in better condition are most likely to breed successfully. It may also allow her to judge whether the male will be a good provider, capable of supporting a breeding attempt.

The handsome buff eggs, well speckled with the dark red-brown of haemoglobin, are a feature of the family. The eggs are ovate, with one end slightly more pointed than the other, and the chemical composition and structure of the shell is also unique. As with all birds, within the family egg size is generally related to body size, and the more dimorphic species tend to have relatively small eggs. Compared with other bird groups, members of this family lay rather large eggs; for example, a 100 g kestrel lays a 15 g egg, whereas a dove of similar weight lays a 6 g egg. This is due in part to differences in the mode of development: the falcon chick hatches in a more advanced state than the dove.

Falconid species lay every second or, occasionally, third day, and if eggs are removed daily a female will continue to lay. Many falcons lay 3-4 eggs per clutch, but kestrels lay more and hobbies less. The hobbies lay a clutch of 2-3, whereas other small falcons and falconets lay up to 6 or so, and larger falcons up to 5 eggs. Species occupying harsher climes tend to lay larger clutches. Caracaras lay 2-3 eggs, and for the unusual Laughing Falcon 1 egg appears to be the norm, perhaps a characteristic of snake-eating raptors, including the accipitrid genera *Circus* and *Spilornis*. If a clutch is lost early in the season, many pairs will relay, starting a minimum of two weeks later.

In general, variability in the availability of food does not greatly affect clutch size, but prey scarcity may lead to non-breeding or a clutch being abandoned. Inclement weather, predators, parasites, human interference and other factors cause egg failure or nestling loss, which often averages approximately one egg per successfully breeding pair. Nesting density may also affect reproductive success. Falconids and other raptors are particularly sensitive to the pesticide DDT, which can cause them to lay thin-shelled eggs and result in egg breakage (see Status and Conservation). On average, clutches laid early in the breeding season are more successful than those laid later, and it often turns out that they are laid by the more experienced pairs. Unlike some of the accipitrids, falconids do not practice siblicide, but chicks that die may be eaten by their parents or nest-mates.

The commencement of incubation is variable even within species, but it does not usually begin at least until the second or third egg has been laid, so that hatching is often, but not always, fairly synchronous. Characteristically, falconids have a single brood patch. The bulk of incubation is carried out by the female, although during the day the male may relieve her for short periods, usually while she feeds or preens; occasionally in some species and some individual pairs the male may take over for longer. For annual breeders, moult usually commences during the egg-laying period for the female, and few weeks later for male. Roughly related to body size, the incubation period averages about 28 days for falconets and smaller falcons, up to 35 days for the large Gyrfalcon. After the chicks have hatched, the eggshells are often eaten; alternatively, they may be removed from the nest.

The Gyr Falcon, the largest and heaviest of the falcons, normally relies significantly on grouse and ptarmigans of the genus *Lagopus*, although ground squirrels and lemmings can be very important locally, as can some colonially breeding seabirds. Prey tends to be caught on the ground and it is often plucked and decapitated on the spot. A lone, unpaired male in Yukon, Canada, was recorded carrying prey back to its territory, where it performed a lengthy "Wail-and-pluck" display, apparently in an attempt to attract a female.

[*Falco rusticolus*,
Yukon, Canada.

Bauer/Bruce Coleman]

Most chicks take 24-72 hours to hatch. They are semi-altricial, rather helpless, and hatch in a sparse coat of white down, with their eyes sealed closed. They are brooded almost continuously, by the female, for about the first 7-10 days. Within a few days the eyes open, only about two days in kestrels and four in Peregrine Falcons, and by the second week a thick, woolly second down (preplumulae) has replaced the first. Growth is rapid and the wing quills begin to appear on about day 6 in the falconets, and day 9 in the larger falcons. The tarsus and bill are fully grown after about three weeks in kestrels and three and a half in Peregrine Falcons. Young are offered pieces of food by the adult, almost always the female, from their first or second day until later in the nestling period when the prey, sometimes partly plucked, may simply be left on the nest. The nestlings can tear prey by half way through nestling period, but they still prefer to be fed by an adult. About a week before fledging, falcon nestlings often reach higher weights than their parents, but this excess weight is lost over the following week. Fledging occurs after about 28-30 days in the nest for small falcons and falconets, up to 49 days for the largest falcons, and perhaps 8 weeks for caracaras. Males fledge a day or two younger than females.

After fledging, the young stay close to the nest, often returning to roost there at night. They gradually hone their flying and hunting skills, which they can learn to master even in the absence of parental guidance. Nevertheless, the parents, particularly the male, must continue to support them by providing some food, and they are often hounded by hungry fledglings. The fledglings of some migratory species, for example Eleonora's Falcon, are said to leave on migration as soon as 15 days after fledging, whereas others, such as the Lesser Kestrel, depart with their parents after 6-8 weeks. The fledglings of most species remain in their natal territory longer, often accompany the parents to hunting areas, and eventually leave after a period ranging from several weeks to several months. Larger species and those with greater size dimorphism tend to take longer to reach full independence, but the fledgling period is highly variable both within and between species, and can in any case be difficult to monitor.

Recent studies have shown that the sex ratio of nestling falcons is often biased, with broods raised early in the season

differing from those raised later. Interestingly, although female nestlings are larger and theoretically more costly to raise, the bias is not always towards males.

The evident difference in size between the sexes, with the female in some species reaching over 150% of the male's weight, has spawned a plethora of theories. Although none has gained widespread acceptance, in general intrasexual selection is thought to be a more influential source of body size differences than intersexual selection. The simplest argument is that in most species with RSD (reversed size dimorphism), the roles of the parents are different. Males provide virtually all the food to the female and young nestlings; because small adults are more agile fliers, small males are favoured. Females compete among themselves for high quality males with territories and nest-sites, and are therefore under intrasexual selection for competitive ability, and hence large size. Selection on the sexes therefore works in opposite directions. The degree of dimorphism is greatest in hunters of agile, difficult or dangerous prey, because there are relatively few competent breeding males in these species, so that competition between females is strong and selection for large size greater than in hunters of less difficult prey.

Small falcons are capable of breeding at one year old, before they attain adult plumage. Typically, larger falcons first breed at two to three years old, with males usually averaging a year older than females. Larger species can breed into their twenties, but smaller species probably for around 15 years. There have been few studies of sufficient scope, but these indicate that reproductive success may increase over the first few attempts, although it does not decline with old age. Lifetime reproductive success of falconids is virtually unknown and remains an exciting challenge for researchers.

Movements

Most species of falconid living in low latitudes and tropical areas, such as the caracaras, forest-falcons and falconets, are sedentary or dispersive. Those that do migrate, mainly members of the genus *Falco*, are principally diurnal migrants, but they tend to be well on their way at first light and may not roost for

The African Pygmy-falcon is remarkable in that it roosts and breeds in the nests of weavers. In southern Africa, it invariably occupies the huge communal nests of Sociable Weavers (*Philetairus socius*), and in the Kalahari region roughly a quarter of all such communal nests have pygmy-falcons resident. Occasionally, the species preys on its host weavers or their young.

[*Polihierax semitorquatus*,
Kalahari Gemsbok
National Park,
South Africa.

the night until after dusk. One Peregrine Falcon, with a radio transmitter attached, flew over open ocean right through the entire night. Some movements are over very long distances, with birds moving south from about 70° N to 35°–40° S. Most of the migration is accomplished by powered flight, so birds may put on weight by depositing extra fat prior to the migration; in the case of the American Kestrel, with a 4% weight increase over midsummer, females gain more than males. Some species, such as Australian Hobbies, follow flocks of migratory passerines that are important prey, and these species may, as with Eleonora's Falcon, catch and feed on prey on the wing; this habit might be especially important for flights over water.

Falcons in which all individuals of the species migrate are the Lesser Kestrel, the Red-footed and Amur Falcons and the Eurasian Hobby, all of which move from Eurasia to Africa, although the hobby is actually a local resident and breeder in areas of North Africa. Two other classic cases are Eleonora's and the Sooty Falcons, which move from the Mediterranean area mainly to Madagascar. The Merlin was at one time considered a completely migratory species, but some remain on their northern breeding grounds in the British Isles, Iceland, some central Asian mountains, for instance the Tien Shan, along Canada's Pacific Coast, and locally in parts of the Canadian south central prairies. Lesser Kestrels and Red-footed and Amur Falcons breed in social groups and often travel in mixed species flocks. Eleonora's Falcon, which breeds typically in rather dense social colonies, apparently migrates singly or perhaps in small groups.

Other species are partial migrants. For example, in one of the truly spectacular Northern Hemisphere migrants, the Peregrine Falcon, populations at middle to low latitudes are resident, with any movement dependent largely on weather and food supplies. Food loss shortly after breeding also determines, for example, when some Prairie Falcons move. Ground squirrels, which constitute the main food supply of this species, go into aestivation during the heat of mid-summer, shortly after the young falcons fledge, and thus the entire population of falcons disperses by mid-summer to find another source of food. In the Southern Hemisphere, movement may take place from south to north in the non-breeding winter season. The Australian Kestrel and Australian Hobby are partly migratory,

as each year some of the population moves north towards New Guinea, the islands of the Torres Straits and as far as Java and Bali.

Regardless of the extent of movement, falconids show a great deal of philopatry, a tendency to return to an area near their place of origin, when ready to breed. This tendency is responsible, in part, for the great geographical variation in such species as the American and Common Kestrels, and the Peregrine Falcon; geographical variation becomes fixed because of constancy in the gene pool.

The Crested Caracara demonstrates one of the problems in trying to understand movements among sedentary species. Throughout its breeding range it can be found in both summer and winter, even at the northern and southern ends of its range, in the southern USA and Tierra del Fuego respectively. This does not mean that given individuals stay put all year round, nor that they do not disperse nor wander. But identification of dispersive movements requires either good ringing data clearly showing any movements, or sightings of birds outside the normal range of that species or subspecies. In North America, some caracaras wander northward outside their resident range into New Mexico and Oklahoma at various times of the year.

Many such dispersive birds are presumed to be younger or non-breeding birds. For example, Australian Kestrels that reach New Guinea are mainly juvenile females. Likewise, in the Gyrfalcon, adults tend to remain on the breeding grounds while juveniles wander. Those Gyrfalcons that show up in the central USA south of about 50° N, some 2000 km south of the breeding grounds, are normally young of the year. However, in years of extreme food scarcity the entire population of the species may move south, so that adults show up in greater numbers. Some wandering juvenile Gyrfalcons with attached radio transmitters, tracked by C. McIntyre and R. Ambrose, were monitored from the ARGOS polar orbiting satellite system. Between 17th September and 18th October, one bird moved from the Seward Peninsula in Alaska some 3400 km to the Sea of Okhotsk, where it remained until signals ceased in March. Another moved from the Seward Peninsula on 12th August, to Anadyr in eastern Siberia by 17th September, and back to mainland Alaska near Norton Sound by 5th October, then south 800 kilometres to Kodiak Island in Alaska by 11th October, where

Falcons do not build a nest, but rather occupy some suitable existing site, which can be, for instance, a tree hollow, a cliff ledge or the nest of another species. The availability of suitable sites can be a limiting factor in some cases. The New Zealand Falcon has been found to have greater breeding success at cliff sites than on flatter ground.

[*Falco novaeseelandiae*.
Photo: M. F. Soper/NHPA]

it remained until February, when signals ceased. All sibling Gyrfalcon groups with radio transmitters attached had disassembled by 15th September, so that fledglings dispersed alone from their natal areas.

The Black Falcon of Australia is another example of a dispersive species with movements that are generally influenced by weather and food. During drought in the interior they may move to coastal areas, and there may be irruptive movements away from the interior, perhaps sparked off by food shortages. Certainly their seasonal movements are partly linked to movements and fluctuation in abundance of their favoured prey, notably quails and grasshoppers. They breed well during rat plagues and then disperse coastward as the rats die out, especially if a drought follows.

In the Northern Hemisphere some species perform "leap frog" migration, with those from farthest north wintering farthest south. For example, members of the Peregrine Falcon's Eurasian subspecies *calidus*, that breeds in the tundra zone, fly in a broad front over some resident populations of nominate *peregrinus* of the southern Eurasian taiga, over *brookei* of the Mediterranean area, and *pelegrinoides* of southern Asia and North Africa, to winter in the breeding ranges of the race *minor* of Africa, *peregrinator* of the Indian Subcontinent, and *ernesti* of south-east Asia and the Papuan subregion. Some taiga breeders of the race *peregrinus* also move south, flying over some of the same races, but wintering north of most members of *calidus*, so that they have a shorter migration, leaving from further south and stopping further north than *calidus*.

There are often sexual differences as seen in the American Kestrel, with females departing first, about eleven days earlier than males, and moving further south. Australian Hobbies and Kestrels that move away from Australia tend to be females, and after winter dispersals male kestrels tend to return to breeding areas earlier than females.

Migrations may take place over a broad front with some falcons, for example, making significant crossings over water. Common and Lesser Kestrels and Red-footed Falcons move in a broad front over the Mediterranean Sea, on their way from

Europe to Africa. Other falcons, such as Peregrine Falcons, move in a broad front over land but then many end up at concentration points along seashores. Some Peregrines end up in the middle of the Pacific Ocean, even south of the equator, several thousand kilometres from their starting points in the Northern Hemisphere. These birds may have been blown off course during migration, or they may have wandered that far as a natural part of dispersal.

Some well observed concentration points, or "bottlenecks", in the Old World, through which the falcons appear to funnel, are Israel, Cap Bon (Tunisia), Malta and Crete. In North America and the Neotropics, typical routes follow the Atlantic seaboard, in Maryland, New Jersey and Florida, while others include the Texas Gulf Coast, Veracruz (Mexico) and the Pacific seaboard of Ecuador and Peru. These migratory concentration points provide important data for judging the population status and trends in some species. For example, at Assateague Island in Maryland (USA) only 41 Peregrines were counted in 1972, when their populations were at low numbers following biocide reductions, but a peak of 813 were counted in 1989, when Peregrines were well on their way to recovery.

Two interesting examples of migration are provided by the Amur and Eleonora's Falcons. The former leaves its breeding grounds in eastern Siberia and northern China in the autumn, taking a route south of the Himalayan massif, across India. Then the birds must cross the Indian Ocean, before hitting land in East Africa, generally south of Somalia, and moving on to winter on mainland Africa mainly between Malawi and the Transvaal of northern South Africa. In spring, they take a different route, passing northward through Somalia, Arabia and Afghanistan, and thence to their breeding grounds. Over parts of both migrations the falcons travel in the company of large flocks of Lesser Kestrels. Eleonora's Falcon breeds in the Mediterranean and North African region from the Canary Islands east to Cyprus. In autumn, movement is eastward through the Mediterranean, then southward, down through Suez and the Red Sea, thence around the Horn of Africa, to end up mainly in Madagascar. Birds from the Canary Islands and coastal West

Merlins nest on trees, cliffs or the ground, depending on local availability. Three to six eggs are laid, and these are incubated for 28-32 days by both sexes, although the male tends to relieve the female only for rather short spells, as is the norm within the family.

[*Falco columbarius*.
Photo: Dennis Green/
Aquila]

Africa must move north-eastwards first, into the Mediterranean, before proceeding east. Few are known to occur inland in North Africa, nor are many seen far inland in East Africa. Some do end up, however, not in Madagascar but on the mainland of southern Africa, as much as 400 km inland. Because the species breeds between late July and early September, young birds must set off on the long journey to their winter quarters only about 15 days after fledging!

Relationship with Man

Although falcons and their kin do not have as long a recorded association with man as do some very large raptors, such as eagles and condors, nor do they generally have the same element of folklore surrounding them, nevertheless there have been many close links between falconids and man over the years.

Forest-falcons are secretive, and generally poorly known, so would rarely attract the attention of man. Falconets are small and similarly do not elicit the sort of attention that could give them a very intimate relationship with man. Caracaras, however, were important in early civilizations of Central America. In AD 1325 the Aztecs began to build the city of Tenochtitlan on a rise of land within the lake where present day Mexico City stands. The ancient omen to be looked for, according to Aztec legend, was an "eagle" perched on a cactus eating a snake. Apparently, when what was presumably a Crested Caracara was seen sitting on a cactus, that was fulfillment of the omen, and the caracara thus became the necessary "eagle". Today, the caracara is the national emblem of Mexico. The caracaras also have a place in the folklore of Ecuador and Peru: one mated with domestic fowl is said to produce a highly desirable fighting cock. Perhaps this is a logical connection for native peoples to make, as caracaras do strut around on the ground rather like chickens, and they are also aggressive.

Most of man's relationship with falconids, however, revolves around the genus *Falco*. At least in the period

2400-2500 BC falcons played a major role in Egyptian religion and mythology. Horus, the Egyptian sky God, or God of the heavens, took the form of a falcon. In fact, there arose several distinct falcon Gods, one in particular was at Nekhen, a place known to the Greeks as Hierakonpolis, meaning "falcon town". Horus was sometimes depicted in Egyptian paintings as a king or ruler, as well as in the form of a God. The eye of Horus had health giving properties and was a popular amulet. It is really not clear what falcon Horus was depicting. Since the Lanner Falcon is a large, conspicuous falcon of that region, often nesting on pyramids and other man-made structures, this may be the falcon on which the Horus representation was based. The desert race *pelegrinoides* of the Peregrine, known as the Barbary Falcon, may be a good candidate too. As sacrificial gifts, preserved "falcons" wrapped in fibre, as though in a burial state themselves, were offered to Horus. At one tomb near Saqqarah, Egypt, dating to 1000-2000 BC, these sacrificial "falcons" number in the thousands. Most are too small to be a Lanner or a Barbary Falcon, and while the number seem too great for them all to be falcons, those few that have been unwrapped have, in fact, proved to be *Falco*, although the species remain unidentified. Because of the small size of the "mummy falcons" they may be small flocking species, such as Lesser Kestrels, that move through the region during migration. It would be an intriguing study to determine the true nature of the species that comprise these "falcons". Old Testament Biblical writings may also refer to a falcon, though not by name in most contemporary translations. The keen-eyed bird of Job, is taken from the Hebrew *ayyah*, meaning "echoing" or "a screamer". The more precise translation for that bird would be "falcon" rather than the "vulture" of most translations.

The Brown Falcon figured importantly in the life of some Australian Aborigines, not only for food but in their legends, such as those dealing with fire. This may have been because the Brown Falcon frequents fires to catch birds and insects flushed by the flames and smoke. Aborigines even went to the extent of lighting bush fires, to their advantage in hunting too,

The semi-altricial chicks hatch with a sparse coat of whitish down, but by the second week a second, thicker coat has already replaced the first. The female Greater Kestrel stays with her brood constantly at first, probably in order to protect them from potential predators, such as crows. The male has to supply all the food at this stage; he delivers it to the female, and she feeds the chicks. Note the adult's pale cream iris, which gives rise to the species' alternative name, White-eyed Kestrel.

[*Falco rupicoloides*
rupicoloides, South Africa.
Photo: J. J. Brooks/Aquila]

so they would have been very familiar with the falcon. In fact, the aboriginals had 29 names for the Brown Falcon, as compared with 20 for the familiar Australian Kestrel and 10 for the Peregrine.

In 1741, during Vitus Bering's historic Second Kamchatka Expedition, when Europeans first encountered Alaska and Aleut natives, Georg Wilhelm Steller recorded the use of falcons in Aleut practices. Steller wrote that, tied to a long stick were two falcons' wings, which the Aleuts laughingly threw into the water towards their boat; he could not tell whether it was meant as a sacrifice or a sign of good friendship. Regardless of the meaning, the stick with falcon wings attached was certainly an important part of Aleut culture. Peregrines are abundant in the Aleutian Islands, often nesting in very accessible locations, so they would have been of easy access to Aleuts.

There has been no closer relationship between man and the falconids than through falconry, and R. T. Peterson wrote that "man has emerged from the shadow of antiquity with a Peregrine on his wrist". The sport of falconry probably had its origin in the dusts of ancient Persia, Arabia, India and China, most certainly as early as 2000 BC, but the earliest recorded images are from the Middle East, dating to about 720 BC. Falconry was known to be extensively practised in China by 650 BC and throughout much of the Far East around AD 300-700. Perhaps the peak of historical falconry, often called the sport of kings, occurred in the period AD 500-1600 among Europeans and Asians. Certainly the great Genghis Khan in the twelfth century was an avid hunter with falcons, as were the royal courts of Britain in the sixteenth and early seventeenth centuries. Falconry must have been a part of everyday life during that period in Britain; even nuns took their falcons to chapels. Shakespeare referred to falcons or falconry in 17 of his plays, for example: "as confident as is the falcon's flight against a bird," or "as...the falcon her bells, so man hath his desires." There was great demand for large falcons, especially white Gyrfalcons, and this resulted in a rather significant trade of birds from Greenland and Iceland (see Status and Conservation).

The sport has probably never been more popular than it is today with perhaps 10,000-20,000 practitioners. Falconry is most identified with the large falcons, such as the Gyrfalcon and the Peregrine, Saker and Lanner Falcons; it has perhaps never been a part of any culture more than in the Arab and Persian worlds. In any given year as many as 3000 falcons are

being trained in the Middle East, 90% of them female Saker Falcons.

As a result of the controversy, problems and negative impacts associated with collecting the birds from the wild, many species are now being bred in captivity for the sole purpose of falconry. Apart from zoos and the breeding of falcons for falconry, many falconids have been bred in captivity for research projects, or simply for amateur interest. Pygmy-falcons, *Microhierax* falconets, and at least 21 species of falcons have been bred thus. Many of these species have been hybridized, mainly by means of artificial insemination, and the implications arising from the results help to support some systematic conclusions. Many of the hybrids have proved to be infertile, depending on the gender, such as a Prairie Falcon crossed with a Peregrine Falcon, or the offspring of a Peregrine and Gyrfalcon being back-crossed with one of the parental types. Outcrossing, such as trihybrid crosses, also produce young. Much of the captive breeding effort started because of the deleterious effects of synthetic chemical biocides, and subsequent efforts to bolster or reintroduce populations that had been reduced or eliminated (see Status and Conservation). Because of the ease of captive breeding, no species of falcon need ever become extinct.

Some falconids have adjusted well to urbanization. For instance, caracaras frequent rubbish dumps, and falcons, such as Peregrines and kestrels, breed on city buildings, smoke stacks, billboard road signs along heavily used roads, and on major bridges joining urban areas.

The names of falconids, in particular the falcons, appear in many ways in everyday life, without our perhaps being truly aware of it. A large housing development near a lake, used as a Peregrine Falcon release site during reintroduction efforts in Utah (USA), was named Peregrine View Estates. Professional as well as secondary school sports teams carry their names: the American football team Atlanta Falcons in Georgia (USA), for example. Some place names are also taken from falconids. In the Brazilian state of Bahia, there is the town of Caracara; Caracara is, in fact, an indigenous name thought to resemble the call of the bird. Other examples are the state of Falcón in Venezuela, Falcon Reservoir on the border between Texas (USA) and Mexico, Falkenberg in Germany, Cap Falcon in Algeria, Capo del Falcone in Sardinia, Falconara Marittima in Italy and Falcon Lake and Peregrine Creek in Alaska. One mountain peak in northern Alaska is named Okiotak Peak, the name coming from Nunamiut Eskimo for "one that stays all

The Common Kestrel, extremely well adapted to environments heavily altered by man, nowadays frequently nests in or on buildings, particularly bridges or church towers. As in other falcons, the male has to do most of the hunting during the first part of the nestling period, while the female stays with the chicks and broods them. Since hatching tends to be fairly synchronous in falconids, the size difference between siblings is less marked than in some of the Accipitridae, although it can still be substantial, as is clearly visible in this brood, especially as female chicks tend to be larger than male ones. Nevertheless, the sibling aggression that typifies some eagles is not found in the Falconidae, so if food is sufficiently plentiful the youngest chicks too can be successfully raised.

[*Falco tinnunculus*.
Photo: Eric & David
Hosking/FLPA]

The Grey Kestrel usually breeds in a Hamerkop (*Scopus umbretta*) nest, either occupying a disused nest, or even, on occasion, ejecting the Hamerkops. Because of the security offered by the huge, elaborate nest, the female can leave the chicks alone unusually early and go off to help the male with the business of searching for food; she normally stays with the chicks only for the first five days.

[*Falco ardosiaceus*.

winter", and referring to the Gyrfalcon; historically, falcons used a conspicuously prominent cliff on that mountain slope.

Status and Conservation

Taking the family as a whole, the Falconidae have fared quite well relative to other raptors, and only one falconid has definitely become extinct in historical times. Nevertheless, all species are included on Appendix II of CITES, except those that are on Appendix I. The species classified as most threatened are all falcons or forest-falcons.

As with most animals during the present century, the sheer density of the human population has reduced the amount of habitat available, and unless species can adjust to human alterations they are eliminated. For example, the building of homes in canyon mouths below cliffs and the turning of native shrub-steppe habitat to agricultural use have locally reduced populations of Prairie Falcons. This falcon has not adjusted to human encroachment in the same manner as the Peregrine Falcon, and it has disappeared from areas adjacent to most conurbations. The continuing commercial logging of tropical forests or their conversion to agriculture must have serious impacts on the forest-falcons, and perhaps also on falconets, that otherwise are seemingly quite secure. Alterations of habitats have both negative and positive effects on falconids. Australian Kestrels and perhaps Black Falcons appear to have expanded their ranges with the clearing of forests, and the man-made permanent water bodies scattered across Australia have probably benefited many *Falco* species, particularly in arid regions. Chimango and Crested Caracaras have benefited from the increasing amounts of carrion and human refuse available. Some caracaras, in particular the Chimango and Yellow-headed Caracaras, seem not to have been adversely affected by habitat alterations, but have probably suffered from direct human persecution.

Two caracaras in particular have suffered considerably at the hands of man, one of them to the extent that it became extinct, the only falconid definitely known to have been lost in modern times, at any rate since 1600. The Guadalupe Caracara was restricted to Guadalupe Island, a small 32 x 10 km

island, 225 km west of the coast of Baja California, in north-west Mexico. This species was completely eliminated by direct and deliberate human persecution. E. Palmer secured the first specimen, which eventually ended up in the hands of R. Ridgway, who described it as a species new to science in 1876. Little did Palmer realize that within 25 years the species would be extinct. The caracara was called "Calalie" by locals on the island, and Palmer wrote that it "...is abundant on every part of the island; and no bird could be a more persistent or more cruel enemy of the poultry and domestic animals. It is continually on the watch, and in spite of every precaution often snatches its prey from the very doors of the houses." Local inhabitants shot caracaras to protect young Angora goats. Caracaras were described as attacking kid goats, sometimes grabbing the kid's tongue and pulling until it was ripped out, leaving the kid to starve to death. By 1885, mention was made of how easily caracaras could be killed with a rifle, when they came to drink from shallow pools; if missed, they would take not the slightest notice of the shot, and would wait quite unaware of their peril. In fact, populations had been so reduced by 1885 that on a two day excursion on the island W. E. Bryant saw only four birds. The final blow seemingly came, unfortunately, from scientists rather than from locals. The scientific collector R. Beck was on Guadalupe on 1st December 1900, when, from a flock of eleven birds flying over, he shot nine, and remarked in a letter "...judging from their tameness and the short time that I was on the island, I assumed...that they must be abundant." None was seen after that. Ironically, the people raising goats left the island shortly after the last caracara had died.

Fortunately, the Striated Caracara has fared rather better. Also an island form, it has a much wider distribution, but is nonetheless restricted to the Falkland Islands east of the southern tip of Argentina, and several islands south of the Beagle Channel on mainland South America. Charles Darwin remarked, during his visit to the Falkland Islands in 1833 and 1834, that the caracara was "exceedingly numerous at the Falklands" and was "extraordinarily tame and fearless, and constantly haunted the neighbourhood of houses to pick up all kinds of offal." Its tameness and habit of preying on weak lambs or sheep was its downfall. Persecuted ruthlessly by

The breeding habits of most of the caracaras is still rather poorly known. One significant difference between these species and the other members of the family is that the caracaras build nests. The Striated Caracara builds a fairly simple nest of dry grass and lines it with wool, if available. In the Falkland Islands, young birds are apparently independent of their parents by March, some three months after hatching.

farmers, by 1910 it had decreased over much of the Falklands, and even today it is generally confined to the extreme west side of West Falkland, outlying islands farther west, and a few islands by the South American mainland, to the south of the Beagle Channel. There are no estimates of population size, probably because of the remoteness of the habitat, but 200 were estimated to be on Barnavelt Island in the 1920's; the species is locally numerous, and seems to be secure for the present.

Two of the six species of forest-falcons have relatively extensive distributions, covering enormous expanses of Neotropical forest, and two others seem fairly common in appropriate habitat. Buckley's Forest-falcon (*Micrastur buckleyi*) is known from very few museum specimens and sight records from Amazonian Ecuador and adjacent north-east Peru. In 1992 it was also reported from Brazil, but the record has now been withdrawn. Seemingly rare, it is so poorly known that most comments about its status are necessarily speculative. The Plumbeous Forest-falcon may be equally rare. It is confined to a very small region on the Pacific slope of south-west Colombia and adjacent north-west Ecuador, in the province of Esmeraldas, and to date all sightings have been made at altitudes below 1000 m; likewise, there are no population estimates. Reliable data on both of these species are particularly hard to come by because Buckley's Forest-falcon is a smaller version of the Collared Forest-falcon and may be confused with it, while the Plumbeous Forest-falcon is sympatric and easily confused with the superficially similar and common Lined Forest-falcon. Deforestation, taking place in the range of both of these apparently threatened species, and the growing human population in Esmeraldas are the current threats to their security, especially if they really are rare. The Slaty-backed Forest-falcon, in spite of its apparent rareness, is not listed in the 1992 Red Data Book of the Americas, perhaps because it has such an extensive range. Surveys may yet show that these three forest-falcons are actually more common than is currently believed, as has proved to be the case with the Lined, Barred and Collared Forest-falcons. The three latter species have been found to have high populations in some areas with home ranges of about 67, 114, and 712 hectares respectively, and in some cases the home ranges of

conspecifics abutted. This genus was so poorly known that nests were not found until 1978, but once it was discovered where exactly to look for them some 50 nests have been located, mostly in Guatemala.

Deforestation is also the main threat to the falconets, although again they are not very well known in general. As most of the species tend to favour forest edge and clearings, rather than the deep interior of the forest, they may be able to withstand a certain amount of habitat alteration, but certainly not complete deforestation. H. Miranda's studies on the Philippine Falconet showed that the species is not seriously threatened except on some of the smaller or medium-sized islands like Mindoro, Negros and Cebu. Population sizes and trends are generally unknown for the genus.

The falcons are the most intimately known members of the Falconidae. Population estimates have been made for many and because of their high profiles have attracted much attention, especially during the major pesticide period from the 1950's to 1970's. The species listed under CITES Appendix I are the Seychelles Kestrel (*Falco araea*), the Mauritius Kestrel, Laggard and Peregrine Falcons and the Gyrfalcon, as well as the possible Aldabra race *aldabranus* of the Madagascar Kestrel (*Falco newtoni*). Recent studies of the Seychelles Kestrel show it to be at carrying capacity on the islands of Mahé and Silhouette, and far more widespread and common than had been thought. It became extinct on Praslin, due primarily to human persecution, which was particularly favoured by its exceptional tameness. A century ago it was thought to occur on several other nearby granitic islands from which it is now absent. In 1981, a total of about 420 pairs was estimated for the islands. The possible subspecies of the Madagascar Kestrel that is confined to the atoll of Aldabra might have a population of about 100 birds. This species might be in a more serious state than some others, because its main population is on Madagascar where habitat degradation and human overpopulation are major problems. Nevertheless, the Madagascar Kestrel actually seems to have benefited from deforestation, and in 1982 it was estimated to number some 30,000-60,000 pairs. Definitely vulnerable, due to low numbers, are some distinctive island races of the Peregrine Falcon: those confined to the Cape Verde Islands and to the Volcano Islands, south

of Japan, may number only a handful of individuals; another race of Fiji, Vanuatu and New Caledonia is very rare, with perhaps only 100 breeding pairs, although it has probably never been much more numerous.

Some falcons are declining over considerable areas. The Lesser Kestrel, in spite of large numbers and a extensive range, is declining over much of the Western Palearctic for reasons that are not altogether clear, although habitat loss and the use of pesticides are probably the main causes. Also declining over most of its European range is the Lanner Falcon, and while pesticides are again thought to be one of the main causes, shooting and removal of birds for falconry constitute other important factors. The Saker Falcon has declined in central and south-east Europe because of a food shortage caused by habitat alterations, but the adaptability of the species may save it. Ground squirrel populations were so severely reduced in the Ukraine and Volga River Delta region that the Saker Falcon essentially disappeared as a breeder until it switched to a secondary staple food, the Rook (*Corvus frugilegus*). In addition, specific tree types in which Sakers typically nested were removed, another factor which hastened the decline; their recovery in the Ukraine was aided by their ability to take over unused stick nests of other species on high tension power poles, while in the Volga Delta region they began nesting in Rook colonies.

Other species are naturally rare, and some with small island populations where human numbers are increasing and habitat decreasing, may be under threat. The Orange-breasted, Grey and Taita Falcons seem to be in the category of naturally rare species. Until the past couple of decades, however, only a handful of Taita Falcon eyries were known in such scattered locations as Kenya, Mount Elgon in Uganda, the Shire Valley in Malawi and the Zambezi River gorge between Zambia and Zimbabwe. Now, several eyries are known on Mount Elgon and at least six within Zimbabwe, while the species has recently been found nesting in South Africa. Nonetheless, wherever studies have been made, researchers believe that when the Taita Falcon occurs alongside the Peregrine Falcon it is forced to accept less favourable cliff nest-sites, resulting in low nesting success. Apart from rareness possibly caused thus by competition with the Peregrine, the Taita Falcon is also under some threat through a proposed dam in one of its major known strongholds along the Zambezi River. As insurance against the loss of that population, it is now being bred in captivity for release into the wild, should this become appropriate.

Some 1000 pairs is the most current estimate for the little studied Grey Falcon. Its range has shrunk, probably due to habitat alteration, but its main habitat, the vast arid interior of Australia, is not under imminent threat, so that the falcon seems relatively secure in its rarity.

P. Jenny and colleagues have been studying the Orange-breasted Falcon since 1979, and 13 nesting sites were known to them by 1992. Certainly, fewer than 25 eyries have been found throughout its immense Neotropical range, and perhaps half of the known eyries occur in Belize. The habitat of this species, expansive unbroken canopy in climax forests, is under threat from a fast-growing human population, with the accompanying problems of logging, slash-and-burn agriculture and livestock grazing; by some estimates there might be no more than a few hundred to a few thousand birds left throughout the entire Neotropics.

The Banded Kestrel was considered rather common in some parts of Madagascar in the 1930's, but it may now be rare throughout much of the island, and indeed there may only be several hundred to 1000 pairs remaining. Fortunately, it seems not to be dependent for survival on the virgin forests in which it evolved, and in places it has now moved into cultivated land near second-growth forest, and also into degraded rain forest. Nevertheless, forests in Madagascar are so intensely degraded and habitat alteration is happening at such a rapid rate that the future of the kestrel can not be viewed with complacency.

There are five main ways in which humans have had direct impact on the status of different falconids, over variable periods of time: systematic persecution through shooting and trapping; egg-collecting; falconry; habitat conversion or alteration; and synthetic chemical biocides. While each of these factors has differed in importance through time and some may have had great local impact, only the latter two seem to have reduced breeding populations permanently, and even then, when biocides were banned, populations began to recover.

Systematic persecution seems to have been mainly important between the eighteenth century and the early twentieth century. Well chronicled histories were recorded primarily in the Northern Hemisphere, and while it is certain that many falconids were likewise persecuted elsewhere, for instance in South America and Africa, it seems that large hawks, eagles and vultures were probably the main targets. Much of the killing of falcons in Europe was by gamekeepers, or bounty-killing of what was regarded as "vermin" (see page 92). For example, on one estate in Glen Garry, in the highlands of Scotland, a gamekeeper reported that between 1837 and 1840, 98 Peregrine Falcons, 78 Merlins, and 462 Common Kestrels were killed. In Finland, in the period 1900-1960, rewards were paid on 35,267 falcons, with 84% of them killed before 1926. The list could go on and on for most European countries, and

Several caracaras are closely associated with man. In central Chile, for example, large numbers of Chimango Caracaras gather around shellfish processing factories, where they search in the heaps of discarded shells for scraps to feed on.

The Banded Kestrel is endemic to Madagascar, where it is found mainly in forest edge and woodland habitats. Although it is still locally common, it is currently declining, as a result of deforestation, and only limited amounts of suitable habitat now remain. In all, no more than 1000 pairs are thought to survive.

[*Falco zoniventris*, Madagascar.

Until recently, virtually nothing was known about the forest-falcons, mainly due to their very secretive nature; indeed, no nest of the genus was found until 1978. However, as a result of the Peregrine Fund's Maya Project in the Tikal National Park in Guatemala, much has now been discovered about two of the species, the Collared Forest-falcon, seen here, and the Barred Forest-falcon (*Micrastur ruficollis*). They are now known to be considerably commoner than was previously thought.

[*Micrastur semitorquatus*, Tikal, Guatemala. Photo: Craig J. Flatten]

North America had no better record. Thousands of falcons were killed during their concentrated migrations at Hawk Mountain, Pennsylvania (USA), even right through the 1930's, after it had been declared a sanctuary in 1934. The Peregrine Falcon was killed for bounty paid by racing pigeon fanciers in Tasmania as late as 1972, and about 50-100 were killed annually, many at the 100 or so eyries on the island. Though no legal or official bounty is offered, it is thought that about 10-20 Peregrine Falcons and 100 Brown Falcons are still trapped annually by pigeon fanciers in Tasmania. The systematic killing of falcons, as of other raptors, was partly a result of their being categorized as destructive, in most cases by what was known as the "usefulness principle". In 1867, in an ornithological publication that was almost a handbook of raptor destruction, special instructions were given on how owls might most effectively be used as lures in attracting and destroying Eurasian Hobbies, Peregrines, Merlins and kestrels. In 1874, the most important German ornithological journal urged the shooting of Eurasian Hobbies and Peregrine, Lanner and Saker Falcons, but suggested that the Common Kestrel should be excepted from the recommendation. The rate of deliberate killing is indicated by data from the period 1913-1962 in Finland where, of 2135 Common Kestrels ringed, with a 6% recovery rate, 53% were reportedly shot or killed in traps. Based on returns of rings, the rate of Prairie Falcons killed by humans up to 1979 was 65%.

A shift in public attitudes and perception toward falcons, starting in the 1950's, may have been an important factor in reducing persecution. In Britain, for example, the number of ringed falcons reportedly killed by man prior to 1954 and after 1954 were respectively, for the Common Kestrel from 41% down to 10%, for the Merlin from 52% down to 16%, and for the Peregrine Falcon from 56% down to 22%. Some falcons killed by humans may not have been reported as such, simply because of publicity against such acts after the 1950's. Fortunately, the systematic persecution and killing has stopped in most developed countries, with a few notable exceptions, such as Malta. It is hard to assess the long-term impact of such systematic persecution on populations, partly because some species have proved to be very resilient. This is illustrated by data on the killing of Peregrine Falcons in Britain during World War II, mainly between June 1940 and February 1946. Because Peregrines killed carrier pigeons with important messages for the war effort, the Secretary of State for Air signed the Destruction of Peregrine Falcons Order, in an attempt to reduce or eliminate the problem. Over 600 falcons were shot during that time, a good many of which were breeding pairs. Estimates are that the entire British population was reduced by about 13%, but some local populations were virtually eliminated. Once the killing stopped, recovery was rapid, and the species was well on its way back within 10 years.

However, as has been seen, direct persecution certainly eliminated the Guadalupe Caracara. Deliberate killing still occurs on a wide scale wherever people own firearms, especially in South America, Africa and Asia, but its effects are probably not generally as severe as in the past. Inadvertent killing goes on in numerous ways. For example, in 1992 it was discovered that perhaps 1000 Gyrfalcons are caught in fox traps annually in Yakutia, Siberia; extrapolating this across the Russian Arctic gives an estimated 2000 Gyrfalcons killed annually by fur trappers. In Australia, 21% of reported deaths of ringed Peregrine Falcons since 1971 were, rather surprisingly, due to collisions with automobiles. Indeed, collision with man-made objects, such as cars, powerlines, windmills and windows, is known to be a major cause of injury to falcons. Secondary poisoning, from poisons targeted at rodents, foxes and dingos in Australia, kills ground foragers, such as Brown Falcons, that are also active scavengers; secondary poisoning also affects some caracaras locally.

Egg-collecting was another of the practices to have a significant impact on falconids, and, in fact, ornithology was nearly synonymous with egg-collecting during the period 1870-1920. Falconid eggs are particularly desirable because of the beautiful mottling and flecking of shades of red, brown, cream

and white. Large falcon eggs had a particular monetary value and literally thousands of clutches were collected. In Dorset, England, the collector Arthur Blinn reportedly took 64 Peregrine Falcon eggs, amounting to about 20 clutches, in 1928 alone, and there is a well publicized picture of him with a coil of rope and a large pile of blown eggs on top of the Dorset cliffs. Again, however, the impact of egg-collecting was probably temporary, especially since habitat was not lost and breeding adults seldom killed in the process.

Falconry falls into much the same category, and its true effects on populations is unknown. Data from Iceland, gathered by O. Nielsen and G. Petursson, show that between 1731 and 1793 a total of 4848 Gyrfalcons were exported from Iceland to Denmark, and thence into the falconry community; of these birds, 4318 were grey local falcons from Iceland, and 530 white migrants from Greenland. Most of these birds were trapped or taken from nests in western Iceland, and as long as the population was healthy in other parts of Iceland (or Greenland, in the case of migrants), whence replacement birds could come, there seems to have been no permanent loss. Today, the Gyrfalcon population in western Iceland is at carrying capacity. Saker Falcons in the Middle East are particularly coveted, and by most estimates some 3000 are held in captivity in any given year. Based on information from 1982, however, there may be over 20,000 breeding pairs over the entire Eurasian range of the species, so at present the number trapped each year may not be too serious a percentage of the total population. Habitat and food resources for the Saker have decreased over the last two or three decades, especially in eastern Europe, and if the trend continues into the next two decades the situation for the Saker may change significantly.

One of the main factors adversely affecting many, probably most, bird species, and indeed most forms of wildlife throughout the world is the degradation and destruction of natural habitats. As the majority of falconid species are mainly associated with fairly open habitats, rather than closed forest, they are probably less affected by it than most other Falconiformes (see page 96). However, most of the forest-dwelling species and even some that inhabit open areas, notably the Lesser Kestrel, are in regression for this reason. Nevertheless, rather than straightforward destruction or conversion, the most serious way in which most falconids suffer from the impover-

ished habitats may well be through the contamination of the environment.

The organochlorine pesticides DDT and its most important metabolite, DDE, the cyclodienes dieldrin and heptachlor, and polychlorinated biphenyls, or PCB's, have all had serious effects on falconids. The major effects of these chemicals started in the late 1940's, and they reached a peak in the late 1960's and 1970's, although by this time most had been banned in developed countries. Their residues still linger on today, but not with the devastating effects of the 1960's and 1970's. They affect falconids in several different ways. Perhaps the most publicized effect is eggshell thinning, which is caused only by DDT: it can occur to such a degree, usually 17% thinning, that the eggs break. The two other main consequences are embryo deaths in contaminated eggs, and occasional adult mortality. In the Peregrine Falcon, the species most severely affected, a value of 15-20 parts per million of DDE (wet weight) was associated with 17% eggshell thinning and subsequent reproductive failure. Bat Falcons and American Kestrels respond at similar levels to Peregrines, but Prairie Falcons and Merlins are more sensitive. In Australia, three species still showed some eggshell thinning in the 1990's: the Australian Hobby with 2.4%; the Grey Falcon with 6.1%; and the Peregrine Falcon with 10% thinning, down from a maximum of 38% thinning in the 1970's. In Africa, eggshell thinning in the 1970's was as high as 22% in the Peregrine Falcon, but by the 1990's it had declined to about 10%, while the Lanner Falcon had comparable thinning and the Taita Falcon showed about half that amount of shell thinning. In the 1970's, South American Peregrine Falcons had about 15% shell thinning, and Crested and Chimango Caracaras, both omnivorous species, showed traces of DDE and PCB's. In Florida, USA, on the other hand, in the

1970's, the Crested Caracara showed levels of about ten times more DDE, although even these amounts were not deleterious. At the moment no species is known to be declining as a direct result of chemical contamination.

Two of the most successful stories in avian conservation biology have been centred on the Mauritius Kestrel and Peregrine Falcon. In the 1850's the Mauritius Kestrel was said to be plentiful wherever the indigenous woods remained. Because of the small size of the island, in conjunction with the territory size of the species, even at the best of times the peak population was thought probably not to number more than a few hundred birds; indeed, in 1982 the highest estimate available put carrying capacity at 328 pairs. The species declined over the decades as a result of habitat alterations and a few other factors, and by 1960 it was thought that only 10 pairs remained. At its lowest population level, at the start of the 1970's, only a single pair and two solitary birds could be found. The total number was unknown, but almost certainly there were more, because in 1973 at least nine birds could be accounted for. During the 1970's, some were taken into captivity for breeding, but success was limited. At the start of the 1980's, all six kestrels in captivity in Mauritius died, while the wild population was estimated to be only 15 birds. However, since the late 1980's captive-bred young, reared both in Mauritius and at Boise, Idaho (USA), have been released into the wild each year, with the 300th released in November 1993. As a direct result of this bolstering, by the 1992-1993 breeding season 45 territorial pairs were known, while 50-55 pairs were suspected, with a floating population of roughly one bird per pair. In November 1993, 50 wild pairs were counted and about 10-15 more were estimated, with perhaps 215-240 birds living in the wild. Aerial photographs of Mauritius taken in 1993 showed there to be over 300 km² of possible habitat for kestrels on the island. In all, it was estimated that the habitat could hold a minimum of 150 territorial pairs, and allowing for pairs in marginal habitat and non-breeding birds, a total population might reach 500-700 kestrels. This is about twice the 1982 estimate for the original population size at carrying capacity. Much of this increase was possible because rather than being tied to native forests as was originally thought, young birds were released into a variety of alien habitats, including open exotic savanna, river valleys, and fragmented native forests, and in such areas they have become successfully established; one pair even lives in a village. The adaptability of the species in capturing a wider range of prey, and in broadening habitat preferences has proved to be greater than thought. Nevertheless, as a warning regarding the cases of all such island endemics, it is worth noting that there is evidence that, like neighbouring islands, Reunion too probably had its own endemic kestrel species; it seems that this form was probably wiped out when the early European settlers arrived, without a specimen ever reaching the hands of a scientist.

Peregrine Falcons were exterminated in the eastern half of the USA and adjacent southern Canada by about the mid-1970's. Many of the countries in Western Europe, such as Belgium and Luxembourg, lost their populations too. From an overall perspective, losses were spotty and sometimes regional, although the extent of loss was largely unknown over vast regions of Asia and through Indonesia. Numbers were at their lowest and declines at their most severe in Western Europe between the mid-1960's and the mid-1970's, though the peak of the decline varied regionally. Some examples of Northern Hemisphere declines were: a 66% decline in Britain; 84% in Austria; about 98% in Fennoscandia and West Germany; 100% in East Germany; about 85% in the western USA; and 100% in the eastern USA. Once the use of chemicals was limited or banned in the 1970's, the species increased again, as shown by some figures from the mid-1980's, for instance a 62% increase in Austria, 50% in Fennoscandia, and 100% increase in France and Switzerland. By 1993, there had been a sharp increase in most localities in Europe and North America.

There are impressive examples of both natural and man-assisted recoveries of this species in both North America and

The widespread Aplomado Falcon is one of several falcon species that appears to have benefited in many areas from the effects of deforestation, as this has opened up new zones for it to colonize. Despite this general tendency, the species has undergone a major decline in the north of its range which is probably connected with the use of dangerous pesticides. The species is now the object of a captive breeding and reintroduction programme in the USA.

[*Falco femoralis*.

The Mauritius Kestrel is the subject of one of the greatest of all conservation successes. The species underwent a catastrophic decline, largely due to habitat alteration, and by the early 1970's only four birds could be found in the wild, although there must have been at least a few more. Captive breeding was initiated around this time with great success, and this was then followed up with reintroductions. By 1993 the total population in the wild was reckoned to be in the region of 215-240 birds.

Europe. In Norway there was a sharp decline from 500-1000 pairs around 1900 to less than 10 known in 1975. Following the ban on the offending chemicals, there was then a modest recovery to over 50 pairs in 1985, and 150-200 by 1992. For Great Britain, an estimated pre-1940's population of 650 pairs declined to about 450 pairs in 1971, but by 1991 there were an estimated 1200 pairs. By 1993, populations of the Yukon River, Alaska, had increased by 175% over their lowest levels, and those of the Colville River, Alaska, increased about 300% over their lowest level; these values are actually more than 50% above known historical levels. In 17 western states of the USA, the 607 pairs known in 1992 were twice that deemed necessary for downlisting from an endangered to a threatened status, and almost twice the 322 historically known pairs. Much of this increase was natural but more than 2451 captive-bred Peregrines had been released by The Peregrine Fund alone up to 1992. In the eastern USA, where the species had become extinct by the 1970's, over 99 pairs had been established by 1992 by means of reintroduction, with the release of 1229 captive-bred falcons; about 275 pairs were known historically. Some 34 pairs have been established in the central USA and extreme south central Canada, with 667 falcons released in the USA sector by several groups up to 1992. Additionally, Canada released 563 Peregrines in 1976-1987 in the provinces between Alberta and Quebec. By 1983 the tundra subspecies *tundrius* was proposed for downlisting from endangered to threatened in the USA, and by 1993 it was ready for removal from the threatened list; in Canada, *tundrius* was downlisted from threatened to vulnerable in 1992. Although eggshell thicknesses are not back to normal, they are generally 4-5% better than the critical 17% thinning level at which eggs break. Thus, the story of the Peregrine Falcon is one of success following two deliberate and conscious actions of man: the banning of pesticides; and, for parts of North America and Europe, the release of large numbers of captive-bred falcons.

In conclusion, there seem to be two important threats facing members of the Falconidae at the population level: habitat alteration; and the continued presence of synthetic organochlorines in the environment. Habitat alterations, especially the removal of primary forest at the rate it is presently occurring, is likely to have major effects on forest-

falcons and the Laughing Falcon, and perhaps also falconets and some kestrels. Most habitat alteration, however, will probably not have much effect on hobbies, most kestrels and some caracaras. The pesticide story is far from over, however, in spite of the great strides made over the past two decades. Eggshell thinning occurs to some degree in most of the Peregrine Falcon populations examined, even in the remote islands of Fiji, and in many other falcon species, as well. The sort of chemical pollution that occurred in the past does not seem to have major effects on caracaras and some falcons, whereas other falcons are probably still at high risk. However, nobody can predict what new chemicals will appear on the market, and, perhaps of equal importance, the critical threshold of most species of falconids to chemicals has not yet been established. The levels of dangerous chemicals currently in the environment may be sufficient to affect particularly sensitive species that have not yet come into contact with them.

In addition to other projects, the Peregrine Fund is releasing captive-bred Aplomado Falcons in the northern part of their range, in the USA and northern Mexico, where they were extirpated earlier in the present century. In 1993, 26 young falcons were released, and while 23 were known to have survived to winter it is too early to know how successful the programme will be. No species of falcon need go extinct if proper management techniques are applied and concerned citizens are apprised of the problems facing falcons.

General Bibliography

Subfamily POLYBORINAE

Genus *DAPTRIUS* Vieillot, 1816

1. Black Caracara

Daptrius ater

French: Caracara noir German: Gelbkehlkarakara Spanish: Caracara Negro
Other common names: Yellow-throated Caracara

Taxonomy. *Daptrius ater* Vieillot, 1816, Brazil.

May merit generic differentiation from *D. americanus*, due to differences in morphology, habitat and behaviour. Monotypic.

Distribution. E Colombia, S Venezuela and the Guianas S through Amazonia to E Peru, NE Bolivia and C Brazil (Maranhão, N Mato Grosso).

Descriptive notes. 41-47 cm; 330-354 g. All glossy black; tail basally white; bare skin of face orange, of throat yellow; iris reddish brown, legs pale orange yellow. Tail pattern and all black underparts separate from *D. americanus*. Immature duller black; spotted or barred buff below; basal two thirds of tail white with 3-4 black bars; iris brown, face dull yellow.

Habitat. Forest, usually near edge or along rivers; wooded savanna, gallery forest, sometimes in mangroves; frequents areas that have been burnt. Absent from areas of apparently suitable habitat in French Guiana.

Food and Feeding. Omnivorous, feeding on carrion, frogs, fish, nestling birds, mammals, dragonflies, spiders, beetle larvae, maggots and ants; fruits, e.g. of palms (*Mauritia flexuosa*, *Eleais*, *Desmoncus*), found in stomachs. Picks ticks off tapirs and deer; on hearing species, tapirs said to call, in order to attract the birds, then lie down while the caracaras pick off ticks. Usually alone or in pairs, but, like *D. americanus*, also often in flocks of up to 7-8 birds.

Breeding. No nests have been described, but in Guyana species said to nest in trees, laying 2-3 eggs in Mar-Jun.

Movements. Nothing known; presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Status very poorly known. Extensive range and catholic taste in terms of habitat and feeding habits suggest species relatively secure. Generally fairly common in suitable habitat in Colombia; locally common in parts of Amazonian Ecuador.

Bibliography. Blake (1977), Dubs (1992), Friedmann & Smith (1950), Griffiths (1994), Haverschmidt (1962), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Ortiz & Carrión (1991), Pinto (1964), Remsen & Traylor (1989), Ruschi (1979), Sick (1985a, 1993), Snyder (1966), Thiollay (1985a, 1989a), Tostain *et al.* (1992), Traylor (1958), Voous (1969), Vuilleumier (1970).

2. Red-throated Caracara

Daptrius americanus

French: Caracara à gorge rouge German: Rotkehlkarakara Spanish: Caracara Gorgirrojo

Taxonomy. *Falco americanus* Boddaert, 1783, Cayenne.

May merit separation from *D. ater* in genus *Ibycter*, on grounds of differences in morphology, habitat and behaviour. Populations from Central America and SE Brazil have been recognized as races *guatemalensis* and *pelzelni* respectively, based primarily on size, but substantial overlap with intervening populations. Monotypic.

Distribution. Extreme S Mexico (Chiapas) S to Colombia, S on Pacific slope to W Ecuador, and E of Andes to C Peru, N & E Bolivia and S Brazil (NW Paraná, Mato Grosso and São Paulo).

Descriptive notes. 48-61 cm; 510-680 g. Mostly glossy black; belly, thighs and undertail-coverts white; facial skin and unfeathered throat red, bordered obscurely with whitish; iris brown to deep red, legs and feet bright orange red. Tail pattern and white on underparts separate from *D. ater*; also has blunter wings and bulkier head. Immature has bare skin more yellowish; sides of face and throat black.

Habitat. Primary rain forest from tropical lowlands up to subtropical zone; dry deciduous forest in Venezuela; *cerrado* in Brazil. Normally occurs in groups of 5-7 individuals, but up to 9-10; smaller groups recorded in logged

forests, but species does not frequent heavily disturbed second-growth forest.

Food and Feeding. Mostly eggs and larvae of wasp and bee nests, amounting to 74% of prey items recorded in a forest in French Guiana; also some hard fruits, including palms; other miscellaneous invertebrates and turtle eggs. Most bee and wasp nests attacked are small (4-20 cm in diameter); no records of ant or termite nests attacked. Groups of birds move in saltatory, apparently random fashion through territory, most of the birds feeding in understorey, while two remain in canopy, perhaps as sentinels. Allofeeding (with different adults feeding each other) recorded, in one case when large nest was found. Despite bare face and throat, with no physical protection from wasps, normally aggressive wasps never attack species, even when feeding on the wasps' colony; wasps stay 1 m away from caracara, suggesting species may have some sort of repellent which protects it; may be unique in animal world. Oropendolas, parrots, toucans, some large cotingas and woodpeckers associate with caracara flock, apparently taking advantage of sentinel behaviour to forage well below canopy in strata of forest in which they are otherwise rarely if ever seen; some individuals of these other species follow caracara group for hours.

Breeding. In Colombia, birds in breeding condition in Jul; in Panama, one about to lay in Mar. Stick nest; one in French Guiana was hidden 22 m up in vine-covered tree. 2-3 eggs. Has complex, stable social structure almost unique among birds of prey. Groups apparently hierarchical, highly territorial and faithful to territory over long periods, at any rate for 5 years. Only group studied in any detail defended territory of 400-450 ha in French Guiana. Apparently only 1 breeding attempt in 5 years. One or 2 birds always near nest, defending it aggressively. Groups very vocal in defending territory, and rely on vocalizations to maintain group cohesion. When another member of flock arrived with wasp nest, one of sentinels left nest area to forage, leaving recent provider on guard duty; up to 4 individuals seen sequentially delivering prey to nest.

Movements. Sedentary. Groups defend territories all year round.

Status and Conservation. Not globally threatened. CITES II. Populations of Panama, and perhaps much of Central America, have declined dramatically since 1950's and 1960's, in part due to deforestation, but also in areas where extensive forest remains; no recent records in N of Costa Rica; has declined greatly on Caribbean slope of Panama, where now rare. Occurs in many forest areas of South America at population densities perhaps surpassed by other tropical forest raptors only by some forest-falcons (*Micrastur*). Average density of at least c. 200 individuals/10,000 ha reported in French Guiana.

Bibliography. Blake (1977), Davis (1972), Dubs (1992), Friedmann (1950), Friedmann & Smith (1955), Griffiths (1994), Haverschmidt (1962), Hilty & Brown (1986), Land (1970), Lowery & Dalquest (1951), Meyer de Schauensee & Phelps (1978), Monroe (1968), Pinto (1964), Remsen & Traylor (1989), Ridgely & Gwynne (1989), Ruschi (1979), Sick (1985a, 1993), Skutch (1959), Slud (1964), Snyder (1966), Stiles & Skutch (1989), Straube & Bornschein (1989), Terborgh & Weske (1975), Thiollay (1989a, 1991b), Tostain *et al.* (1992), Voous (1969), Vuilleumier (1970), Wetmore (1965).

Genus *PHALCOBOENUS* d'Orbigny, 1834

3. Carunculated Caracara

Phalcoboenus carunculatus

French: Caracara caronculé German: Streifenkarakara Spanish: Caracara Carunculado

Taxonomy. *Phalcoboenus carunculatus* Des Murs, 1853, Colombia.

Formerly treated as race of *P. megalopterus*, as was *P. albogularis*; these three form superspecies, in which some authors also include *P. australis*. Genus closely related to *Polyborus*, and sometimes even merged with it. Monotypic.

Distribution. Andes of Ecuador and SW Colombia.

Descriptive notes. 50-56 cm; wingspan 110 cm. Mostly glossy black, but boldly patterned with white streaks on breast; underwing, lower belly, undertail-coverts and tip of tail all immaculate white; crown with moderately apparent, curled crest. Iris hazel to blackish grey, cere and bare skin of face and throat bright orange to deep red; throat skin wrinkled forming wattles (caruncles); feet and legs bright yellow. Pattern on underparts separates from congeners. Immature tawny to fuscous brown with dark shaft streaking; head, rump and underparts with some white mottling; legs and feet dusky.

Habitat. Treeless areas of upper temperate

zone, at 3000-4000 m; in páramo or grassy pastures with scattered bushes.

Food and Feeding. Worms, maggots, small rodents, birds, lizards, vegetable matter; said to take almost anything edible. Considerable local variation (see page 230). Feeds mainly on the ground by scavenging; often walks or runs about. Groups of up to 8 (or perhaps even 40) individuals seen feeding together, typically in vicinity of cattle.

Breeding. Eggs Sept-Oct; fledging Jan, but one well developed nestling collected in late May. Nests on cliffs with somewhat more substantial nest than *P. megalopterus*; 1 nest on pine tree.

Movements. Presumably sedentary. Outside breeding season, may gather in flocks of 100+ birds.

Status and Conservation. Not globally threatened. CITES II. Uncommon to locally common; in Colombia, commonest in Cumbal area of S Nariño, near border with Ecuador; currently spreading into Cauca valley. In Ecuador, common in páramo zones around Mt Antisana, and fairly common in some other protected areas. Probably relatively secure at present, as habitat not under significant pressure; no reports of persecution.

Bibliography. Amadon (1964), Blake (1977), Ejlsdå & Krabbe (1990), Hilty & Brown (1986), Ortiz & Carrión (1991), de Vries *et al.* (1983), Vuilleumier (1970).

4. Mountain Caracara

Phalcoboenus megalopterus

French: Caracara montagnard German: Bergkarakara Spanish: Caracara Andino

Taxonomy. *Aquila megaloptera* Meyen, 1834, Cordillera of Chile.

Formerly considered to include *P. albogularis* and *P. carunculatus* as races; these three form superspecies, in which some authors also include *P. australis*. Possible hybrids with *P. albogularis* reported. Monotypic.

Distribution. Andes from N Peru (Piura), through Bolivia to NW Argentina and C Chile (Colchagua).

Descriptive notes. 48-54 cm; c. 795 g. Glossy black, with belly to undertail-coverts and underwing-coverts pure white; as in congeners, primaries narrowly tipped white, tail with broader white tip. Iris brown, bare facial skin reddish orange or red, legs and feet orange-yellow. Pattern on underparts separates from congeners. Immature tawny to fuscous brown; very similar to immature *P. carunculatus*, but without rufous barring on upper tail-coverts; dusky legs and feet.

Habitat. Treeless areas of upper temperate zone, typically in puna; generally at 2000-4000 m, but in Chile occasionally down to 1000 m. Breeds and roosts in rugged country near cliffs; for feeding, moves into flatter country, especially puna grassland, often near lakeshores.

Food and Feeding. Large arthropods, young rodents or birds; also carrion and rubbish. Often gathers, in numbers near towns, to feed on carrion and refuse; fills niche of large Corvidae in comparable N

Hemisphere habitat. A strong flier, but all feeding seems to be done on foot, with bird scratching or stomping to disturb insects; like some of its congeners, a most atypical raptor.

Breeding. Eggs in Oct-Nov in S of range. Nests on cliffs; most reports indicate nests often nothing more than a bit of cow dung, but some nests observed on concrete electricity towers were more substantial, made of large sticks with llama's or sheep's wool worked into nest. Usually 2 eggs, sometimes 3.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. A common bird in suitable

habitat; of no conservation concern. Abundant in N Altiplano of Peru and Bolivia.

Bibliography. Amadon (1964), Blake (1977), Fjeldså & Krabbe (1990), Housse (1938), Jaksic & Jiménez (1986), Johnson (1965), Parker *et al.* (1985), de la Peña (1992), Remsen & T aylor (1989), Vuilleumier (1970), White & Boyce (1987), Wolfe (1951), Zimmer & Osgood (1930).

5. White-throated Caracara

Phalcoboenus albogularis

French: Caracara à gorge blanche **German:** Weißkehlikarakara **Spanish:** Caracara Araucano
Other common names: Darwin's Caracara

Taxonomy. *Polyborus (Phalcoboenus) albogularis* Gould, 1837, Santa Cruz, Patagonia.

Formerly treated as race of *P. megalopterus*, as was *P. carunculatus*; these three form superspecies, in which some authors also include *P. australis*. Possible hybrids with *P. megalopterus* have been reported. Monotypic.

Distribution. S Chile (Ñuble) and S Argentina (S Mendoza) S to Tierra del Fuego.

Descriptive notes. 49–55 cm; wingspan c. 120 cm. Weak crest; somewhat less glossy black above than congeners, with uppertail-coverts and tip of tail white; all white below from chin to undertail, and on underwing-coverts; base of primaries banded black and white from below; facial skin yellow-orange, iris hazel, legs and feet yellow. White underparts separate from congeners. Immature may be indistinguishable in the field from immature *P. megalopterus*, but has weaker crest and is darker above; larger than *Milvago chimango*, with smaller pale areas in wings and tail.

Habitat. Open mountain slopes and humid

forest, including beech (*Nothofagus*) forest; up to 3000 m in N of range, down to sea-level in S.

Food and Feeding. Virtually no information available; food probably similar in general to that of *P. megalopterus*; known to take carrion e.g. dead guanaco. Usually solitary, but seen in small groups with vultures at carcasses; on Isla Grande (Tierra del Fuego), gathers in numbers at rubbish dumps, or sites where sheep slaughtered.

Breeding. Eggs probably laid in Oct–Nov. Builds stick nest on rock ledge. 2–3 eggs.

Movements. No information available.

Status and Conservation. Not globally threatened. CITES II. Indeterminate, said to be common in *Nothofagus* beech forest. Common at rubbish dump near Ushuaia (S Tierra del Fuego), but occurs at very low density in forests of adjacent national park. Habitat not subject to much disturbance, and no persecution reported, so presumably not a species of immediate concern.

Bibliography. Amadon (1964), Blake (1977), Clark, R. (1986), Fjeldså & Krabbe (1990), Goodall *et al.* (1957), Humphrey *et al.* (1970), Jaksic & Jiménez (1986), Johnson (1965, 1972), Koepcke (1970), de la Peña (1992), Vuilleumier (1970)

6. Striated Caracara

Phalcoboenus australis

French: Caracara austral **German:** Falklandkarakara **Spanish:** Caracara Austral
Other common names: Forster's Caracara, Johnny Rook

Taxonomy. *Falco australis* Gmelin, 1788, Staten Island.

Sometimes considered to form part of the *P. megalopterus* superspecies, but apparently more distinctive than congeners. Monotypic.

Distribution. Islets off extreme S South America, including Staten (Isla de los Estados), Navarino and Cape Horn, and Falkland Is; irregularly to S & E coasts of Isla Grande, Tierra del Fuego.

Descriptive notes. 53–65 cm; c. 1187 g. Black to brownish black overall; upper back, neck and breast streaked with white or tawny; tail broadly tipped white; underwing-coverts and thighs bright rusty rufous; white patch at base of primaries. Facial skin salmon pink to yellowish orange, iris brown, legs and feet bright orange-yellow. Largest *Phalcoboenus*; rufous thighs separate from congeners. Immature takes at least 5 years to reach full adult plumage; starts all black or blackish brown, and gradually attains streaking; facial skin, feet and legs pale grey.

Habitat. Open lowlands, from tidal zone per-

haps to low coastal mountains; most typically along rocky coasts.

Food and Feeding. Dead adults and chicks of colonial seabirds, when these are actively breeding. Scavenges in colonies of penguins, albatrosses, etc., not known to kill healthy chicks. While seabirds away from their colonies, present species scratches for insects and grubs along tidal zone. Will attack weak or stranded shore.

Breeding. In Falkland Is, hatching in Dec. Builds modest nest of dried grass, lined with wool when available, on rock ledge or under tussock of grass. Usually 2 eggs (1–4). Loosely colonial; nests can be as close as 6–7 m apart.

Movements. Not migratory, but may move seasonally up into coastal mountains. On N coast of Navarino I, and S & E coasts of Tierra del Fuego, may occur only as winter visitor.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Rare overall. Heavily persecuted in past on main Falkland Is. due to its attacks on weak or stranded sheep; bounty paid for its destruction, leading to extinction from East Falkland I; now mostly restricted to smaller islands of the group, especially in W, where reported to be locally numerous. May be similarly numerous on small islands near Cape Horn; surveys desirable.

Bibliography. Blake (1977), Cawkwell & Hamilton (1961), Clark, R. (1986), Cobb (1933), Fjeldså & Krabbe (1990), Humphrey *et al.* (1970), Jaksic & Jiménez (1986), Johnson (1965), Meyburg (1986), de la Peña (1992), Vuilleumier (1970), Wallace, G.E. (1991), Woods (1988).

Genus *POLYBORUS* Vieillot, 1816

7. Crested Caracara

Polyborus plancus

French: Caracara huppé **German:** Schopfkarakara **Spanish:** Caracara Carancho
Other common names: Common Caracara; Guadalupe Caracara (*lutosus*)

Taxonomy. *Falco plancus* J. F. Miller, 1777, Tierra del Fuego.

Recent proposal to replace traditional genus name *Polyborus* with *Caracara* on grounds of indeterminate type description, but *Polyborus* should be retained (see page 219). Closely related to *Phalcoboenus*, and less closely to *Milvago*, both of which genera sometimes included within *Polyborus*. Extinct form *lutosus* of Guadalupe I (off W Mexico) frequently treated as full species, but now generally considered a race of *P. plancus*. Race *audubonii* of doubtful validity, and often merged with *cheriway*; race *ammophilus* described from W Mexico, but even more dubious, and normally included within *audubonii*. Four extant subspecies usually recognized.

Subspecies and Distribution.

P. p. pallidus Nelson, 1898 - Tres Marias Is, off W Mexico.

P. p. audubonii Cassin, 1865 - S USA (Florida; Texas to Arizona) through Central America to W Panama; Cuba, I of Pines

P. p. cheriway (Jacquin, 1784) - E Panama through C & E Colombia to the Guianas and S to N Peru and R Amazon; Aruba (Netherlands Antilles) E to Trinidad.

P. p. plancus (J. F. Miller, 1777) - C Peru and C Bolivia E to Amazon Delta and S to Tierra del Fuego; Falkland Is.

Descriptive notes. 49–59 cm; male averages 834 g, female 953 g, in Panama, but species averages 1150–1600 g in Chile and Peru; wingspan 120–132 cm. Black cap and crest; bare face red; throat and neck white or buff; mantle pale white to brownish, streaked brownish black, with rest of back brownish to black, finely barred whitish; rump and tail whitish, finely barred black, with black tip to tail; creamy white vent. In flight, from above primaries show conspicuous whitish patch at base. Iris dull yellow or brown, long legs and feet yellow. Immature browner, with breast and back streaked or blotched whitish; bare parts

duller. Races separated on size, and extent of barring on nape, upper belly, vent and upperwing-coverts; *pallidus* similar to *audubonii*, but slightly smaller; extinct *lutosus* generally paler, with extensive barring on underparts, back and upperwing-coverts.

Habitat. Open and semi-open country; pastures, palm savannas, river edges and especially ranch land, e.g. in llanos; sometimes in forested and marshy areas. Mainly in lowlands, but increasingly in upland areas of Colombia and Ecuador; in Argentinian Patagonia, frequents grassy foothills, shrub-steppe and river valleys. Widely distributed in lowlands of Bolivia, but one juvenile seen, associated with juvenile *Phalcoboenus megalopterus*, at 3800 m.

Food and Feeding. Opportunist. Feeds mainly on carrion, roadkills, livestock and dead or dying fish. Also takes some live prey, including freshwater turtles, iguanas, geckos, snakes, crabs, earthworms, Curculionidae and other Coleoptera, and larvae of Lepidoptera; 3–4 individuals seen chasing and killing egret. Plunders nests of small birds and colonies of egrets and spoonbills; even nests of other caracaras (*Milvago*). Feeds on coconut flesh at harvest time on plantations in Guyana. Spends much time on ground. Seen wading in shallow water peering under vegetation, perhaps looking for frogs. Pirates food from other caracaras, other raptors and even pelicans. Pursues vultures in flight until they regurgitate, catching regurgitated food before it reaches ground. Dominant over individual Turkey Vultures (*Cathartes aura*) and American Black Vultures (*Coragyps atratus*) at carcass, but usually arrives at carcass early, before vultures are soaring and before they arrive at food.

Breeding. Season prolonged, sometimes with second clutch in same year; nesting Sept–May in Colombia and Venezuela (mostly dry season in latter); laying Jan–Feb in Florida (USA); Dec in Paraguay and Tierra del Fuego; in Argentina, nest building as early as Mar, eggs Jul–Oct. Nest large, c. 80 cm wide, c. 30 cm deep; dishevelled structure of sticks, with or without lining, on top of palm or cactus, in dense tangle of branches on tree, or on ground. Usually 2 eggs (1–3, rarely 4); incubation c. 28–32 days; chicks have pinkish buff down, darker brown on crown and back; fledging period prolonged, perhaps lasting c. 3 months.

Movements. Generally sedentary; possibly some local movements, as species most common along R Paraguay in Jun, and also common in Oct. Transient throughout year in highlands of W Guatemala.

Status and Conservation. Not globally threatened. CITES II. Fairly common to locally abundant. Locally persecuted in some farming regions (e.g. in S Chile) as accused of preying on lambs; declines reported in S Argentina in areas where strychnine used by sheep ranchers. Conversion of farmland to citrus plantations, and other forms of habitat loss, threaten Florida population. Elsewhere, conversion of forest to cattle pastures almost certainly beneficial to species, and range probably expanding. Form *lutosus* became extinct around 1900, as result of heavy persecution, mainly by shooting, often when birds gathered at water-holes.

Bibliography. Amadon (1954, 1964), Banks & Dove (1992), Blake (1977), Cabot & Serrano (1986), Contreras *et al.* (1990), Donazar, Ceballos *et al.* (1993), Ehrlich *et al.* (1992), Fjeldså & Krabbe (1990), Glazener (1964), Haverschmidt (1947), Hayes (1991), Hilty & Brown (1986), Humphrey *et al.* (1970), Jaksic & Jiménez (1986), Johnson (1990), Johnson (1965, 1972), Mader (1981), Marchant (1960), Menner (1968), Morrison (1993), Olrog (1979), Palmer (1988), de la Peña (1992), Pinto (1964), Richmond (1976), Ridgely & Gwynne (1989), Rivera-Rodriguez & Rodriguez-Estrella (1993), Rodriguez-Estrella & Rivera-Rodriguez (1992), Ruschi (1979), Siek (1985a, 1993), Shud (1964), Snyder & Snyder (1991), Stiles & Skutch (1989), Thiollay (1980b), Thomas (1979), Tostain *et al.* (1992), Vannini (1989), Vuilleumier (1970), Wallace, G.E. (1991), Wallace, M.P. & Temple (1987a), Wetmore (1965)

Genus *MILVAGO* Spix, 1824

8. Yellow-headed Caracara

Milvago chimachima

French: Caracara à tête jaune **German:** Gelbkopfkarakara **Spanish:** Caracara Chimachima
Other common names: Chimachima Caracara

Taxonomy. *Polyborus chimachima* Vieillot, 1816, Paraguay.

Genus related to *Polyborus* and *Phalcoboenus*, and has been included in former; closest of the caracara genera to *Falco*. Despite some areas of overlap, may be regarded as forming superspecies with *M. chimango*. Two subspecies recognized.

Subspecies and Distribution.

M. c. cordatus Bangs & Penard, 1918 - S Costa Rica and Panama (including Pearl Is) through Colombia to the Guianas and Trinidad and S (E of Andes) to Amazon.

M. c. chimachima (Vieillot, 1816) - E Bolivia and Brazil S of Amazon to Paraguay, N Argentina and Uruguay.

Descriptive notes. 40-45 cm; male averages 315 g, female 335 g; wingspan 74 cm. Head, neck and underparts, including underwing-coverts, buff to creamy yellowish white; dark streak behind eye; back blackish brown; rather long, rounded tail and uppartail-coverts buff with dusky bars; tail with black subterminal band. In flight, conspicuous whitish patch at base of primaries. Iris reddish brown, bare skin around eyes bright yellow, legs pea green. Immature browner above, below streaked with brown. Race *cordatus* has head and underparts darker buff, and narrower tail bars.

Habitat. Open country with scattered trees, ranchland, pastures, palm savannas, forest edge and along rivers; up to c. 1800 m in Colombia, and recently recorded at 3600 m in Ecuador.

Food and Feeding. Omnivorous: carrion, from small roadkills to dead crocodiles; insects, including many caterpillars; frogs and toads; fish; birds' nests; fruits of oil palm (*Elaeis*); maize; and horse dung. Often walks about on ground. Perches on cattle to pick off ticks; picks flesh from open wounds on backs of cattle, which often seem oddly indifferent to the process.

Breeding. Season appears to be protracted: Aug (wet season) in Venezuela; laying in May in Guyana; Sept in S Brazil. Stick nest, usually high in tree, often on palm; where trees not available, nests on mounds in marshy areas, or amongst thistles in *pampas*. 1-2 eggs. No further information available.

Movements. No evidence of any movements.

Status and Conservation. Not globally threatened. CITES II. Widespread and very common. Perhaps colonizing deforested highlands in Andes, and will certainly move into lowland areas as they are converted from forest to cattle ranches or to small or to medium-scale farming.

Bibliography. Blake (1977), Clark, R. (1986), Contreras *et al.* (1990), ffrrench (1985), Fjeldsá & Krabbe (1990), Haverschmidt (1962), Hilty & Brown (1986), King, J.R. (1989), Mader (1981), Meyer de Schauensee & Phelps (1978), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Ruschi (1979), Sick (1985a, 1993), Snyder (1966), Stiles & Skutch (1989), Tostain *et al.* (1992), Voous (1969), Vuilleumier (1970), Wetmore (1965), Woods (1988), Young (1925).

9. Chimango Caracara

Milvago chimango

French: Caracara chimango **German:** Chimangokarakara **Spanish:** Caracara Chimango
Other common names: Chimango (Hawk)

Taxonomy. *Polyborus chimango* Vieillot, 1816, Paraguay and Río de la Plata.

May form superspecies with *M. chimachima*; has been placed (with *M. chimachima*) in *Polyborus*. Birds of Tierra del Fuego sometimes awarded separate race, *fuegiensis*. Possible race *azarae* normally included within nominate. Two subspecies recognized.

Subspecies and Distribution.

M. c. chimango (Vieillot, 1816) - N & C Chile and N & C Argentina through Paraguay to Uruguay and adjacent Brazil.

M. c. temucoensis W. L. Slater, 1918 - S Chile (from near Concepción) and S Argentina (from R Chubut) S to Tierra del Fuego and Cape Horn. Introduced to Easter I (S Pacific).

Descriptive notes. 38-41.5 cm; male 289 g, female 300 g. All brownish, with dark streaks on sides of head and hindneck; below mottled or barred rufous brown, underwing-coverts cinnamon barred fuscous brown; rather long tail mottled greyish and white, with broad black subterminal band; in flight, conspicuous white uppartail-coverts and pale buff "window", formed by pale grey primaries with black tips; face more extensively feathered than in *M. chimachima*. Iris brown, bare facial skin reddish pink, feet bluish grey. Similar to immatures of *Phalcoboenus*, but considerably smaller. Immature strongly tinged rufous, often with white

spots. Race *temucoensis* darker, smokier brown and more heavily marked.

Habitat. All kinds of open country; found equally in grassy foothills of Andes, heathland, shrub-steppe, marshes, fields, open woods, river valleys and villages; also along coast. Straggles to temperate Andean slopes in C Chile and adjacent Argentina; recorded up to 4000 m. Sometimes forages over burnt land.

Food and Feeding. Feeds on carrion and also live prey, including insects, anurans, eggs and nestling passerines, lizards and worms; turtle eggs taken as they are being laid. Very versatile (see page 230). Hundreds of individuals follow farmers ploughing. Gathers at swarms of large insects, feeding copiously. Can be an important predator on nestlings of (colonial) waterbirds, e.g. Brown-hooded Gulls (*Larus maculipennis*), Southern Lapwings (*Vanellus chilensis*). In C Chile, items in diet: 87%

insects, mostly Coleoptera and Orthoptera; 9% worms (Oligochaetes); and 4% rodents, unidentified birds and lizards. Jumps and runs after prey on ground. Will attack other raptors. In SC Chile, large numbers congregate, along with Kelp Gulls (*Larus dominicanus*), around shellfish processing factories, feeding on remains left attached to discarded shells; also seen taking live clam, and opening it to feed on flesh, breaking shell into pieces in process.

Breeding. In Argentina, laying Sept-Nov (austral spring), with peak in Oct; flying young being fed by adults in Jan, in Tierra del Fuego. Nests colonially: 56 nests in 0.7 ha at one site in Argentina, where nests as little as 10 m apart. Usually nests in trees, but will nest on ground; tree nest c. 35 cm wide, built of sticks often with wool lining. Usually 3 eggs (average 2.77), but up to 5 recorded; incubation 26-27 days, beginning with first egg; fledging 32-34 days.

Movements. S populations appear at least partially migratory, but transition to resident populations not known. Vagrant to Falkland Is.

Status and Conservation. Not globally threatened. CITES II. Currently thriving, and is commonest raptor through much of Chile and Argentina. In SC Chile, fairly common to abundant around many towns, and especially fishing villages; common in Río Grande do Sul, S Brazil. Often closely associated with man, feeding on discarded rubbish.

Bibliography. Belton (1984), Blake (1977), Burger (1974), Contreras *et al.* (1990), Fjeldsá & Krabbe (1990), Fraga & Salvador (1986), Humphrey *et al.* (1970), Jaksic & Jiménez (1986), Johnson (1965), Olog (1962), de la Peña (1992), Pinto (1964), Ruschi (1979), Sick (1985a, 1993), Vuilleumier (1970, 1985), Yáñez *et al.* (1982)

Genus *HERPETOTHERES* Vieillot, 1817

10. Laughing Falcon

Herpetotheres cachinnans

French: Macagua rieur **German:** Lachfalke **Spanish:** Halcón Reidor

Taxonomy. *Falco cachinnans* Linnaeus (ex Rolander MS), 1758, Surinam.

Distinctive genus, most closely allied with *Micrastur*, sometimes awarded its own tribe or even subfamily. Different authors recognize 2-6 races; possible race *excubitor* included within *chapmani*; *maestus* and *fulvescens* within nominate. Three subspecies normally recognized.

Subspecies and Distribution.

H. c. chapmani Bangs & Penard, 1918 - Mexico (S Sonora and San Luis Potosí) S to Honduras.

H. c. cachinnans (Linnaeus, 1758) - Nicaragua to Colombia and S to Peru and C Brazil.

H. c. querubundus Bangs & Penard, 1919 - E Bolivia and E Brazil (S to São Paulo) to Paraguay and N Argentina.

Descriptive notes. 45-53 cm; male 567-686 g, female 626-800 g. Relatively large, aberrant falconid, with short wings and long tail, more typical of proportions of forest-dwelling species of *Micrastur* and *Accipiter*. Large head and underparts cinnamon buff to pale whitish (varying with individual, and with bleaching), with broad black mask from eyes to hindneck; above dark brown to blackish brown; buff underwing-coverts and primary bases contrast with dark barred flight-feathers; rounded tail evenly barred black and whitish and tipped whitish. Stout tarsi and short toes typical of snake-eating raptors. Iris dark brown, cere, legs

and feet dull yellow. Immature has back and wings narrowly edged rufous or buffy brown; whiter below, with thighs sometimes spotted or streaked fuscous brown or buff. Races separated on size and overall intensity of plumage coloration.

Habitat. Tropical and subtropical zones: common at forest edge and open forest in Surinam; mixed palm savanna and forest in Venezuela; rare in stretches of undisturbed forest N of Manaus, NC Brazil, where more common in disturbed, second-growth forest; also along rivers, in clumps of trees and in *cerrado*. Does not occur in interior of primary rain forest; always near clearings, edges, tracks, secondary growth, etc. Nests in all forest types in the Petén (Guatemala), e.g. low swamp forest, closed primary forest near large clearings. Occurs mainly in lowlands, but up to 2400 m in Colombia.

Food and Feeding. Almost exclusively snakes, both terrestrial and arboreal, including large and venomous ones, although most typically harmless ones, e.g. vine snakes (*Philodryas*, *Liophis*). In Petén, of all snakes recorded (c. 20 species): 59% terrestrial; 30% arboreal; and 11% unidentified. In human-altered landscape with some agriculture, rodents, lizards and even fish and a bird have been recorded. In Brazil, reported to take bats leaving a roost at dusk. Typically hunts from open perch, with good visibility; bird sits still for long periods with head slightly bowed.

Breeding. In Costa Rica, eggs in Feb; in Venezuela, Sept (rainy season); in Argentina, Jan; male in breeding condition in May. SW Colombia. In Petén (Guatemala), nests in Feb-Mar (middle of dry season), with hatching probably in Mar-Apr (middle to late dry season), and fledging early in rainy season. Nests 3-33 m above ground using tree cavities, old stick nests, scrapes on epiphytes, or cliffs; tree nests always isolated from surrounding vegetation, either in emergent tree over 5 m above surrounding canopy, or in isolated tree in more disturbed areas or more open forest; little or no building. Pair engages in long (9 min), loud duet near nest, at dawn or dusk; courting pairs often roost near potential nest, vocalizing loudly at dawn and dusk. Usually 1 egg (one record of 2 from Argentina); incubation by female; chick has very soft pale brownish buff down, darker on back, with dark facial mask; fledging c. 57 days; 1 month after fledging, young and parents of one nest seen only 50 m apart, c. 6 km from nest-site. In Petén, of 4 nests found, 2 had ant colonies in the cavity, and only these 2 nests fledged young; in nests without ants, young heavily infected by ectoparasites, dying without having fledged. In continuous forest, has very large home range (up to 2500 ha), which is six times average territory size known for other species of similar size; smaller territories (400-900 ha) seem to be used in more open, disturbed habitats.

Movements. Presumed to be mainly sedentary, but presence said to be temporary all over Brazil.

Status and Conservation. Not globally threatened. CITES II. Uncommon to fairly common within extensive range, e.g. Colombia, Surinam; local throughout most of Brazil. In primary forest seems to maintain lower densities than in disturbed forest.

Genus *MICRASTUR* G. R. Gray, 1841

11. Barred Forest-falcon

Micrastur ruficollis

French: Carnifex barré German: Sperberwaldfalke Spanish: Halcón-montés Agavilánado

Taxonomy. *Sparvius ruficollis* Vieillot, 1817, South America = Rio de Janeiro. Distinctive genus specialized for life in dense forest: long tail and short wings for manoeuvrability; large ear openings and facial ruff indicate importance of hunting by sound. Most closely related to *Herpethotes*. Until recently considered to include *M. gilvicolis*, but voice and morphology support specific status for *M. gilvicolis*, which is widely sympatric with present species. Possible races *oaxaca* and *kalinowskii* currently included in races *guerilla* and *zonothorax* respectively. Six subspecies normally recognized.

Subspecies and Distribution.

- M. r. guerilla* Cassin, 1848 - S Mexico to Nicaragua.
- M. r. interstes* Bangs, 1907 - Costa Rica and Panama to W Colombia and W Ecuador.
- M. r. zonothorax* (Cabanis, 1865) - Colombia and Venezuela, in E Andean foothills, S perhaps to Bolivia.
- M. r. concentricus* (Lesson, 1830) - S Venezuela, the Guianas and Amazonia.
- M. r. ruficollis* (Vieillot, 1817) - S of Amazonia in Brazil, Paraguay and NC & NE Argentina.
- M. r. olrogi* Amadon, 1964 - NW Argentina, in subtropical forests.

Descriptive notes. 33-38 cm; male 161-167 g, female 196-232 g. Plumage highly variable within and between races; rufous and grey morphs present in some races. Blackish grey to rufous brown above; throat white to rufous; white below, with variable amounts of fairly heavy black or grey barring; tail almost black, with three (occasionally two or four) narrow white bars; facial skin yellow-orange, iris brown. Very similar to *M. gilvicolis*, from which distinguished by iris colour, longer tail and generally stronger barring on underparts. Female larger, tinged brownish in some races; sometimes more heavily barred than male. Im-

mature tends to be more brownish than adults, varying from white to cinnamon buff below, with more or less barring; some white spotting on uppertail-coverts in Amazonian race *concentricus*. Races separated primarily on size, amount of barring and grey or rufous background colour to underparts.

Habitat. Humid and wet tropical forests; in Central America, high, mature forests; in Amazonia and S Brazil, most often in second-growth forest, including forest edge habitat, tidal swamp forest, and gallery forest. In Amazonia, customary use of secondary habitat contrasts with tendency of sympatric *M. gilvicolis* to occur more commonly in primary forest; also differs from latter in tolerance of forests with more pronounced dry season, even semi-deciduous forests; much less abundant in areas where co-exists with *M. gilvicolis*. Commonly ranges up to 2500 m, with single record at 3000 m in Colombia.

Food and Feeding. Most frequently lizards; also birds, including motmots, toucanets, robins and flycatchers; arthropods, bats, snakes, frogs and one crab. Of 587 prey items identified in the Petén (Guatemala); most were lizards (41%); only 14% birds; but 33% unidentified. By biomass, birds and lizards equally important (33%) in diet during breeding season. In general, morphologically convergent with forest-dwelling members of *Accipiter* in having short wings and long tail, but does not share long, narrow toes of specialist bird-eaters. Present species follows army ant (*Eciton burchelli*) swarms more frequently than congeners. Present species follows small birds following ant swarm immediately upon arrival, but spends most of time perched over swarm, dropping down to ground and often running after small prey items flushed by ants. Once seen "passively anting", fluffing feathers and squatting into ant swarm, as if brooding, for a minute before flying off.

Breeding. Virtually all data from Petén (Guatemala). Laying in May (late dry season); in Manaus (NC Brazil), recently fledged young in early Jun. Courtship entails calling, which begins c. 30-40 minutes before sunrise, and courtship feeding. Female stays by nest, defending it from potential competitors (toucans and parrots). Nests in tree cavities, which may be reused at least 3 years running; unlike case of *M. semitorquatus*, nest-site has very few vines around, but very dense canopy cover, generally higher than in areas used by *M. semitorquatus*; prefers breaks in canopy around nest tree, perhaps to reduce predation by snakes. Nest cavity c. 12-23 m high, with entrance usually c. 15 cm wide; nests with larger entrances lost clutches to predation. Averages 2-8 eggs, second clutch can be laid after nest failure; incubation 35 days; fledging c. 38 days (35-44), fledglings with tails only half-grown. Within 2 weeks of fledging, young begin to catch arthropods on ground, and scratch in leaf litter for insects; by week 3, follow army ant swarms, catching *Anolis* lizards; by week 5, young range 500 m from nest, and begin to chase birds; by week 6, prey delivery by male greatly reduced. Male delivers all of food during incubation, and most (over 66%) of food throughout nesting period. Hatching success 45% of hatched eggs, 84% fledged; net productivity of 1-1 young per nesting attempt. During breeding, home range of female averaged 67 ha, of male 114 ha, with some overlap of territories. One immature female maintained a fledgling, apparently after successful breeding. High mate and nest-site fidelity, low annual mortality or turnover.

Movements.

Conservation. Sedentary. Not globally threatened. CITES II. Along with *M. gilvicolis*, probably one of most abundant raptors in Amazonian forests. Average estimated density of at least c. 10 individuals/10,000 ha of forest in French Guiana; in Petén (Guatemala) c. 1 pair/100 ha. Locally fairly common in Colombia, especially in foothills and on lower slopes; reported to be uncommon in Panama, although possibly due to fact that species is very unobtrusive. Virtually all data available on breeding biology is result of Peregrine Fund's remarkable Maya Project, involving studies of 38 nesting attempts in the Petén of Guatemala.

Bibliography. Amadon (1964), Bierreguard (1988), Blake (1977), Contreras *et al.* (1990), Darrieu & Martinez (1984), Enquist *et al.* (1992), Friedmann (1950), Hilty & Brown (1986), Monroe (1968), Oniki & Willis (1982), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Ridgway (1875), Schwartz (1972), Sick (1985a, 1993), Slud (1964), Smith (1969), Stiles & Skutch (1989), Terborgh & Weske (1975), Thiollay (1989a), Thorstrom (1989, 1990a, 1993), Thorstrom & Morales (1993), Thorstrom, Morales & Maleo (1992), Thorstrom, Quixachán & Morales (1991), Thorstrom, Turley *et al.* (1990), Wetmore (1965), Willis & Oniki (1978), Willis *et al.* (1983).

12. Plumbeous Forest-falcon

Micrastur plumbeus

French: Camifex plombé German: Einbinden-Waldfalke Spanish: Halcón-montés Plomizo
Other common names: Sclater's Forest-falcon

Taxonomy. *Micrastur plumbeus* W. L. Sclater, 1918, Río Bogotá, Esmeraldas, Ecuador.

Has been included within *M. gilvicolis*; sympatric with *M. ruficollis interstes*, so when *gilvicolis* was included within *M. ruficollis*, *plumbeus* was elevated to species rank; now that *M. ruficollis* and *gilvicolis* have been shown to be separate species, status of *plumbeus* unclear, but generally retained as full species; further research required to clarify taxonomic status. Monotypic.

Distribution. SW Colombia (Cauca, Nariño) and NW Ecuador (Esmeraldas).

Descriptive notes. 30-37 cm. Above slate grey, with head, neck and centre of back paler; throat and breast grey, fading to whitish with fine blackish barring on lower breast, flanks and belly; black tail tipped white, with single narrow white bar through middle. Cere and feet yellow, iris yellowish to reddish brown. Tail pattern separates from congeners. Immature white below, with faint barring on flanks and breast.

Habitat. Interior of wet forest in lowlands and foothills of Pacific slope at 20-1000 m; may reach subtropical zone.

Food and Feeding. Virtually nothing known.

Stomach contents of 1 bird were a land crab and a lizard.

Breeding. No information available. Probably nests in tree cavities, as do congeners of which nests have been found.

Movements. Presumably sedentary.

Status and Conservation. VULNERABLE. CITES II. Suffering from deforestation and degradation of habitat within limited range, both in Colombia and Ecuador; surveys and protection required. Recorded within Munchique National Park, Colombia; also very near Cotacachi-Cayapas Ecological Reserve, Ecuador, which undoubtedly holds the species, but this large reserve is now being opened up for logging. Apparent rarity may be due also to secretive nature of *Micrastur*, and confusion with similar sympatric *M. ruficollis*.

Bibliography. Amadon (1964), Blake (1977), Brown & Amadon (1968), Collar & Andrew (1988), Collar *et al.* (1992), Hilty & Brown (1986), Meyburg (1986).

13. Lined Forest-falcon

Micrastur gilvicolis

French: Camifex à gorge cendrée Spanish: Halcón-montés Cabecigrís
German: Zweibinden-Waldfalke

Taxonomy. *Sparvius gilvicolis* Vieillot, 1817, no locality = Cayenne.

Recently split as valid species from *M. ruficollis*. Often considered to include *M. plumbeus* as race. Monotypic.

Distribution. E Colombia through S Venezuela to the Guianas, and S throughout Amazonia.

Descriptive notes. 33-38 cm; 172-223 g (average 211 g). Back pale grey; white below, with barring very variable in extent, from heavy all over, to much lighter and restricted to breast; dark tail has white tip and 2 (occasionally 1) narrow white bars. Iris white, facial skin typically reddish orange, legs yellow. Differs from *M. ruficollis* in colour of iris; tail usually has fewer bars; tail shorter, wings longer than in *M. ruficollis*, giving very different wing/tail ratios for the two species. Differs from *M. plumbeus* in tail pattern. Immature slightly browner; iris brown.

Habitat. Primary tropical forests in lowlands; in Colombia, occurs in humid *terra firme* forest. May range up to 1600 m.

Food and Feeding. Not well documented. Lizards and large insects; some birds; in French Guiana, mostly snakes. Hunts primarily in forest understorey. Follows army ant swarms, although less frequently and for shorter periods than *M. ruficollis*. Takes some birds (causes considerable mortality amongst birds trapped in mist-nets), but does not have foot structure of specialist on avian prey; passerines foraging near it, over army ant swarms, do not seem particularly afraid of it, in contrast to their behaviour when a small *Accipiter* approaches.

Breeding. Only nest record is of a stick nest, but this would be uncharacteristic of *Micrastur*; probably based on misidentification, as all other records for the genus involve cavity nests. Tail of a female trapped near Manaus, NC Brazil, was dirty, bent and broken off (all feathers roughly same length), as would be expected if the bird had been incubating in a small tree cavity. Breeding biology probably similar to closely related *M. ruficollis*.

Movements.

Conservation. Sedentary. Not globally threatened. CITES II. Probably the most abundant diurnal raptor over much of lowland forest of Amazonia, where it attains very high densities; territories

On following pages: 14. Slaty-backed Forest-falcon (*Micrastur mirandollei*); 15. Collared Forest-falcon (*Micrastur semitorquatus*); 16. Buckley's Forest-falcon (*Micrastur buckleyi*); 17. Spot-winged Falconet (*Spizapteryx circumcinctus*); 18. African Pygmy-falcon (*Polihierax semitorquatus*); 19. White-rumped Pygmy-falcon (*Polihierax insignis*); 20. Collared Falconet (*Microhierax caeruleus*); 21. Black-thighed Falconet (*Microhierax fringillarius*); 22. White-fronted Falconet (*Microhierax latifrons*); 23. Philippine Falconet (*Microhierax erythrogenys*); 24. Pied Falconet (*Microhierax melanoleucus*).

in central Amazon are c. 100 ha, with fairly even distribution throughout the forest. Average estimated density of at least c. 70 individuals/10,000 ha of forest in French Guiana, where the only raptor species apparently more abundant was *Daptrius americanus*.

Bibliography. Amadon (1964), Bierregaard (1988), Blake (1977), Hilty & Brown (1986), Klein & Bierregaard (1988a, 1988b), Koepcke (1972), Meyer de Schauensee & Phelps (1978), Pinto (1964), Schwartz (1972), Sick (1985a, 1993), Snyder (1966), Thiollay (1989a), Willis *et al.* (1983).

14. Slaty-backed Forest-falcon

Micrastur mirandollei

French: Carnifex ardoisé **German:** Graurücken-Waldfalke **Spanish:** Halcón-montés Dorsigrís

Taxonomy. *Astur mirandollei* Schlegel, 1862, Surinam.

Birds from NW of range have occasionally been placed in separate race, *extimus*, but not normally recognized. Monotypic.

Distribution. Costa Rica, Panama and Colombia (including W slope of Andes) through the Guianas and Amazonia to E Brazil (Espírito Santo).

Descriptive notes. 40-45 cm; c. 556 g. Slate grey above, darker on crown and tail; tail shorter than in other *Micrastur* species, with three often indistinct pale bands and narrow white tip; underparts, including wing linings, white or tinged buff. Very similar to immature *Accipiter bicolor* and some immatures of *M. ruficollis*, and also to *Leucopternis semiplumbea* and *Accipiter poligaster*; differs in structure, notably in longer legs and more extensive bare facial skin, and in fine details of plumage. Iris yellowish brown, cere yellow, legs and feet bright yellow. Immature brownish above; off-white to yellowish buff below,

with feathers edged fuscous brown, giving scaly effect.

Habitat. Lowland tropical rain forest, often in fairly undisturbed parts but also in tall secondary growth. In areas of overlap with *M. semitorquatus*, present species occupies canopy or upper levels of forest.

Food and Feeding. Very little information available. Feeds on birds. Hunts in middle to lower levels of forest. Reportedly perches low in understorey, uttering calls that elicit mobbing response from small birds; once flock of birds is attracted, forest-falcon moves stealthily, sometimes on foot, to another perch, where it resumes calling; birds caught as they move about trying to relocate the calling forest-falcon; these unusual observations require corroboration.

Breeding. No information available. Presumably nests in tree cavities, as do congeners.

Movements. Presumably sedentary.

Status and Conservation. Not globally threatened. CITES II. Status very poorly known, perhaps in part because so easily confused with other species. Widely distributed, but everywhere rare. One of rarest forest raptors in French Guiana, with estimated minimum average density of only 4 individuals/10,000 ha of forest.

Bibliography. Amadon (1964), Blake (1977), Brown & Amadon (1968), Hilty & Brown (1986), Meyer de Schauensee & Phelps (1978), Pinto (1964), Remsen & T aylor (1989), Ridgely & Gwynne (1989), Sick (1985a, 1993), Slud (1964), Smith (1969), Snyder (1966), Siles & Skutch (1989), Thiollay (1989a), Tostain *et al.* (1992), Wetmore (1965).

15. Collared Forest-falcon

Micrastur semitorquatus

French: Carnifex à collier **German:** Kappenwaldfalke **Spanish:** Halcón-montés Collarejo

Taxonomy. *Sparvius semi-torquatus* Vieillot, 1817, Paraguay.

Sometimes, especially in past, considered to include *M. buckleyi*. Two subspecies normally recognized.

Subspecies and Distribution.

M. s. naso (Lesson, 1842) - NC Mexico (Sinaloa to Tamaulipas) S through Central America to N & W Colombia and Ecuador.

M. s. semitorquatus (Vieillot, 1817) - E Colombia E to the Guianas, and S through E Peru, N & E Bolivia and Brazil to Paraguay and N Argentina.

yellow. Considerably larger than *M. buckleyi*, usually with more tail bands. Female similar to male, but larger. Immature varies from pale morph to a darker one, but all intermediate plumages have been found, suggesting progression of moults leading to adult plumage, reached only in third year; above dark brown, with contour feathers edged pale brown (edging gradually phased out with age); brownish nuchal collar inconspicuous or lacking; crown blackish; tail blackish, with barring white or brownish; underparts white to cinnamon buff, conspicuously barred brownish black; breast can be washed with chestnut; dark morph is all dark brown with rufous or white barring on thighs, belly and secondaries. Race *naso* generally very similar, but slightly larger and a little darker in all plumages.

Habitat. Lowland tropical rain forest, typically seen at forest edge; second-growth forest, especially with dense understorey, also occurs in mangroves. Widely distributed in semi-deciduous and semi-evergreen forests throughout Yucatán. Recorded up to 1950 m in Panama. In areas of overlap with *M. mirandollei*, present species occupies understorey.

Food and Feeding. Mammals and birds, including large species, e.g. chachalacas, toucans, cocks-of-the-rock, Great Curassow (*Crax rubra*), Ocellated Turkey (*Meleagris ocellata*), Crested

Guan (*Penelope purpurascens*) and Mottled Owl (*Ciccaba virgata*). Of 223 prey items recorded in Petén (Guatemala) during breeding season: 46% of identified items were mammals, mostly medium-sized, e.g. squirrels, rats, bats; 35% birds; and 20% lizards and snakes; 1 frog. Appears to locate prey by hearing, and will often run prey down on the ground. Infrequently follows army ant swarms, when takes prey flushed by ants. Like *M. mirandollei*, reportedly attacks birds attracted to rapid, whining call made from a low branch, only 1-2 m above ground; this needs corroboration.

Breeding. Virtually all data from Petén (Guatemala). Laying in Mar-Apr (late dry season) in Petén. Calls both before dawn and after sunset; courtship feeding. Female remains near potential site, to defend against potential usurpers; unlike *M. ruficollis*, no evidence for territoriality. Nests in cavities, usually with multiple entrances, 12-20 m above ground; nests in very large, mature trees in areas with many large and small vines, a less densely closed canopy and generally lower canopy level than in case of *M. ruficollis*. 2-3 eggs (average 2.1); incubation 46 days; fledging 46-50 days. In latter part of nestling phase, male begins to deliver food to nest, if female away hunting. Male fed young for 1 month after fledging, at which point another adult male "adopted" the young, providing 36 prey items (almost all toucans) during period 4-14 weeks after fledging; the apparent natural parents disappeared after week 4. Young range up to 3 km from nest during first 3 months after fledging; begin to pursue potential prey 6 weeks after fledging. Fidelity to mate and nest-site high: one site used 5 years running; young fledged successfully from one nest 3 years in a row, so no prolonged post-fledging dependency.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Not uncommon over vast range; secretive nature presumably reduces threat from hunters. In French Guiana, average estimated density of at least c. 12 individuals/10,000 ha. Non-breeders in Petén had home ranges of 2.3-8.8 km², breeding pairs of c. 11 km². First nest for genus only discovered in 1978; since then, virtually all data available on breeding biology of species is result of Peregrine Fund's Maya Project, involving studies of 8 nests in Tikal National Park, Petén (Guatemala).

Bibliography. Blake (1977), Contreras *et al.* (1990), Enquist *et al.* (1992), Friedmann (1950), Hilty & Brown (1986), Lowery & Dalquest (1951), Mader (1979b), Mays (1985), Monroe (1968), Peeters (1963), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Rivera & Córdova (1992), Russell (1964), Sick (1985a, 1993), Slud (1964), Smith (1969), Smithe & Paynter (1963), Siles & Skutch (1989), Thiollay (1989a), Thorstrom (1989, 1990b, 1993), Thorstrom *et al.* (1990, 1991b), Trail (1987), Vannini (1989), Wetmore (1965, 1974), Willis *et al.* (1983).

16. Buckley's Forest-falcon

Micrastur buckleyi

French: Carnifex de Buckley **German:** Traylorwaldfalke **Spanish:** Halcón-montés de Buckley
Other common names: Lesser Collared/Traylor's Forest-falcon

Taxonomy. *Micrastur melanoleucus buckleyi* Swann, 1919, Sarayacu, Ecuador.

Known only from about a dozen specimens and a few sightings; formerly considered a variant of *M. semitorquatus*. Monotypic.

Distribution. Amazonian reaches of Ecuador and Peru; single record from SE Colombia; apparent recent record from Brazil (R Jurua, Acre) has now been withdrawn.

Descriptive notes. 41-51 cm. Above black, with some white feather edging on wing-coverts; black of cap extends down behind the eye; prominent white collar; immaculate white below; tail black with narrow white bands, three on central, four on outer rectrices. Smaller version of *M. semitorquatus*, to which nearly identical in plumage; invariably only four white bands in outer tail feathers; proportionately shorter tarsi. Female similar to male, but has white spots on scapulars and secondaries. Immature (1 subadult) black above, as adult, with buffy breast and broadly spaced dark barring on belly.

Habitat. Said to occur in lowland forest, but recorded at 1800 m in Cordillera Cutucú, Ecuador; one record in middle storey of inundated primary forest, possibly referring only to single bird.

Food and Feeding. No information available. One report (from museum label) of a small tree-rat (*Mesomys*). Small feet suggest species is not specialist on avian prey; short tarsi suggest it may feed in trees.

Breeding. No information available. One record of a recently fledged young (c. 1 week after fledging) in Jul in Boca Manu, Peru. Probably nests in tree cavities, as is typical of genus.

Movements. Presumably sedentary.

Status and Conservation. INSUFFICIENTLY KNOWN. CITES II. Status virtually unknown. Secretive nature of genus and sympatry with very similar *M. semitorquatus* render estimates of population levels very difficult. Surveys required to establish limits of range and densities. Evidence suggest that species is not immediately threatened; however, at least in part of range, habitat is in process of being cleared.

Bibliography. Amadon (1964), Blake (1977), Collar & Andrew (1988), Collar *et al.* (1992), Hilty & Brown (1986), Meyburg (1986), Meyer de Schauensee (1982), O'Neill & Pearson (1974), T aylor (1948, 1958).

Subfamily FALCONINAE

Genus SPIZIAPTERYX Kaup, 1852

17. Spot-winged Falconet

Spizapteryx circumcinctus

French: Carnifex à ailes tachetées **German:** Tropfenfalke **Spanish:** Halcóncito Argentino

Taxonomy. *Haipagus circumcinctus* Kaup, 1852, Chili: error. Mendoza, Argentina. Taxonomic position unclear, and species frequently placed in present subfamily or in Polyborinae; variously associated with Old World genus *Polihiarax*, or with aberrant Neotropical falconids

Micrastur, *Herpetotheres* and caracaras; sometimes considered closest to caracaras, but alternatively placed apart in separate subfamily alongside only *Herpetotheres*. Monotypic.

Distribution. E Bolivia (Santa Cruz) through Paraguay to N & C Argentina (S to Río Negro).

Descriptive notes. 28.5-33 cm; c. 150 g. Diminutive. Back, head and wings greyish brown; pale streak above and behind eye, black ear-coverts and narrow black moustachial streak; shoulders spotted white, rump white; throat and lower belly white; breast, sides and upper belly greyish, narrowly streaked brown; central rectrices dark, rest of tail barred white, with white tip; conspicuous white spots on wing, white underwing-coverts. Iris pale yellow, cere, feet and legs yellow. Female similar, but slightly larger. Unlike other falconids, no distinct immature plumage.

Habitat. Savanna, woodland with scrub and semi-desert. Chaco in Bolivia; semi-open Chaco forest in Argentina.

Food and Feeding. Feeds on insects (Orthoptera, cicadas), lizards and birds. Bird prey includes adult and young Monk Parakeets (*Myiopsitta monachus*); present species roosts in communal nests of these parakeets in winter, and nests in them in summer; actually observed roosting in active Monk Parakeet nests, with parakeets entering chamber after the falconets, and spending the night with them.

Breeding. Very little information available. Laying in Nov-Dec, in Argentina. Nest in woven, closed nests of other species, e.g. cachaletes (Furnariidae) and sometimes active Monk Parakeet colonies; near Córdoba (NC Argentina), 15 out of 70 Monk Parakeet nests also had a nesting pair of falconets. For nesting, Monk Parakeet nest entrances are enlarged to 20 cm high x 30 cm wide, and nest chamber enlarged into roughly spherical cavity c. 30 cm wide. 2-4 eggs; fledging probably c. 33 days.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Status virtually unknown; habitat is not amongst most seriously devastated in the region. Single record from Paraguay.

Bibliography. Blake (1977), Cabot *et al.* (1988), Contreras *et al.* (1990), Dean (1971), Griffiths (1994), Kratter *et al.* (1993), Martella & Bucher (1984), Mariella *et al.* (1985), Meyburg (1986), Narosky *et al.* (1992), Olson (1976), Pereyra (1937), de la Peña (1992), Remsen & Traylor (1989), Straneck & Vasina (1982).

Genus *POLIHIERAX* Kaup, 1847

18. African Pygmy-falcon

Polihierax semitorquatus

French: Fauconnet d'Afrique **German:** Halsband-Zwergfalke **Spanish:** Halconcito Africano
Other common names: Pygmy Falcon

Taxonomy. *Falco semitorquatus* [sic] A. Smith, 1836, Kuruman, Botswana.

N population sometimes separated as race *castanonotus*, but poorly differentiated, although widely separated geographically. Monotypic.

Distribution. S Ethiopia, Somalia, NE Uganda and Kenya to NC Tanzania; S Angola and Namibia to NW South Africa.

Descriptive notes. 20 cm; 54-67 g; wingspan 37 cm. Tiny shrike-sized falconet with white-spotted wings and tail. Female with chestnut back when juvenile and adult. Juvenile has buff breast. No consistent colour or size differences between separate populations.

Habitat. Arid and semi-arid steppe with sparse ground cover and scattered large trees or tree-like *Aloe* plants. Relies on weaver nests for roost- and nest-sites, especially those of Sociable Weaver (*Philetairus socius*) in S Africa, and of White-headed Buffalo-weaver (*Dinemellia dinemelli*) in NE Africa. Pairs or families often roost together in the same

weaver nest-chamber, or an adjacent one. Sometimes roosts in nests of sparrow-weavers (*Plocpasser*) and some starling species.

Food and feeding. Mainly small lizards and large insects, but also some rodents, birds and other arthropods. Pounces on prey from a perch and takes most items on the ground, rarely after a short aerial chase. Occasionally catches the host weavers or takes their chicks.

Breeding. Sometimes polyandrous. Laying Jun-Dec in NE Africa; Aug-Mar in S Africa; double-brooded in some years. Calling, head-bobbing and bowing displays, with tail-pumping, increase prior to nesting. Pair occupies a weaver nest-chamber, the nest lip becoming obviously coated with white droppings that turn pink with age. Usually 3 eggs (2-4); incubation 28-30 days; chicks have white down; fledging 27-40 days; juveniles remain in parental territory for up to 2 months after fledging.

Movements. Resident in most areas but some local movement in drier parts of range, leaving areas during periods of extreme aridity. Also vagrant to moister habitats in Kenya, S Tanzania and probably NE South Africa and S Mozambique. Confined to nest chamber for up to 15 hours a day during winter, with moderate hypothermia.

Status and Conservation. Not globally threatened. CITES II. Widespread and common in most areas, range of its weaver host in S Africa being extended by availability of nest-sites on utility poles and other man-made structures. Land use within its range does not require pesticides, and species may even benefit where grazing by livestock reduces ground cover. Occurs within some large game reserves and national parks. Favours larger weaver nest masses, occupying about 12-25% of nest masses available; uses up to six chambers for each of its nests; pairs spaced 1.84-2.1 km apart in the Namib and Kalahari Deserts.

Bibliography. Ash & Miskell (1983), Brown, C.J. (1989b), Brown, L.H. *et al.* (1982), Dancel (1966b), Ginn *et al.* (1989), Griffiths (1994), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1970, 1993), Marx & Adam (1986), Pickford *et al.* (1989), Sapsford (1986), Snow (1978), Steyn (1982), de Swardt (1990b), Thomsett (1991b).

19. White-rumped Pygmy-falcon

Polihierax insignis

French: Fauconnet à pattes jaunes

German: Langschwanz-Zwergfalke

Spanish: Halconcito Asiótico

Other common names: Fielden's Falconet, White-rumped Falcon

Taxonomy. *Polihierax insignis* Walden, 1872, Tongoo, Upper Burma.

Sometimes awarded separate, monotypic genus, *Neohierax* (see page 219). Racial variation slight; validity of subspecies requires reassessment. Three subspecies currently recognized.

Subspecies and Distribution.

P. i. insignis Walden, 1872 - W & C Burma, especially in valley of R Irrawaddy.

P. i. cinereiceps Stuart Baker, 1927 - S Burma (Tenasserim) and Thailand.

P. i. harmandi Oustalet, 1876 - S Indochina, in S & C Laos, S Vietnam (S Annam, Cochinchina) and Kampuchea.

Descriptive notes. 23-28 cm; 84-112 g; wingspan 43-49 cm. Large grey and white falconet with conspicuous white uppertail-coverts; larger than *Microhierax* falconets. Head, nape and upper back grey in male, rufous in female. Juvenile similar to adult male, but with white collar and brown streaking on underparts. Races differ very slightly, if at all, in plumage: *cinereiceps* said to be somewhat darker above; *harmandi* apparently has head paler in male.

Habitat. Open woodland, often around clearings; also in savanna. Occurs from lowlands up to 700 m.

Food and Feeding. Large insects and small birds; also frogs, snakes, lizards and small mammals. Hunts from exposed perches, making sallies to take flying insects and birds, and also dropping to ground to capture grasshoppers, lizards and small mammals. Flight rather weak and fluttery.

Breeding. Little studied. Season Feb-Apr; pair breeding in Feb; female with egg in Mar. Reported to use stick nest previously occupied by other raptors or by corvids. No further information available.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Uncommon and local in Thailand. Little known, but appears to be relatively secure at present; reasonably broad habitat tolerance suggests species may be adaptable to human pressure that is rather intense throughout most of range.

Bibliography. Brown & Amadon (1968), Deignan (1945), Griffiths (1994), King *et al.* (1975), Lekagul & Round (1991), Riley (1938), Smythies (1986).

Genus *MICROHIERAX* Sharpe, 1874

20. Collared Falconet

Microhierax caerulescens

French: Fauconnet à collier

German: Rotkehlfalkchen

Spanish: Falconete Acolorado

Other common names: Red-thighed/Red-legged/Red-breasted Falconet

Taxonomy. *Falco caerulescens* Linnaeus, 1758, Asia = Bengal.

Genus apparently closest to Afrotropical *Polihierax semitorquatus*. Races differ little, with *burmanicus* doubtfully valid. Two subspecies normally recognized.

Subspecies and Distribution.

M. c. caerulescens (Linnaeus, 1758) - E Himalayas of India (Kumaon) and Nepal to NE India (N Assam).

M. c. burmanicus Swann, 1920 - Burma E to C & S Indochina.

Descriptive notes. 15-18 cm; 30-50 g; wingspan 30-34 cm. A falconet very shrike-like in size and behaviour. Thick black eyestripe, rufous belly and legs, and white collar distinctive. Female very similar to male, but slightly larger; tends to have more white in wing, with nuchal collar less conspicuous. Some individual variation may exist: birds with rufous brow and white throat sometimes said to be adult females, but most, perhaps all, are probably immatures. Dubious race *burmanicus* smaller; nuchal collar said to be wider, breast whiter.

Habitat. Open forest and forest edge, often near rivers or streams, from sea-level up to

900 m.

Food and Feeding. Feeds mainly on large insects, especially butterflies; also birds, some rather large, and lizards. Hunts from exposed perch in dead tree or large open tree above forest canopy, at forest edge, or along stream or river; occasionally hunts in small groups of up to 7 individuals. Prey usually taken in the air, but also from leaves and small branches; captured after swift, powerful, shrike-like attack flight; taken back to perch for consumption. Tends to be most active around dusk, sometimes catching moths. Perched bird frequently bobs tail.

Breeding. Season usually Feb-May. Nests in old nest-holes of barbets, occasionally in holes in buildings. Display flights not recorded; courtship includes allopreening. Normally 4-5 eggs, but sometimes as few as 2. Parents aggressive in nest defence. Nest-hole may be occupied all year round. No further information available.

Movements. Sedentary. Vagrant to Yunnan (SC China).

Status and Conservation. Not globally threatened. CITES II. Fairly common to uncommon throughout much of extensive range. Tolerance of disturbed habitats, along with fairly varied diet, suggests species in no danger.

Bibliography. Ali & Ripley (1978), Brown & Amadon (1968), Cheng Tso-hin (1987), Deignan (1945), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), Ripley (1982), Smythies (1986).

21. Black-thighed Falconet

Microhierax fringillarius

French: Fauconnet moineau **German:** Finkenfalkchen **Spanish:** Falconete Indonésio
Other common names: Black-legged/Black-tailed/Black-sided/Malay Falconet

Taxonomy. *Falco fringillarius* Drapiez, 1824. "Indes" = Sumatra.

Sometimes regarded as race of *M. caerulescens*, but plumage distinct, with no intergradation recorded. Monotypic.

Distribution. S Burma (S Tenasserim) and S Thailand through Peninsular Malaysia to Sumatra, Borneo, Java and Bali.

Descriptive notes. 14-17 cm; 28-55 g; wing-span 30-34 cm. Small falconet, similar to *M. caerulescens* but more rufous on underparts; black flanks and thighs; lacks white collar. Female similar to male but larger. Juvenile has rufous wash on white parts of head.

Habitat. Open forest, forest edge and clearings from sea-level up to 1300 m. In Sumatra, sometimes attracted to patches of active slash-and-burn forest destruction, where prey presumably more abundant and more readily available; also hunts over nearby cultivation.

Food and Feeding. Preys mainly on large insects, including butterflies, moths, cicadas and

termites; also birds, some rather large, and lizards. In Malaysia, prey ranged in size from small insects 0.5 cm in length to large moth with wingspan of c. 20 cm. Hunts from exposed perch in dead tree or large open tree above forest canopy, at forest edge, or along stream or river; sometimes hunts in groups of up to 10 individuals. Feeds communally, with up to 4 falconets eating from single prey item; communal hunting and feeding may be important for young to learn which insects are suitable prey. Prey usually taken in the air, but also from leaves and small branches; captured after swift, powerful attack flight. Perched bird frequently bobs tail. In Malaysia, most strikes made level with perch or below it; 46% success rate recorded in 57 attempted strikes. **Breeding.** Laying Nov-Dec in Borneo; normally Feb-Mar in Peninsular Malaysia, Sumatra and Java; three fledglings in Aug, in Malaysia; evidence of active breeding in Feb, Apr, Jun and Sept in Padang-Sugihan Reserve (S Sumatra). Nests c. 6-20 m up, in old nest-holes of barbets, occasionally in holes in buildings. Display flights not recorded; courtship includes allopreening, with bouts often lasting 30 minutes; one record of pair copulating, while another individual perched less than 1 m away. Normally 4-5 eggs, but sometimes as few as 2. Nest-hole occupied all year round. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Fairly common to common, e.g. in reserve of Padang-Sugihan (S Sumatra) in mid-1980's. Tolerance of disturbed habitats, along with fairly varied diet, suggests species in no danger.

Bibliography. Brown & Amadon (1968), Holmes & Burton (1987), Kemp & Crowe (1994b), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Phillips (1993), Madoc (1976), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee & Ripley (1940), Molesworth (1955), Riley (1938), Smythies (1981, 1986), Thiollay & Meyburg (1988), Wilkinson *et al.* (1991a, 1991b).

22. White-fronted Falconet

Microhierax latifrons

French: Fauconnet de Bornéo **German:** Weißscheitelfalkchen **Spanish:** Falconete de Borneo
Other common names: Bornean Falconet

Taxonomy. *Microhierax latifrons* Sharpe, 1879, Lawas River and Lumbidan, Borneo. Monotypic.

Distribution. N Borneo, in extreme NE Sarawak and Sabah.

Descriptive notes. 15-17 cm; 35-65 g. Typical falconet, distinguished from sympatric *M. fringillarius*, and indeed from all congeners, by having forehead and forecrown white in male, chestnut in female; pale tan wash on belly. Juvenile almost identical to adult female.

Habitat. Open forests and clearings from sea-level to above 1200 m.

Food and Feeding. Mainly insects, including bees, but also reported pursuing birds. Family parties observed; probably hunting gatherings similar to those reported for *M. fringillarius*. Presumably hunts in similar fashion to latter

species.

Breeding. Thought to breed in Mar-Apr; account of family group in Nov probably refers to hunting group, rather than evidence of recent breeding. Reported to nest in old woodpecker and barbet holes. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Status uncertain, but species appears to be fairly common within its restricted range. Long

term threat could be loss of forest habitat. Research required especially on breeding biology; surveys also recommended, in order to clarify status.

Bibliography. Brown & Amadon (1968), MacKinnon & Phillips (1993), Meyburg (1986), Smythies (1981).

23. Philippine Falconet

Microhierax erythrogenys

French: Fauconnet des Philippines **German:** Zweifarbenfalkchen **Spanish:** Falconete Filipino

Taxonomy. *Hierax erythrogenys* Vigors, 1831, near Manila.

Often erroneously spelt *erythronys*. Two subspecies recognized.

Subspecies and Distribution.

M. e. erythrogenys (Vigors, 1831) - Luzon, Mindoro, Negros and Bohol (Philippines).

M. e. meridionalis Ogilvie-Grant, 1897 - Samar, Leyte and Cebu to Mindanao (Philippines).

Descriptive notes. 15-18 cm; 37-52 g. Typical falconet, lacking any rufous in plumage. Juvenile very similar to adult, but with ochre ear-coverts.

Habitat. Open wet forest, forest edge and clearings from 300 to 1200 m; particularly fond of exposed branches on emergent trees in forest.

Food and Feeding. Preys primarily on insects, with a few lizards; in one study most of insects were dragonflies (Odonata). Hunts from exposed perch in dead tree or large open tree above forest canopy, at forest edge, or along stream or river. Prey captured in the air,

after swift, powerful attack flight; if prey missed, bird does not chase, but returns to perch. Often hunts in small groups of up to 6 individuals. One function of communal hunting may be defence against predators, as one group gave alarm calls when a Besra (*Accipiter virgatus*) was sighted; may also serve for teaching young birds which insects are suitable for capture; young may continue to hunt with their parents in group until the next breeding season.

Breeding. Usually Mar-May; copulation seen in mid-Feb. Nests in old barbet or woodpecker holes in dead trees, usually 6-8 m above ground. Groups of 3-4 fledglings recorded. Adults vigorous in defence of nest. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Fairly common to common in forest habitat. Not immediately threatened overall, but extirpated from many areas which have suffered comprehensive deforestation.

Bibliography. Brown & Amadon (1968), Dickinson *et al.* (1991), DuPont (1971), Gonzalez (1983), McGregor (1909-1910), Meyer de Schauensee & DuPont (1962), Miranda (1991), Parkes (1973), Potter (1953), Rabor (1938, 1977), Rand & Rabor (1960), Wolfe (1938).

24. Pied Falconet

Microhierax melanoleucus

French: Fauconnet noir et blanc **German:** Elsterfalkchen **Spanish:** Falconete Pío
Other common names: White-legged Falconet

Taxonomy. *Ierax melanoleucus* Blyth, 1843, Assam.

Monotypic.

Distribution. NE India (Assam) E across S China to Zhejiang, and S to N Laos and N & C Vietnam.

Descriptive notes. 18-20 cm; 55-75 g; wing-span 35-37 cm. Largest of *Microhierax* falconets; black above and white below, lacking any rufous; forehead sometimes white, sometimes blackish; white supercilium separates from *M. erythrogenys*. Juvenile similar to adults.

Habitat. Forest edge and open areas of moist-deciduous and evergreen forest; also recorded in tea plantations. Occurs from sea-level up to 1500 m.

Food and Feeding. Preys on large insects, particularly butterflies, dragonflies and grasshoppers; also small to medium-sized birds;

reported to take lizards and small mammals on ground. Hunts from an exposed perch in a dead tree or large open tree above forest canopy, at forest edge, or along stream or river; does not remain at any perch for long period, but perpetually moves to new perches. Prey captured in the air after swift, powerful, shrike-like attack flight. Has been observed in small hunting groups typical of genus.

Breeding. Laying usually Mar-May. Nests in old barbet or woodpecker holes 13-30 m above ground. Clutch size unknown, but usually 3-4 fledglings. Adults aggressive in nest defence. No further information available.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Fairly common to uncommon; adaptability to habitats transformed by man, along with varied diet, suggests species unlikely to be in immediate danger.

Bibliography. Ali & Ripley (1978), Andrew (1992), Brown & Amadon (1968), Cheng Tso-hin (1987), Etchécopar & Hue (1978), King *et al.* (1975), Meyer de Schauensee (1984), Ripley (1982).

Genus *FALCO* Linnaeus, 1758

25. Lesser Kestrel

Falco naumanni

French: Faucon crécerellette German: Rötelfalke Spanish: Cernícalo Primilla

Taxonomy. *Falco Naumanni* Fleischer, 1818, southern Germany and Switzerland; error = Sicily. Monotypic.

Distribution. SW Europe and N Africa E through E Europe, Asia Minor and Iran to Mongolia and N China (E to Shandong). Winters in Africa S of Sahara; also and irregularly in parts of S Asia.

Descriptive notes. 29-32 cm; male 90-172 g, female 138-208 g; wingspan 58-72 cm. Unspotted above; greater upperwing-coverts blue-grey; underparts less spotted than in *F. tinnunculus*. Female very similar to that of *F. tinnunculus*, but slightly smaller; with claws white, not black; central two rectrices protrude slightly. Juvenile almost identical to female.

Habitat. Open areas in hot, dry climates; little or low vegetation, e.g. steppe, pastures, semi-desert, extensive cultivation; also in and around towns. Normally in flat or undulating terrain in lowlands, although in Asia regularly breeds up to 1500 m. In winter affects savanna, steppe, low scrub and cultivation. Highly dependent on presence of buildings or rock faces on which to nest. During migration and in winter quarters, large numbers gather at roosts in old buildings, or suitable trees; sometimes thousands of birds congregate.

Food and Feeding. Fair variety of aerial and terrestrial insects, often constituting over 90% of prey. Mainly Orthoptera (grasshoppers, locusts, crickets) and large beetles; also other invertebrates, e.g. centipedes; in winter quarters, when abundant, consumes large quantities of flying termites, Orthoptera and flying ants. Vertebrates generally less important: small lizards and to lesser degree rodents, e.g. voles, mice, shrews; small birds and their fledglings. Flies low, stooping on prey in air or on ground; typically faces into wind and hangs without beating wings, or hovers briefly; also hunts from perch or even on ground. Hunts in groups; in Africa enormous gatherings may form, following swarming insects. Takes advantage of prey disturbed by grass or scrub fires, or by tractors turning soil. Can travel 1-7 km from breeding colony to feed, sometimes more.

Breeding. Laying mainly in May; in NW Africa and S Spain from mid-Apr. Colonial, normally in groups of no more than 25 pairs; sometimes, in past commonly, up to hundreds of pairs. Nests mainly in human constructions, e.g. large old buildings, houses, walls and ruins, in towns or on outskirts; also in natural sites, e.g. rock faces, clay banks and quarries. Nest placed in hollow or below eaves. Normally 3-6 eggs (average c. 4), laid at intervals of 2 days; replacement laying occurs; incubation 26-28 days, by both adults; both adults also feed chicks; chicks have first down white, second down creamy white; fledging c. 36 days; independence 1 week later. Hatching success 62-75%; on average 2 chicks fledge per clutch, although significant annual variations; annual survival about 67% for adults, 30% for juveniles. Sexually maturity in first year. Oldest recorded bird in captivity 11 years old.

Movements. Mainly trans-Saharan migrant, although some birds winter in NW Africa and in various regions of S Europe and S Asia, e.g. S Spain, S Turkey, Azerbaijan; occurrence in India, and perhaps in Burma, probably refers to birds on passage, with only stragglers overwintering. Most birds migrate to S Africa. Nomadic movements in winter related to local concentrations of insects. Following post-breeding dispersal, birds fly to winter quarters, mainly in Sept; return to breeding areas varies with latitude, Feb in Morocco, Mar-Apr in Europe; juveniles return later. Migrates across broad front, often in large flocks, sometimes mixed with *F. vespertinus* or *F. tinnunculus*.

Status and Conservation. RARE. CITES II. Drastic and apparently widespread decline in second half of 20th century. In 1980's only important populations in Europe were: 4200-5100 pairs in Spain (end 1980's); not more than 150 pairs in Portugal (end 1980's); estimated 320-400 pairs in Italy; 120-130 pairs in Romania; and 2000 pairs in Greece estimated in early 1980's, with marked decline later. Little information regarding populations in Asia and former USSR, where status appears worrying, although estimated 1500-2000 pairs in Georgia and Azerbaijan in early 1990's; now very rare in S Ukraine, with rapid decline due to exploitation of steppes; apparently still numerous in parts of former USSR, e.g. Kazakhstan. Estimated 3000-4000 pairs in Turkey (1993); 300 pairs in Israel in early 1980's, where recovering after near extinction due to rodenticide poisoning. Perhaps 1000 pairs in Morocco in 1980's; in South Africa 154,000 birds counted in winter census of roosts in 1967, but by mid-1980's numbers possibly reduced by half. Causes of decline include: massive use of pesticides, resulting in drastic reduction in prey, poisoning, and reduced breeding success during period of DDT use; rebuilding or demolition of old buildings habitually used for nesting, leading sometimes to disappearance of colonies; habitat loss, through intensification of agriculture, desertification and overgrazing in winter quarters, etc. Since 1980's, successful protection measures, including: control of refurbishing of buildings hosting colonies; installation of artificial nests; and in some areas reintroduction. As result, some populations stable or increasing, at least locally.

Bibliography. 26. Common Kestrel

Falco tinnunculus

French: Faucon crécerelle German: Turmfalke Spanish: Cernícalo Vulgar
Other common names: European/Eurasian/Rock Kestrel

Taxonomy. *Falco Tinnunculus* Linnaeus, 1758, Sweden.

May form superspecies with *F. sparverius*, with *F. newtoni*, *F. punctatus* and *F. araea*, and with *F. moluccensis* and *F. cenchroides*. Several races poorly differentiated, and may be invalid. Eleven subspecies normally recognized.

Subspecies and Distribution.

F. t. tinnunculus Linnaeus, 1758 - N Africa, Europe and Middle East E to E Siberia and Soviet Far East.

F. t. interstinctus McClelland, 1840 - Tibet E through N Indochina and S & C China to Korea and Japan; winters S to India, Malay Peninsula and Philippines.

F. t. oburgatus (Stuart Baker, 1927) - S India (W & E Ghats) and Sri Lanka.

F. t. canariensis (Koenig, 1890) - Madeira and W Canary Is.

F. t. dacotiae Hartert, 1913 - E Canary Is.

F. t. neglectus Schlegel, 1873 - N Cape Verde Is.

F. t. alexandri Bourne, 1955 - SE Cape Verde Is.

F. t. rupicolaeformis (C. L. Brehm, 1855) - NE Africa and Arabia.

F. t. archerii Hartert & Neumann, 1932 - Somalia, coastal Kenya and Socotra.

F. t. rufescens Swainson, 1837 - W & C Africa, E to Ethiopia and S to S Tanzania and N Angola.

F. t. rupicolus Daudin, 1800 - N Angola, S Zaire and S Tanzania S to S South Africa.

Descriptive notes. 32-39 cm; male 136-252 g, female 154-314 g; wingspan 65-82 cm. Head and tail grey, with subterminal black band on tail; outer half of upperwing dark; rest of upperwing and back chestnut spotted black; pale underparts also spotted, especially on breast and underwing-coverts. Female generally more uniformly coloured and more heavily spotted, lacking grey areas; barred tail. Juvenile very similar to female; broader streaks below; cere, legs and feet paler. Races separated on coloration, density of markings, tail pattern and size; African forms generally darker and more rufous; races of tropics and

S Africa show reduced sexual dimorphism.

Habitat. Adaptable to great variety of open or moderately wooded terrains, normally with herbaceous vegetation or low shrubs; grassland, steppe and even sub-desert, moorland, cultivation, wetlands with light vegetation; also in villages, towns and even cities, on outskirts and in lightly built-up areas. From coast to pastures above tree-line in mountains, occasionally reaching 4500 m. Requires suitable sites on which to perch and roost, e.g. trees, telegraph poles, buildings, rock faces.

Food and Feeding. Mainly small mammals, in Europe up to 90% voles, with some mice and shrews; open area passerines normally less important, although fledglings often seasonally important; also lizards and insects, e.g. beetles, grasshoppers, locusts, crickets; other invertebrates, e.g. earthworms. In Mediterranean and Africa, insects may predominate or be very important, even in terms of biomass, especially beetles, locusts, termite alates and solifugids; to lesser extent, lizards. Normally hunts from rather low flight or from perch, carefully surveying the ground; frequent characteristic hovering flight to detect small mammals and other terrestrial prey. Prey taken in air mainly insects, also birds and sometimes bats.

Breeding. Laying dates very variable. In Europe and Asia N of Himalayas normally lays Apr-May (Mar-Jun); very variable in Africa, often Aug-Dec S of Sahara, normally coinciding with dry season or S spring. Nest-site variable: ledges and holes in rock faces, quarries and buildings; trees, in holes or old nests of other birds, particularly corvids; sometimes in small colonies of up to several tens of pairs. Normally 3-6 eggs (1-7), laid at intervals of 2 days; replacement laying occurs; incubation 27-31 days, by female; in first phase of nestling period only male brings food; chicks have first down white, second down buff-grey; fledging 27-35 days; chicks dependent on adults and fed 2-4 weeks more. Breeding success variable: in Britain average 3-7 chicks fledge per successful pair, but perhaps only 2-5 per breeding pair; breeding success often related to abundance of voles. Sexual maturity during first year. Mortality c. 50-70% in first year, c. 30-40% in later years. Oldest recorded bird 16 years.

Movements. Nominate race migratory in N and E of breeding range; sedentary or dispersive in rest of range, although partially migratory in C Europe and elsewhere at middle latitudes; large numbers of migrants cross to Africa, moving S to Angola and Zimbabwe. Race *interstinctus* migratory in most of range, wintering in coastal China, Korea and Japan, and S to India and Indochina. Other races sedentary or dispersive; juveniles generally dispersive, even in sedentary populations.

Status and Conservation. Not globally threatened. CITES II. Commonest diurnal raptor throughout much of range, at least in W Europe and NW Africa. Some decline following generalized use of organochlorine insecticides and other pesticides, mainly in 1950's and 1960's; however, decline much less severe than in other raptors, e.g. Eurasian Sparrowhawk (*Accipiter nisus*); recovery detected, following restriction or banning of these products. In 1980's and early 1990's population changes in much of Europe seem to be result of natural fluctuations, due to factors such as abundance of rodents or cold winters. However, not all populations so healthy, and species in decline in former USSR, especially in S. Total population estimated at 1,000,000-2,000,000 pairs; population of Europe (excluding former USSR) estimated at 192,000-340,000 pairs; in European Russia perhaps 60,000 pairs. In 1990, Canary Is held c. 400 pairs of race *dacotiae* and perhaps over 4000 pairs of race *canariensis*.

27. Madagascar Kestrel

Falco newtoni

French: Crécerelle malgache **German:** Madagaskarfalke **Spanish:** Cernícalo de Aldabra
Other common names: Newton's Kestrel, Aldabra Kestrel

Taxonomy. *Tinnunculus newtoni* Gurney, 1863, Madagascar.

Considered closest to *F. punctatus* and *F. araea* in the *F. tinnunculus* species group. A separate race, *aldabranus*, sometimes recognized for birds from Aldabra Is. Monotypic.

Distribution. Madagascar and Aldabra Is; perhaps rare vagrant to the Comoro Is.

Descriptive notes. 25 cm; male 90–117 g, female 131–153 g. Occurs in two colour morphs: pale morph (c. 80% of birds) with upperparts rufous, head grey and underparts white, streaked with black on upper breast; rufous morph has head and neck very dark, and the back and underparts deep chestnut. Female similar, but generally browner overall and more heavily marked below. Juvenile similar to adult but flight-feathers edged buff and underparts more heavily streaked. Aldabran birds smaller and lighter, especially females, some of which have unmarked underparts.

Habitat. Open country to 1830 m, in areas of

natural grassland, but now mainly in cropland around towns and villages or along road verges; even roosts under eaves of buildings.

Food and feeding. Mainly insects, especially grasshoppers and beetles, but also takes small mammals, reptiles and some birds and frogs. Hunts mainly from low perches but also hovers in search of prey and hawks some insects in flight. Pumps tail up and down when perched. Often crepuscular in hunting, sometimes in company of *F. eleonorae* and *F. concolor*.

Breeding. Laying Sept–Nov. Nests in cavities in buildings, cliff faces and trees, among epiphytes and in old nests of Black Kite (*Milvus migrans*) and Pied Crow (*Corvus albus*). Usually 4 eggs; female does most incubation, being called off the nest for food by the male.

Movements. No regular movements reported, but appearance of vagrants on the Comoro Is suggests some dispersal.

Status and Conservation. Not globally threatened. CITES II; possible race *aldabranus* included on CITES I. Common and widespread on Madagascar, where cultivation, urbanization and deforestation have increased its habitat; total population reckoned to number c. 30,000–60,000 pairs in 1982. Recorded at about 1 bird every 4 km along roads in the deforested central highlands, but only every 48 km among the forested E lowlands, where *F. zoniventris* is commoner. Rare and local on the Aldabra atoll, where c. 100 pairs exist, possibly only recent colonists, since the advent of man with his buildings and palm trees, and also an associated increase in abundance of available old crow nests. Not known to be affected by pesticide use.

Bibliography. Benson (1960a), Benson & Penny (1971), Brown & Amadon (1968), Cade (1982), Dee (1986), Gaymer (1967), King (1978/79), Langrand (1990), Langrand & Meyburg (1984), Louette (1988), Milon *et al.* (1973), Penny (1974), Rund (1936), Siegfried & Frost (1970).

28. Mauritius Kestrel

Falco punctatus

French: Crécerelle de Maurice **German:** Mauritiusfalke **Spanish:** Cernícalo de la Mauricio

Taxonomy. *Falco punctatus* Temminck, 1821, Mauritius.

Considered closest to *F. newtoni* and *F. araea* in the *F. tinnunculus* species group. Probably also close to endemic kestrel species of Reunion, extinct since 17th century, but known from bones and some anecdotal accounts. Monotypic.

Distribution. Mauritius I. SW Indian Ocean.

Descriptive notes. 20–26 cm; male averages 178 g, female 231 g. A small stout kestrel with relatively short, rounded wings, a long tail and long legs and toes. Juvenile has facial skin blue-grey becoming yellow within a year; otherwise ages and sexes not readily distinguishable, possibly neotenic, with juvenile features persisting in adults.

Habitat. Originally occupied evergreen forest from seashore to the highest peaks, of which only a remnant patch remains in SW Mauritius. Recently induced to live in secondary forest and scrub.

Food and feeding. Mainly *Phelsuma* geckos,

augmented with other lizards, small birds, insects such as dragonflies, a few mice and shrews. Hunts mainly from a perch, usually below the canopy, snatching prey from trunks, branches, foliage or the ground in short strikes. May also soar or quarter over the canopy; sometimes hovers over more open habitat, hawks dragonflies in flight, or runs and hops through vegetation and along the ground in pursuit. Mean attack distance 13.3 m; 38% of attacks successful overall.

Breeding. Laying Aug–Nov. Nested originally in holes in cliff faces or large trees, but recently induced to breed in captivity and in artificial nestboxes. Usually 3 eggs (2–5); incubation 30 days; fledging 38–39 days; juveniles remain on the parental territory until the following breeding season. 17–22% annual mortality.

Movements. No regular movements expected within the small island range.

Status and Conservation. ENDANGERED. CITES I. One of the rarest birds in the world by 1974, when only two pairs remained in the wild, due to cumulative loss of forest habitat, pesticides and depredations of introduced hunters, including macaque monkeys, rats, cats and mongooses. Captive propagation since 1984 with innovative harvesting and management, including supplementary feeding, provision of artificial nestboxes, predator control and reintroduction to secondary habitats, raised population in the wild to at least 50 breeding pairs and over 200 birds by 1993 (see page 246). Despite the limited extent (4000 ha) of primary forest habitat that remains in the Black River Gorges of SW Mauritius, this effort has bolstered the remaining population, and enabled recolonization of the Bambous and Moka Mountains in E and N Mauritius. Pairs have a home range of c. 120 ha. The original population may have been no more than 300 pairs, and conservation activities continue, with a goal of at least 100 pairs. Was, and may still be, vulnerable to pesticide use.

Bibliography. Brown & Amadon (1968), Cade (1982), Cade & Jones (1993), Cheke (1987), Collar & Andrew (1988), Collar & Stuart (1985), Diamond (1987), Fox *et al.* (1993), Herremans (1990), Jones, C.G. (1981, 1984a, 1984b, 1987, 1991), Jones *et al.* (1991), King (1978/79), McKelvey (1978a, 1978b), Meinertzhagen (1912), Pasquier (1980a, 1980b), Staub (1971), Temple (1974a, 1974b, 1977, 1986, 1987).

29. Seychelles Kestrel

Falco araea

French: Crécerelle des Seychelles

Spanish: Cernícalo de las Seychelles

German: Seychellenfalke

Taxonomy. *Cerchneis araea* Oberholser, 1917, Seychelles.

Considered closest to *F. newtoni* and *F. punctatus* in the *F. tinnunculus* species group. Monotypic. **Distribution.** Islands of the Seychelles, W Indian Ocean. On Mahé and its satellites (St Anne, Cerf, Longue and probably Thérèse), Silhouette and North. Reintroduced to Praslin; vagrant to La Digue; and historically on Curieuse, Félicité, Marianne and possibly Sisters.

Descriptive notes. 15–23 cm; male averages 73 g, female 87 g. A very small falcon with a very dark head and a relatively long tail. Female slightly paler than male. Juvenile has paler facial skin and is spotted and streaked black on underparts.

Habitat. Dense secondary forest, the degraded original habitat on these hilly granitic islands; extends now to cultivated and open urban areas.

Food and feeding. Mainly lizards, especially *Mabuya* skinks and *Phelsuma* geckos, but the diet includes insects, small birds and mice. Hunts from perches, snatching prey from

trunks, branches, foliage or the ground. Not known to hover.

Breeding. Laying Aug–Oct. Nests in cavities, mainly (69%) in rock faces more than 200 m above sea-level; or on old Common Myna (*Acridotheres tristis*) nests at the base of coconut palm fronds at lower elevations; or on ledges on buildings or in holes in trees. 2–3 eggs; incubation 28–31 days; fledging 35–42 days; post-fledging dependence 9–24 weeks. Most successful on cliffs (76%), less so on trees and buildings (68–35%) and least in palms (19%). Some competition for sites with the introduced Barn Owl (*Tyto alba*) and Common Myna, which, with the black rat (*Rattus rattus*), are also important nest predators.

Movements. No movement expected within the restricted island habitats, except for some dispersion between islands.

Status and Conservation. Not globally threatened. CITES I. Total population estimated at 420 pairs: 370 on Mahé in 1976, probably at carrying capacity; and at least 10 re-established on Praslin by 1981; mean territory size of 40 ha. Well studied, showing high hatching success (90%); no special conservation action implemented other than translocation to Praslin. Has adapted well to lowlands altered by human occupation, nesting on coconut palms and buildings, although with lower success than on cliffs in natural areas. Not known to be affected by pesticide use.

Bibliography. Brown & Amadon (1968), Bullock (1990), Cade (1982), Collar & Stuart (1985), Feare *et al.* (1974), Gaymer *et al.* (1969), King (1978/79), Penny (1968, 1974), Temple (1977), Vesey-Fitzgerald (1940), Watson (1981, 1989, 1992b, 1993).

30. Spotted Kestrel

Falco moluccensis

French: Crécerelle des Moluques **German:** Molukkenfalke

Spanish: Cernícalo Moluqueño

Other common names: Moluccan Kestrel

Taxonomy. *Tinnunculus moluccensis* Bonaparte, 1850, Ambon.

Forms superspecies with *F. cenchroides* and probably also with rest of *F. tinnunculus* complex. Traditionally split into four additional races, with recognition of *bernsteini* (N Moluccas), *javanensis* (Java, Bali), *timorensis* (Timor) and *renschii* (Sumba). Two subspecies currently recognized.

Subspecies and Distribution.

F. m. moluccensis (Bonaparte, 1850) – Moluccas, from Morotai and Halmahera S to Buru, Seram and Seram Laut.

F. m. microbalia (Oberholser, 1919) – Sulawesi and surrounding small islands; Java and Lesser Sunda E to Tanimbar Is.

Descriptive notes. 28–33 cm. Similar to *F. tinnunculus* in size, plumage and habits, but darker, with less pronounced sexual dimorphism in size and plumage. Race *microbalia* paler, particularly on underparts; ear-coverts greyer.

Habitat. Open country, cultivation and urban areas throughout range; normally occurs up to 2200 m, but occasionally over 2800 m in mountains.

Food and Feeding. Small mammals, lizards, large insects and small birds. Hunting behaviour similar to that of *F. tinnunculus*; hunts from exposed perches and by hovering, in

both cases over open areas. Prey usually taken on ground.

Breeding. Not well known. Breeds Apr-Aug in Java; Mar-Sept on Flores; Mar-Aug in Sulawesi. Nests in old stick nests of other birds, or in holes in trees. Single recorded clutch of 4 eggs. No further information available, but breeding biology likely to be similar to that of rather similar *F. tinnunculus*.

Movements. Apparently sedentary. Vagrant to Borneo.

Status and Conservation. Not globally threatened. CITES II. Widespread and common to uncommon; most numerous in lowlands.

Bibliography. Andrew (1985), Bishop *et al.* (1995), Bowler & Taylor (1989), Brown & Amadon (1968), Cade (1982), Gibbs (1990), Hoogerwerf (1965), MacKinnon (1988), MacKinnon & Philipps (1993), Mayr (1941), Smythies (1981), Stresemann (1940a), Thiollay & Meyburg (1988), White & Bruce (1986).

31. Australian Kestrel

Falco cenchroides

French: Crécerelle d'Australie **German:** Graubartfalke **Spanish:** Cernícalo Australiano
Other common names: Nankeen Kestrel

Taxonomy. *Falco Cenchroides* Vigors and Horsfield, 1827, New South Wales. Forms superspecies with *F. moluccensis*. Two subspecies recognized.

Subspecies and Distribution.

F. c. cenchroides Vigors & Horsfield, 1827 - Australia, Tasmania, Lord Howe I, Norfolk I and Christmas I (Indian Ocean). Winters irregularly from Lesser Sundas and Moluccas through Aru I and S New Guinea; occasionally to New Zealand.

F. c. baru Rand, 1940 - montane WC New Guinea.

Descriptive notes. 30-35 cm; 121-255 g; wingspan 66-78 cm. A typical small kestrel, paler than most. Female larger and heavier; has rufous head and tail. Juvenile often more rufous and more heavily marked. Males of New Guinea race *baru* have darker and more extensive grey head.

Habitat. All lightly wooded and treeless terrestrial habitats, including open woodland, savanna, grassland, farmland, beaches and urban areas; from sea-level up to 2000 m in Australia, to 3400 m in New Guinea. Nests in trees, buildings, caves and cliffs.

Food and Feeding. Mostly invertebrates, particularly insects such as grasshoppers and crickets; also small mammals (mice), birds up to size of sparrow and starling, and reptiles (mainly skinks), especially when breeding. Forages by high quartering and hovering, or still-hunting from perch. Seizes prey on ground by dive or glide; hawks flying insects; rarely chases small birds.

Breeding. Aug-Dec in Australia, Jul in New Guinea. Solitary; semi-colonial in concentrated breeding habitat amid extensive hunting habitat. Nests in variety of sites inaccessible to ground predators: from sink-holes and mine-shafts below ground, to tree hollows, old nests of other birds, cliffs and ledges on buildings and machinery, 2-31 m above ground. Eggs laid on depression or scrape. Usually 3-5 eggs (1-6); incubation 28-29 days; chicks have white down; fledging 31-35 days; post-fledging dependence up to 3 weeks. Nest success 68% of attempts; hatching success 66% of eggs laid; fledging success 45% of eggs laid; 1-6 young fledged per attempt. Sexually mature and sometimes breeds at 1 year. Oldest ringed bird 5 years.

Movements. Resident and partly migratory populations; many pairs sedentary in temperate regions. Birds breeding at high latitudes and altitudes tend to winter in coastal and lowland areas; many migrate N, some (mostly females) reaching New Guinea and Indonesia, W to Java and N to Moluccas. Also irruptive movements to arid regions after good rains and to local plagues of prey species.

Status and Conservation. Not globally threatened. CITES II. Widespread and abundant throughout Australia, where has increased in numbers; has benefited from agriculture and introduced prey. Has recently colonized several islands, including Lord Howe I, Norfolk I and Christmas I (Indian Ocean), and may be in process of colonizing New Zealand. Eggshell thickness not significantly reduced by DDT; seldom shot.

Bibliography. Baker-Gabb (1984b, 1985e), Beehler *et al.* (1986), Bollen (1991b), Coates (1985), Cupper & Cupper (1981), Dickman *et al.* (1991), Genelly (1978), Hollands (1984), Lewis, M.J. (1987), Marchant & Higgins (1993), Newgrain *et al.* (1993a), Olsen & Marples (1993), Olsen & Olsen (1980a, 1980b, 1987a, 1987b, 1987c), Olsen, Crome & Olsen (1993), Olsen, Vestjens & Olsen (1979), Paull (1991), Schodde & Tidemann (1988).

32. American Kestrel

Falco sparverius

French: Crécerelle d'Amérique **German:** Buntfalke **Spanish:** Cernícalo Americano
Other common names: American Sparrowhawk, Sparrow Hawk (1)

Taxonomy. *Falco sparverius* Linnaeus, 1758, America = South Carolina.

Has been placed in either *Cerchneis* or *Tinnunculus*. Often considered to form superspecies with *F. tinnunculus*. Seventeen subspecies normally recognized.

Subspecies and Distribution.

F. s. sparverius Linnaeus, 1758 - North America, from Alaska to Newfoundland, and S to W Mexico, except SE USA and coastal W Mexico; winters S through C America to Panama.

F. s. paulus (Howe & King, 1902) - South Carolina to Florida, USA.

F. s. peninsularis Mearns, 1892 - S Baja California, Sonora and Sinaloa, Mexico.

F. s. tropicalis (Griscom, 1930) - S Mexico to N Honduras.

F. s. nicaraguensis Howell, 1965 - lowland pine savannas in Honduras and Nicaragua.

F. s. sparveroides Vigors, 1827 - Cuba and I of Pines; Bahamas.

F. s. dominicensis Gmelin, 1788 - Hispaniola.

F. s. caribaeum Gmelin, 1788 - Puerto Rico to Grenada.

F. s. brevipes (Berlepsch, 1892) - Aruba, Curaçao and Bonaire (Netherlands Antilles).

F. s. isabellinus Swainson, 1837 - Venezuela to N Brazil.

F. s. ochraceus (Cory, 1915) - mountains of E Colombia and NW Venezuela.

F. s. caucae (Chapman, 1915) - mountains of W Colombia.

F. s. aequatorialis Mearns, 1892 - subtropical N Ecuador.

F. s. peruvianus (Cory, 1915) - subtropical SW Ecuador, Peru and N Chile.

F. s. fernandensis (Chapman, 1915) - Robinson Crusoe I (Más a Tierra), in Juan Fernández Is. off WC Chile.

F. s. cinnamominus Swainson, 1837 - SE Peru, Chile and Argentina S to Tierra del Fuego.

F. s. ceareue (Cory, 1915) - tablelands from NE Brazil S and W to E Bolivia.

Descriptive notes. 21-31 cm; male 80-143 g, larger female 84-165 g; wingspan 51-61 cm (all data from North America, but considerable variation throughout range). Sexually dimorphic in plumage. Male has blue wings, solid red tail with wide black tip, and underparts pale with spots; female brown with upperparts barred, underparts streaked and barred tail. Both sexes have conspicuous malar stripe and second stripe behind ear-coverts. Only *Falco* in which juveniles resemble adults in sexually dimorphic plumage; juvenile males generally have breast more heavily spotted and streaked than adult males. Races

vary mostly in colour, but also in size; *sparveroides* most distinctive with two colour morphs, one dark with red underparts, and one with white underparts.

Habitat. Ubiquitous. Most habitats except tundra, from tropical lowlands and deserts (even below sea-level) to near tree-line in mountains, at 3700 m in North America and 4300 m in South America; readily occupies urban centres. Common in altered, disturbed and agricultural land.

Food and Feeding. Largely insects (c. 60%) and small vertebrates, mainly small rodents, up to 89 g (c. 40%) in nominate *sparverius*. Lizards constitute 53% of diet in biomass, in tropical Caribbean populations. Lizards and insects are main food in tropical Venezuela and Costa Rica. In N Hemisphere deserts, small passerines may represent 35% (by biomass), small mammals 32% and lizards 28%. Hunting generally from perch, which is more successful (see page 232), with vantage point towards prey on or near ground, but up to 30% of attempts may be from flight; commonly hovers or hangs in updraughts. Highest success against prey on or near ground, and lowest success against aerial prey. Food often cached for later consumption. Some hunting takes place in family groups, as fledglings learn foraging skills.

Breeding. Somewhat dependent on latitude: Mar-Jul in North America; Mar-Jun in Cuba; Dec-Feb in Venezuela; may be double-brooded, especially if first brood early; in Chile first brood in Oct, second in Dec-Jan. Solitary. Some extra-pair copulation. No nest built; site variable from hole in tree, dirt bank or cliff, an unused stick nest e.g. of magpie (*Pica*), artificial nestbox, ledge on urban building, or depression in top of royal palms. Usually 4-6 eggs in N Hemisphere (average 4-8 in Canada, 4-0 in Florida), average 2-1 in Cuba and 3-7 in Venezuela; incubation 27-32 days; chicks have white down; fledging 29-31 days. Nest success: c. 67-89% in hatching; 72-89% in fledging; in double-brooded pairs average 85% success with first brood, and 73% with second brood. May breed at 1 year old. First year mortality c. 57%; average survival of 12-6 months. Oldest ringed bird 9 years 10 months.

Movements. Resident or sedentary over most of range. Race *sparverius*, from Alaska, Canada and N USA, moves S in winter: complex situation, but leap-frog migration suggested; birds from farthest N are longer range migrants; some birds move c. 2700 km, occurring S to at least Panama. Movement over water also occurs with birds from North America moving to Caribbean islands. Males tend to winter farther N than females; juveniles seemingly move farther than adults, and juvenile males disperse farther from natal areas than females. Vagrant to Falkland Is, with some birds overwintering.

Status and Conservation. Not globally threatened. CITES II. Ubiquitous, and perhaps commonest New World falconid overall. Expanding range and increasing numbers in many regions; invading urban areas, readily occupying artificial nestboxes. Wintering population of North America estimated at 236,000 birds, and total breeding population at 1,200,000 pairs. No reliable estimates for most of Neotropical range. Decreasing in parts of SE USA, e.g. Florida (with entire population of race *paulus*), because of habitat alterations; scarce or decreasing in some other regions of USA, e.g. Texas and Arkansas.

33. Greater Kestrel

Falco rupicoloides

French: Crécerelle aux yeux blancs **German:** Steppenfalke **Spanish:** Cernícalo Ojiblanco
Other common names: White-eyed Kestrel

Taxonomy. *Falco Rupicoloides* A. Smith, 1829, South Africa.

May form superspecies with *F. alopec*, but quite different in ecology and proportions. Three subspecies recognized.

Subspecies and Distribution.

F. r. fieldi (Elliot, 1897) - N & E Ethiopia, NW Somalia

F. r. arthuri (Gurney, 1884) - NE Tanzania, Kenya.

F. r. rupicoloides A. Smith, 1829 - Namibia, Botswana, SW Zambia and Zimbabwe to South Africa.

Descriptive notes. 33-36 cm; 181-334 g (S Africa), 178-252 g (E Africa); wingspan 84 cm. Only rufous kestrel with pale cream eye in adult. Barred flanks and upperparts with grey rump and tail distinctive. Most similar to female *F. naumanni*, but larger and heavier; more uniform coloration than *F. tinnunculus*. Sexes indistinguishable. Juvenile has rump and tail rufous, eye dark brown. Races differ mainly in size, with *arthuri* smaller, and *fieldi* smaller still and paler.

Habitat. Open desert, steppe and short grassland up to 2150 m. Requires a few scattered trees and bushes for roost- and nest-sites.

Food and feeding. Mainly arthropods, especially grasshoppers and solifugids, and small vertebrates, mainly birds and lizards. Hunts from a prominent perch or while hovering; during breeding, males deliver and make more strikes at large prey, especially birds, and females increasingly hover for arthropods. Occasionally makes fast aerial pursuits of flying birds and insects.

Breeding. Laying Jul-Feb (peak Sept-Oct) in S Africa; Jan-Nov (peak Apr-May) in E Africa; Apr-Jun in Somalia. Courtship includes flicker-diving displays with fast wingbeats, shrill cries and flashing of the white underwing. Uses an old nest of another bird, usually a corvid, especially Black Crow (*Corvus capensis*), but as large as a vulture or Secretarybird (*Sagittarius serpentarius*); nest placed low in a bush or high in a tree or electricity pylon, rarely in a tree cavity. Usually 3-4 eggs (2-7); incubation 32-33 days; chicks have first down cream, second down dark grey; fledging 30-34 days; female hunts for chicks in nest area and during the post-fledging period of at least 30 days.

Movements. Resident and territorial in many parts of its range, but nomadic in more arid areas, where only present during times of adequate rainfall and food. No regular movements described, but some movements of over 300 km recorded from ringing data. Enters taller grasslands during times of drought.

Status and Conservation. Not globally threatened. CITES II. Widespread and generally common in S Africa, with estimated 6000 pairs in Transvaal (South Africa), home range of 570-770 ha, and densities of 1 pair/16-29 km². Less common and more local in E and NE Africa. Benefits from bush clearing in more wooded areas, and provision of plantations and utility pylons in treeless areas, but still relies more on natural grasslands than exotic crops and pastures. Not known to be affected by pesticide use.

Bibliography. Ash & Miskell (1983), Brown, C.J. (1988d), Brown, C.J. *et al.* (1987), Brown, L.H. *et al.* (1982), Dean *et al.* (1968), Ginn *et al.* (1989), Hunt (1978), Hustler (1983c), Kemp (1978, 1984, 1991), Kemp & Crowe (1993), Kemp & Filmer (1989), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1962), Maclean (1993), Osborne & Colebrook-Robjent (1982), Pickford *et al.* (1989), Pinto (1983), Steyn (1982), Tarboton & Allan (1984).

34. Fox Kestrel

Falco alopex

French: Crécerelle renard

German: Fuchsfalke

Spanish: Cernícalo Zorro

Taxonomy. *Tinnunculus alopex* Heuglin, 1861, Gallabat, Sudan.

Possibly forms superspecies with *F. rupicoloides*, but quite different in ecology and proportions. Monotypic.

Distribution. Senegambia E through N Cameroon and Sudan to Red Sea coast of Ethiopia, S to NE Zaire, NW Kenya and NE Uganda.

Descriptive notes. 35-39 cm; 250-300 g. A large, long-tailed kestrel, deep chestnut all over, streaked with black. Size and uniform coloration differ from *F. tinnunculus* and *F. naumanni*. Sexes indistinguishable. Juvenile more heavily streaked, with broader black bars in tail.

Habitat. Rocky hills, cliffs and outcrops adjoining open arid Sahelian savanna, up to 2200 m.

Food and feeding. Large insects, small mammals, lizards and small birds reported as prey. Hunts from a perch, taking prey on ground, but also attracted to grass fires for grasshopper, but also attracted to grass fires for grasshopper, but also attracted to grass fires for grasshopper.

pers so disturbed and to emergences of termite alates which are taken on the wing. Long, broad wings and graduated tail suggest buoyant flight and good hovering ability; reported to remain on the wing for long periods, but species remains little known.

Breeding. Laying variable locally, Mar-May. Pairs soar and call near nest-site. Nests in cavities or on ledges in rock faces; may use same site in successive years. Several pairs may nest in close proximity, with 20-25 pairs breeding almost colonially, e.g. in NW Kenya. 2-3 eggs; only female recorded incubating; no other details recorded.

Movements. Sedentary in some intermediate areas, but generally moves S from drier areas across whole range in dry season (Oct-Mar) to attend bush fires, then N with rains to nest on rocky outcrops; some vagrants further S into Kenya, NE Tanzania and NE Zaire in Sept-Feb after breeding. Population breeding furthest S, in Turkana Valley (Kenya), may be resident.

Status and Conservation. Not globally threatened. CITES II. Little studied and may be vulnerable through limited and localized breeding range on rocky hills, although these eminences are usually less subject to habitat degradation than the surrounding savanna. Little pesticide use within its range.

Bibliography. Bannerman (1953), Bouet (1955), Brown, L.H. (1970a), Brown & Amadon (1968), Brown *et al.* (1982), Cade (1982), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957, 1970), Pakenham (1979), Salvan (1968), Serle *et al.* (1977), Snow (1978).

35. Grey Kestrel

Falco ardosiaceus

French: Faucon ardoise

German: Graufalke

Spanish: Cernícalo Pizarroso

Taxonomy. *Falco Ardosiaceus* Vieillot, 1823, Senegal.

Sometimes united in subgenus *Dissodectes* with other grey kestrels *F. dickinsoni* and *F. zoniventris*. Monotypic.

Distribution. Senegambia E to Ethiopia and S through W Kenya and W Tanzania to Angola, N Zambia, N Namibia and NW Botswana.

Descriptive notes. 30-33 cm; male 205-255 g, female 240-300 g. Stocky, dark grey kestrel with a heavy bill. Plumper and shorter-winged than *F. concolor*, more heavily built and uniformly coloured than *F. dickinsoni* or *F. zoniventris*. Juvenile has pale green, not yellow, facial skin and a brown wash to plumage.

Habitat. Woodland and savanna with dense stands of large trees or palms, adjacent to the open glades or burnt areas preferred for hunting.

Food and feeding. Mainly grasshoppers and small reptiles, such as lizards, snakes and

chameleons; also small birds, rodents, bats, frogs, earthworms and many insects, including termite and ant alates, and other arthropods such as crabs and myriapods. Sometimes eats oil palm fruits. Hunts mostly from a high, open perch, especially during warmer part of day when main prey active; usually takes prey from the ground or low foliage. May also perform slow prospecting flight, fast aerial chase with rapid wingbeats, or aerial hawking of insects, but rarely hovers.

Breeding. Laying Jan-Apr in W Africa; Aug-Oct in S Kenya, Tanzania and Angola. Nest in tree cavities, old stick nests or most often cavities of old Hamerkop (*Scopus umbretta*) nests, even usurping active nests. 3-5 eggs; incubation c. 30 days; fledging c. 30 days. Pair will copulate and roost in nest when breeding.

Movements. Resident in most areas; no regular movements reported, and remains in vicinity of Hamerkop nests throughout the year in Kenya.

Status and Conservation. Not globally threatened. CITES II. Common in parts of range, e.g. W Africa and Angola; large areas of natural habitat remain, sometimes in nature reserves. Home range of 100-300 ha. May even have benefited from clearance of tropical rain forest, and often hunts on agricultural land. Not known to be affected by pesticide use.

Bibliography. Brown *et al.* (1982), Cade (1982), Ginn *et al.* (1989), Gore (1990), Lewis & Pomeroy (1989), Loosemore (1963), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Serle (1939, 1943), Sinclair & Dean (1974), Steyn (1982), Thiollay (1975a, 1976b, 1977c), Thiollay & Clobert (1990), Wells (1965), Wilson & Wilson (1983).

36. Dickinson's Kestrel

Falco dickinsoni

French: Faucon de Dickinson

German: Schwarzfückenfalke

Spanish: Cernícalo Dorsinegro

Other common names: White-rumped Kestrel

Taxonomy. *Falco dickinsoni* P. L. Sclater, 1864, Chibasa, Shire River, Malawi.

Sometimes united in subgenus *Dissodectes* with other grey kestrels *F. ardosiaceus* and *F. zoniventris*; most similar in size and proportions to the latter. Monotypic.

Distribution. SC Africa, from Angola E through S Zaire to SC Tanzania (including Zanzibar and Pemba), and S to N Namibia, N Botswana and NE South Africa.

Descriptive notes. 28-30 cm; male 169-207 g, female 207-235 g; wingspan 67 cm. Whitish head, rump and narrow bars across tail distinctive. Individual variation in intensity of grey coloration, possibly with dark and light morphs. Bill less heavy than *F. ardosiaceus*, and not uniformly coloured as in *F. concolor*. Flies with fast, choppy wingbeats and on landing sometimes clings parrot-like on trees. Juvenile has facial skin pale green, not yellow, and plumage tinged brown.

Habitat. Wooded savanna or clumps of palm trees adjacent to patches of open grassland, scrub, swamp or floodplain.

Food and feeding. Mainly small birds, lizards and chameleons, together with insects, snakes, rodents, frogs, solifugids and crabs; bats taken at dusk. Hunts mainly from perch on dead tree and takes prey on the ground; sometimes performs fast aerial chases of birds, hawks insects or hovers. Attracted to bush and cane fires for small birds and insects flushed or confused by the smoke.

Breeding. Laying Jul-Nov (peak Sept-Oct). Nests in a cavity in a baobab (*Adansonia digitata*) or other large tree, palm stump or old Hamerkop (*Scopus umbretta*) nest; once nested in a bridge. Usually 3 eggs (1-4); incubation c. 30 days; chicks have pale grey first down, dark grey second down; fledging 33-35 days. Adults sometimes provision offspring from a cache.

Movements. Territorial pairs resident in many areas of C Africa. Some local movements reported, e.g. in Zimbabwe, especially at periphery of range, e.g. S Kenya (Jun-Aug). Botswana and Transvaal; in such cases enters new areas as ground cover recedes, leaving when it becomes too dense or too dry.

Status and Conservation. Not globally threatened. CITES II. Uncommon in much of range, but large areas of good habitat remain, some of it in national parks. Common on Pemba in 1970's. Often overlooked and may be patchily distributed in many areas, with only 50 pairs estimated for NE South Africa. Not known to be affected by pesticide use.

Bibliography. Benson & Benson (1975), Borello & Borello (1980), Brooke (1972), Brooke & Howells (1971), Brown *et al.* (1982), Cade (1982), Clancey (1968b), Colebrook-Robjent (1976), Colebrook-Robjent & Tanner (1978), Cook (1971), Ginn *et al.* (1989), Hammer (1978), Hammer & Blackwood (1982), Lewis & Pomeroy (1989), Mackworth-Praed & Grant (1957-1973), Maclean (1993), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Steyn (1982), Tarboton & Allan (1984).

37. Banded Kestrel

Falco zoniventris

French: Faucon à ventre rayé

German: Bindenfalke

Spanish: Cernícalo Malgache

Other common names: Barred Kestrel, Madagascar Banded Kestrel

Taxonomy. *Falco (Hypotriorchis) zoniventris* W. Peters, 1854, St Augustin Bay, Madagascar.

Sometimes united in subgenus *Dissodectes* with other grey kestrels *F. ardosiaceus* and *F. dickinsoni*; most similar to the latter. Monotypic.

Distribution. Madagascar.

Descriptive notes. 25-29 cm; c. 180-240 g. Underparts white, streaked with brown on the throat and upper breast, and barred with broad grey bands below. Female slightly darker than male. Eye pale yellow. Appears acuminated-like in flight and at rest, but heavy bill and large head distinctive. Plain underparts and dark eye distinguish migrant *F. concolor*. Juvenile undescribed.

Habitat. Favours forest edge and woodland up to 2000 m, including secondary forest, clearings and even dry woodland in S and SW Madagascar.

Food and feeding. Mainly arboreal lizards, especially chameleons and *Phelsuma* geckos, augmented by small birds and insects. Hunts from

a perch, within a radius of c. 150 m, and takes prey off branches, foliage or the ground; rarely hunts in flight after a swift dash through the foliage. Spends long periods perched on lower branches; hovers rarely, if at all.

Breeding. Laying Sept. Recorded nesting in tree cavities, scrapes among epiphytes on tall forest trees, or old nests of Sickle-billed Vanga (*Falculia palliata*). One clutch of three eggs. Courtship feeding observed at nest-sites.

Movements. No movements recorded within its limited island habitat.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Locally common but habitat limited and declining through deforestation. Not more than 1000 pairs predicted as total population, but able to exist in secondary habitats in some areas. Fairly common in W and S, rare in N and E, and absent from deforested central highlands. Not known to be affected by pesticide use.

Bibliography. Cade (1982), Colebrook-Robjent (1973), Dee (1986), Langrand (1990), Langrand & Meyburg (1984), Milon *et al.* (1973), Rand (1936).

38. Red-necked Falcon

Falco chicquera

French: Faucon chicquera German: Rothalsfalke Spanish: Alcotán Turumti
Other common names: Red-headed Merlin/Falcon, Turumti

Taxonomy. *Falco chicquera* Daudin, 1800, Bengal.

Allied with *F. columbarius* on hunting behaviour, but probably not closely related, and eggs more hobby-like. African birds may not deserve separation into two races. Three subspecies recognized.

Subspecies and Distribution.

F. c. chicquera Daudin, 1800 - SE Iran E through Pakistan and India to Nepal and Bangladesh.
F. c. ruficollis Swainson, 1837 - Senegambia E to Ethiopia and S Somalia, then S to Zambia, Malawi and N Mozambique.
F. c. horsburghi Gunning & Roberts, 1911 - S of R Zambezi, from Zimbabwe and S Mozambique W to Botswana, Namibia and S Angola, and S to N South Africa.

Descriptive notes. 30-36 cm; male 139-178 g, female 190-305 g; wingspan 69 cm. Head and neck chestnut; tail grey barred black, with broad black subterminal bar and white tip. Juvenile plumage with brown wash. Considerably smaller than *F. biarmicus*, which has chestnut confined to crown. African races darker and more heavily marked, separated from each other on size, but larger specimens in S may be end of cline, rather than separate population.

Habitat. Patches of trees adjoining open country, from along watercourses in desert to *terai* to woodland surrounding open dambos.

Especially common in *Borussus* and *Hyphaene* palm savannas adjoining rivers, floodplains and coastal plains.

Food and feeding. Mainly small birds, of 10-150 g and up to the size of doves, and bats; also some rodents, reptiles, and insects, such as termite alates and locusts. A dashing hunter, with deep, rapid wingbeats. Most hunts started from a perch within cover, or close to the ground in open areas. Prey taken after aerial pursuit (sometimes over hundreds of metres), fast dashes behind cover or high ringing flights. Usually hunts in pairs, which later share prey, and sometimes in company of Gabar Goshawks (*Micronisus gabar*). Often attacks birds at water-holes; rarely pirates other raptors. Hunting success 29-31% overall.

Breeding. Laying mainly in dry season: Jan-May in India; Feb-Apr in Pakistan; Feb-May in Sahel zone; Jul-Aug in E Africa; May-Oct in S Africa. Nests in old nest-structure of a crow or other raptor, usually in a thorny tree (Pakistan, NE Kenya, SW Africa), or in a palm stump, or at the base of a palm frond. Usually 3 eggs in Africa, 4 in Pakistan (2-5); incubation 32-35 days; chick has white first and second down; fledging 35-40 days. Nests may be damaged by baboons.

Movements. Resident in many areas, but nomadic in others, in both Asia and Africa. Enters desert areas of SW Africa to feed on larks and other seed-eaters attracted by good rains; moves temporarily into better watered areas of W Transvaal during drought.

Status and Conservation. Not globally threatened. CITES II. Most common in areas of low rainfall. Easily overlooked, generally uncommon, but widespread; range includes several large nature reserves. Common on Deccan Plateau, EC India; widespread but uncommon in Pakistan; densities of 1 pair/2.6-83.3 km² in Zambia; and 1 pair/168 km² in Namib Desert. Not known to be affected by pesticide use.

Bibliography. Ali & Ripley (1978), Bednarek (1993), Brewster (1991), Brown, C.J. (1988d), Brown, L.H. *et al.* (1982), Cade (1982), Clark & Schmitt (1993), Colebrook-Robjent & Osborne (1974), Finch-Davies & Kemp (1980), Fry (1964), Ginn *et al.* (1989), Gore (1990), Guhrs & Osborne (1988), Herholdt (1994), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1962), Maclean (1993), Malan (1991), Malherbe (1963), Newby (1981), Olwagen (1984), Olwagen & Olwagen (1984), Osborne (1981, 1984), Pakenham (1979), Paxton & Brown (1984), Roberts (1991), Steyn (1982), Worden (1985).

39. Red-footed Falcon

Falco vespertinus

French: Faucon kobez German: Rotfußfalke Spanish: Cernícalo Patirrojo
Other common names: Western Red-footed Falcon

Taxonomy. *Falco vespertinus* Linnaeus, 1766. Ingria = Province of St Petersburg.

Very close to *F. amurensis*, with which has frequently been considered conspecific; these two form superspecies. Monotypic.

Distribution. E Europe, from Estonia and Hungary, E through NC Asia to extreme NW China and upper R Lena. Winters mainly in SW Africa, from Angola, Namibia and N South Africa through Botswana to Zimbabwe and Zambia.

Descriptive notes. 28-31 cm; 130-197 g; wingspan 65-75 cm. Mostly slate grey, contrasting with chestnut lower belly, undertail-coverts and thighs; legs, cere and eye-ring red. Female very different, with rusty orange or yellowish underparts; upperparts and tail blue-grey with black transversal bands; head pale with rusty crown and blackish eye patch and slight moustache; bare parts orange. Male differs from that of *F. amurensis* by grey underwing-coverts, paler crown and mantle, and darker tail and underparts; female quite different from that of *F. amurensis*. Juvenile similar to that of *F. subbuteo*, but different build; forehead paler, crown and upperparts browner and divided by whitish collar on hindneck.

Habitat. Open habitats with some tree cover for perching, roosting and breeding. Steppe, wooded steppe, cultivation and pastures with stands or fringes of trees, or copses; e.g. riparian woodland; also orchards, marshy land; reaches open taiga. Normally in lowlands; although up to 1500 m in Asia. In African winter quarters, affects grassland, savanna and scrubland, roosting colonially, in groves of eucalypts and in towns or villages; up to thousands of birds together.

Food and Feeding. Mainly insects, especially Orthoptera (crickets, locusts, grasshoppers); also beetles, dragonflies, butterflies, moths, cicadas. Wide variety of invertebrates, but chicks may be mainly fed with vertebrates, e.g. fledglings of small birds, voles, mice, shrews, amphibians, lizards. In Hungary, mice and toads are important. In Africa, captures and eats flying ants and termites on wing, also locusts and grasshoppers. Most active around dawn and dusk. Hunts with fairly low flight, often over rivers, capturing insects; uses hovering flight to detect prey on ground; often drops down on insects from posts or wires.

Breeding. Laying mostly in May. Solitary or colonial, with 10's and up to 100's of pairs at colonies. Occupies old nests of corvids or raptors, preferring upper part of tree; sometimes in cliffs or tree holes, or even on ground protected by shrub. Normally 3-4 eggs (1-5), laid at intervals of 2 days; incubation possibly c. 27-28 days, by both adults; male brings food for chicks, as does female in later stages; chicks have first down white, second down greyish white; fledging from 27-30 days; independence from c. 1 week later. Sexual maturity in first year. Greater breeding success in colonies than for solitary pairs. Oldest recorded bird 12 years old.

Movements. Migratory, travelling great distances between Palearctic breeding areas and S African winter quarters. Migrates over broad fronts across Mediterranean; up to 5750 birds counted in autumn in Israel, and several thousand over NW Turkey in mid-May; main autumn route over E Mediterranean; spring migration further W. Stays in winter quarters mainly between Nov and late Feb; reaches breeding areas from mid-Apr to mid-May, most birds leaving in Sept.

Status and Conservation. Not globally threatened. CITES II. Marked decline, particularly in S of breeding range, probably due, directly or indirectly, to pesticide use. Estimates of c. 20,000 pairs in European Russia, but declining; in Byelorussia perhaps only 10-50 pairs in early 1990's, following drastic decline; quite common in Ukraine, especially in S. Generally scarce in rest of E Europe, where some small breeding nuclei have disappeared: 500-600 pairs in Hungary in 1970's, where population apparently stable in 1980's; in 1980's, perhaps c. 20 pairs in Bulgaria, and c. 80 pairs in Yugoslavia; 100-120 in Romania in 1970's. Still common in Asia; occasionally breeds in C Europe and even Scandinavia; local distribution within normal breeding range varies from year to year with food supply.

Bibliography. Brown *et al.* (1982), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Etchécopar & Hue (1978), Flint *et al.* (1984), Fulop & Szilvka (1988), Günsel (1986), Ginn *et al.* (1989), Goodman *et al.* (1989), Handrinos & Demetropoulos (1983), Haraszy & Bagyura (1993), Horváth (1955, 1956, 1963, 1975), Kemp & Crowe (1993), Keve & Szilji (1957), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Martin, B.P. (1992), Meier Zwicky & Schmid (1990), Paz (1987), Pickford *et al.* (1989), Pinto (1983), Ragucheva (1992), Simeonov *et al.* (1990), Thiollay (1989c).

40. Amur Falcon

Falco amurensis

French: Faucon de l'Amour German: Amurfalke Spanish: Cernícalo del Amur
Other common names: Eastern Red-footed/Manchurian Red-footed/ Amur Red-footed Falcon

Taxonomy. *Falco vespertinus* var. *amurensis* Rudde, 1863, Zeya River, Amurland.

Very close to *F. vespertinus*, of which has frequently been considered subspecies, but differs in plumage, especially of female, morphology and behaviour; these two species form superspecies. Monotypic.

Distribution. Transbaikalia (SE Siberia) and NE Mongolia E to Amurland and S to N & E China and N Korea; has bred in Assam (NE India). Winters in S Africa, mainly from Malawi to Transvaal.

Descriptive notes. 28-30 cm; male 97-155 g, female 111-188 g. Male resembles that of *F. vespertinus*, but axillaries and underwing-coverts white. Female quite different from that of *F. vespertinus*, with crown and nape grey, larger blackish moustache, and underparts whitish, densely spotted black. Juvenile similar to female, but head and neck paler; upperwing-coverts and back edged rufous.

Habitat. Open wooded zones, sometimes with marshy areas; woods and margins of woodland, both coniferous and deciduous; avoids treeless steppes and dense forest. In winter, occurs in savanna and grassland, roosting colonially in clumps of trees; these roosts may be traditional, and may be used by hundreds and up to thousands of birds.

Food and Feeding. Mainly insects, such as locusts, grasshoppers, beetles; also small birds and some amphibians. In African winter quarters, feeds mainly on swarming termite and ant alates, which become abundant in association with tropical rainstorms, but also takes locusts and grasshoppers. Often hunts from perch on tree or power cables, and will rest for long periods on same perch; captures prey in air, but also on ground; sometimes uses hovering flight. Normally hunts more in early morning and late evening; outside breeding season often occurs in flocks.

Breeding. Lays in May-Jun. Solitary or in small colonies, in old nests of corvids, or in tree holes, in conifers or broad-leaved trees. Normally 3-4 eggs (2-6), laid at interval of 2 days; incubation probably c. 28-30 days; both adults incubate and feed chicks; fledging c. 1 month. Sexual maturity possible in first year, still with juvenile plumage.

Movements. Migratory, travelling massive distance between E Asia and S Africa. Often migrates in large groups, of up to thousands, sometimes in company of *F. naumanni* or other small falcons. Leaves N breeding grounds in second half of Sept; possibly flies over Indian Ocean, from India to E Africa; reaches winter quarters, mainly from Malawi S to Transvaal, in late Nov and early Dec; leaves late Feb and mainly Mar, and reaches breeding grounds in Apr and early May. See page 238.

Status and Conservation. Not globally threatened. CITES II. Size of population not known; may be stable; at least locally common, e.g. SE of L. Baikal and in Mongolia. Total of 892 birds counted

passing over Beidaihe (NE China) from late Aug to late Oct 1987. Visible in enormous flocks of up to 4000-5000 birds, at roosts in winter quarters; census of such roosts highly desirable, allowing at least approximate evaluations of total numbers, and perhaps eventually indications of trends.

Bibliography. Ali & Ripley (1978), Austin (1948), Benson (1951), Benson & Benson (1975), Brazil (1991), Brazil & Hanawa (1991), Brown *et al.* (1982), Cheng Tso-hin (1987), Clancey (1966), Crick & Jones (1992), Dementiev & Gladkov (1951), Etchécopar & Hue (1978), Flint *et al.* (1984), Ginn *et al.* (1989), Hines, C.J.H. 41. Eleonora's Falcon

Falco eleonora

French: Faucon d'Éléonore **German:** Eleonorenfalk **Spanish:** Halcón de Eleonora

Taxonomy. *Falco Eleonora* Gené, 1839, Sardinia.

Sometimes considered to form superspecies with *F. concolor*. Monotypic.

Distribution. Islands and rocky coasts from Canary Is and NW Morocco E through Mediterranean to Lemnos, N Sporades, Cyclades, Dodecanese, Crete and Cyprus. Winters mainly in Madagascar, but also in E Africa and Mascarene Is.

Descriptive notes. 36-42 cm; male 350 g, female 388 g; wingspan 90-105 cm. Polymorphic, with pale and dark morphs and also some intermediates; from below, dark underwing-coverts contrast with paler flight-feathers. Commoner pale morph has throat and cheeks whitish, breast and belly cream-coloured to reddish brown streaked black. Dark morph all blackish. Female slightly larger. Juvenile also dimorphic, generally browner than corresponding adult plumages; pale morph paler than adult, underparts greyish with dark spots on underwing-coverts, and flight-feathers barred.

Habitat. Normally small islands and islets, typically uninhabited or very peaceful, on migratory routes of small birds; may appear on mainland coasts to hunt or during dispersal, but infrequently to nest. Breeds only within narrow latitudinal limits in Mediterranean zone. In winter quarters in Madagascar, occurs in and around open woodland and forest, as well as wetlands, paddyfields and lakes.

Food and Feeding. Large flying insects and small birds; specially adapted to take advantage of autumn migrations. Insects taken mainly outside migration peak, and in winter quarters; feeds on, e.g. Lepidoptera, Coleoptera, Odonata, Orthoptera and flying ants; insects eaten by bird in flight. Very wide range of birds taken, varying locally and seasonally: various warblers (*Phylloscopus*, *Sylvia*), shrikes (*Lanius*), Common Redstart (*Phoenicurus phoenicurus*), Common Nightingale (*Luscinia megarhynchos*), Spotted Flycatcher (*Muscicapa striata*), Whinchat (*Saxicola rubetra*); in Balearic Is, Eurasian Swift (*Apus apus*) commonly taken, especially fledglings; rarely hunts prey larger than Hoopoe (*Upupa epops*), which is locally important. Normally hunts birds over sea; in certain conditions several individuals will hover and form a barrier to intercept migrants. Before breeding, may travel tens of kilometres from colony to areas with greater abundance of insects or non-migratory birds, e.g. other islands, mainland coasts, often wetlands. Marked tendency to hunt crepuscularly; nocturnal hunting has been reported.

Breeding. Lays very late, mostly from mid-July to Aug, so that rearing of young coincides with autumn migration of small birds. Colonial, with up to 300 pairs together, though normally tens; nesting principally on islets. Nest-site in holes and ledges of sea cliffs, or on ground, under bushes or in crevices; distance between nests varies with space available, but sometimes only a few metres. Normally 2-3 eggs (1-4), laid at interval of 2-3 days; incubation 28-30 days, mainly by female; chicks have creamy white first down; fed on small birds; fledging c. 37 days; chicks can leave colony 2 weeks later. Breeding success varies annually and locally; 1.3-2.5 young fledged per breeding pair, and 1.6-2.6 per successful pair. Sexual maturity at 2-3 years.

Movements. Migratory. Leaves Mediterranean and Atlantic colonies from mid-Oct to early Nov, flying presumably over Mediterranean and Red Seas and Somalia, S to main winter quarters in Madagascar; some birds winter in E Africa and Mascarene Is, but little known. Presence in Madagascar coincides with rainy season, favouring abundance of insects; returns to breeding areas in late Apr and May. See page 238.

Status and Conservation. Not globally threatened. CITES II. No drastic changes noted in total population, apart from some natural fluctuations; local increases or declines dependent on human pressure. In 1980's, probably c. 4000 pairs distributed among c. 100 colonies, almost all in Mediterranean zone, especially in Aegean Sea: c. 2500 pairs in Greece; also sizeable population of 480-500 pairs in Italy; and over 500 pairs in Balearic Is in 1991. In Atlantic sector, 90 pairs in Morocco in 1986, and at least 65 pairs in Canary Is in late 1980's. Traditionally persecuted and exploited by local human populations, particularly through theft of chicks and eggs, mainly for food; also affected by tourist development, which leads to lower breeding success. In Morocco, decline in 1960's and 1970's due to human disturbance and persecution; seems stable in Canary Is; increased in Balearic Is during 1980's; stable in Italy, despite interference in breeding colonies. Main problems caused simply by lack of regard for species and its colonies; species has responded very well when protected effectively.

42. Sooty Falcon

Falco concolor

French: Faucon concolore **German:** Schieferfalk **Spanish:** Halcón Pizarroso

Taxonomy. *Falco concolor* Temminck, 1825, Senegal, etc. = Barqan Island, Gulf of Aqaba.

Sometimes considered to form superspecies with *F. eleonora*. Monotypic.

Distribution. E Libya through Egypt, Israel and Jordan to coasts of Red Sea and Persian Gulf, E to SW Pakistan. Winters in Madagascar, and also in SE Africa.

Descriptive notes. 32-36 cm; wingspan 78-90 cm. Medium-sized, all grey falcon. Considerably paler than dark morph of *F. eleonora*; slightly smaller, with more wedge-shaped tail. Larger than *F. ardosiaceus*, with longer wings and unbarred flight-feathers. Existence of purported dark morph from Red Sea zone now generally rejected. Juvenile very similar to juvenile *F. eleonora*.

Habitat. Rugged or mountainous desert areas with canyons, cliffs, or at least some small crags; hot, very arid zones, almost without vegetation; also small coral islands. In winter, much wetter areas, e.g. open wooded country,

savanna, edges of woods, marshy areas and paddyfields. From sea-level up to 1500 m in Madagascar.

Food and Feeding. In breeding season, mainly small birds on autumn migration, as native vertebrate fauna is very rare in breeding areas; occasionally bats and other vertebrates. In winter, mainly insects, e.g. locusts, grasshoppers, flying termites, flying ants, dragonflies. Birds taken include variety of small passerines, bee-eaters, Eurasian Golden Oriole (*Oriolus oriolus*), Hoopoe (*Upupa epops*), swallows, swifts, waders and small seabirds, such as petrels and terns. Searches for prey up to 5 km or more from nest, flying to oases or areas with some vegetation. Hunts alone or in pairs; in winter may hunt in small parties, sometimes in company of *F. eleonora*. Birds mainly captured in air, species stooping in flight or from prominent perch; also flies low to flush prey, and in winter hawks insects from perches. Hunts mainly at dawn and dusk.

Breeding. Laying in Jul-Aug, with raising of chicks timed to coincide with peak in migration of small birds. Solitary or in loose colonies; up to 100 pairs on small islands in Red Sea and Gulf of Oman, with at least 40 m between nests; in Negev Desert (Israel), normally 2-5 km between pairs, but in areas of desert with few suitable nest-sites, nests up to tens of kilometres apart. Nests in cracks or hollows in upper part of cliffs, sometimes in old nests of ravens; sometimes in rocky or coral outcrops; on islands, also nests on ground, under bushes; same nest-site may be reused repeatedly. Normally 2-3 eggs (1-4); incubation 27-29 days, mainly by female; male hunts alone until 2 weeks after chicks have hatched; chicks have white down; fledging 32-38 days; chicks fed some weeks more. Up to 4 chicks fledge, but normally 2-3, with mean of 2.34 per successful pair. At least in some cases, species can breed successfully at one year old.

Movements. Migratory, wintering mainly in Madagascar; also, to lesser extent, on African mainland, in coastal Mozambique and E South Africa, with some birds perhaps further inland. Arrives in Madagascar from late Oct; last birds leave in early May, arriving in breeding areas mainly in Apr, in Israel from late Apr. Rare spring passage migrant to NW Somalia, where often claimed to breed.

Status and Conservation. Not globally threatened. CITES II. Numbers possibly stable. Indirect estimates of total population have been made, based on greater numbers than *F. eleonora* in shared winter quarters: present species found to outnumber *F. eleonora* 10:1, giving estimate of 5000 birds in 1000 km² in W Madagascar. Based on total population of 4000 pairs of *F. eleonora* in 1980's, present species might number c. 40,000 pairs; however, this figure does not correspond at all with normally very low density of species within breeding range, although breeding populations still very little known. At least c. 100 pairs in 1980's in Israel, where previously considered very rare.

Bibliography. Ali & Ripley (1978), Baha El Din (1984), Booth (1961), Brown *et al.* (1982), Clancey (1968a), Cramp & Simmons (1980), Frumkin (1984, 1986, 1988a, 1993), Frumkin & Pinshow (1983), Gaucher, Daunicht & Eichacker (1994), Gaucher, Petit & Symens (1988), Gænsbøl (1986), Ginn *et al.* (1989), Goodman *et al.* (1989), Kemp & Crowe (1993), Langrand (1990), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Moreau (1969), Milon *et al.* (1973), Paz (1987), Pickford *et al.* (1989), Richardson (1990), Roberts (1991), Walter (1979c).

43. Aplomado Falcon

Falco femoralis

French: Faucon aplomado **German:** Aplomadofalk **Spanish:** Halcón Aleto

Taxonomy. *Falco femoralis* Temminck, 1822, Brazil.

Has been known as *F. fuscoaculeus*, but this form is unidentifiable. Closely allied to *F. deiroleucus* and *F. ruficularis*. Three subspecies recognized.

Subspecies and Distribution.

F. f. septentrionalis Todd, 1916 - S USA (Arizona, New Mexico and Texas) S locally through Mexico to Guatemala.

F. f. femoralis Temminck, 1822 - Nicaragua and Belize through Panama to Colombia, E to the Guianas, and S through E Bolivia and Brazil to Argentina, extending S to Tierra del Fuego.

F. f. pichinchae Chapman, 1925 - temperate zones of SW Colombia, Ecuador, Peru and W Bolivia S to N Chile and NW Argentina (Tucumán).

Descriptive notes. Male 37-38 cm, average 261 g; female 43-45 cm, average 407 g. Tail rather long, in comparison with other falcons. Dark or bluish slate above; pale supercilium extends from behind eye onto russet nape; whitish throat and cheek patches separated by dark malar stripe; breast buff, with band across belly blackish barred white; vent, undertail-coverts and thighs rufous; tail blackish, with five off-white bands and white tip. Iris dark brown to yellowish brown, cere and legs pale yellow. Female similar, but significantly larger. Immature blackish brown above; underside breast and belly whiter than in adult.

Subspecies. breast streaked blackish; tail bars less distinct. Race *septentrionalis* larger and paler overall; race *pichinchae* darkest, larger than nominate, with breast band incomplete.

Habitat. Grassland, savanna and shrub-steppe in wide variety of climatic regimes, from moist tropical lowlands and dry savannas to Altiplano and puna in Andes, and comparable habitat in Tierra del Fuego; occurs up to 4000 m.

Food and Feeding. Claimed to feed heavily on insects and rodents; more detailed studies show birds as staple diet, with some rodents, bats, insects and lizards; insects numerically important.

but only c. 6% by biomass. Very poorly studied in South America: one study in C Chile gave mostly birds (56% by number, 97% by biomass). In Mexico, 50 bird species reported as prey. Prey includes large birds, e.g. teal, tinamous, chachalacas, pigeons and grackles; on average, avian prey items weigh 88 g. Most birds taken early in day, followed by long bouts of hawking insects. Most commonly captures prey by perch-hunting. Very rarely hunts by stooping from soar; consequently, does not take faster-flying birds, e.g. swifts. Pirates food from other raptors e.g. *F. sparverius*, White-tailed Kite (*Elanus leucurus*). One individual said to have stolen crayfish from herons. Often forages at grass fires. Hunts in tandem: 29% of all hunts recorded, and 66% of attempts to capture birds, in tandem; 45% success in capturing birds by tandem hunting, but only 21% when solitary. Male often initiates attacks on distant prey spotted from perch; if female does not follow, male calls her. Female will burst into shrubs to flush out birds; if prey not easily flushed, female pursues on ground while male hovers overhead. Eight young birds, reared in captivity, hunted together when released into the wild in Texas. Uneaten prey cached; cache sites defended from other predators.

Breeding. Very poorly known. Nest in dry season, Venezuela: eggs in Nov, Argentina. Uses abandoned nests of corvids (*Psittorhinus*, *Corvus*) or other raptors (*Elanus*, *Buteo*); one pair nested repeatedly in abandoned nests in active colony of *Milvago chimango*. Usually 2-3 eggs (up to 4); incubation 31-32 days (1 nest), by both sexes; fledging 4-5 weeks. In Venezuela, 1 nest produced 3 young.

Movements. C American populations predominantly migratory, although some overwinter (in Belize); some birds in Panama seem to be resident. Non-migratory through central part of range; appears in small migrant flocks in SE Brazil in Aug, but source of these birds, and resident or migratory status of southernmost populations remain to be confirmed.

Status and Conservation. Not globally threatened. CITES II. Throughout most of its extensive range, populations stable or perhaps increasing, where deforestation is opening up new grassland habitat. Only occasionally reportedly from Guatemala. Virtually eliminated for poorly understood reasons in S USA and N Mexico; decline may have started as early as 1909, but species probably nested until 1950's; probably related to habitat change associated with cattle grazing and invasion of mesquite, although recent improvements in the habitat have not led to population increase. Significant DDT contamination and eggshell thinning reported in E Mexico. In Panama, increased area of sugar cane cultivation and spreading human population may explain apparent recent slump there. Declines reported in S Argentina in areas where pesticide use has been poorly controlled (if at all). Captive breeding and reintroduction programme being carried out in N of range by Peregrine Fund (see page 247).

44. Merlin

Falco columbarius

French: Faucon émerillon

German: Merlin

Spanish: Esmerejón

Other common names: Pigeon Hawk

Taxonomy. *Falco columbarius* Linnaeus, 1758, America = South Carolina.

Formerly placed in genus *Aesalon*. Has been allied with *F. chicquera*, but no clear relationship. Nine subspecies normally recognized.

Subspecies and Distribution.

F. c. subaeson C. L. Brehm, 1827 - Iceland.

F. c. aesalon Tunstall, 1771 - N Eurasia, from Faeroes E to C Siberia.

F. c. insignis (Clark, 1907) - Siberia, E of R Yenisey to R Kolyma.

F. c. pacificus (Stegmann, 1929) - Soviet Far E, including Sakhalin I.

F. c. pallidus (Sushkin, 1900) - steppes of Asia, from near Aral Sea to Altai Mts.

F. c. lymani Bangs, 1913 - mountains of C Asia, in Turkestan, E Russia, NW China and Mongolia.

F. c. suckleyi Ridgway, 1873 - Pacific coast of North America, from Alaska and British Columbia to N Washington.

F. c. columbarius Linnaeus, 1758 - North America, except Pacific coast and Great Plains.

F. c. richardsoni Ridgway, 1871 - Great Plains of North America, from C Alberta S to Wyoming.

Descriptive notes. 24-33 cm; male 150-210 g, female 189-255 g; wingspan 50-67 cm. Distinctive small, stocky, dashing falcon. Male has upperparts dark or pale bluish, underparts from dark and heavily streaked to pale buff and lightly streaked; usually conspicuous pale bands in tail. Female browner, without blue tones; plumage generally more uniform, less contrasted than in male. Juvenile similar to female. Races differ in overall plumage tone, with upperparts of male deep blackish blue in forested or moist regions, but pale greyish blue in arid steppe regions; *suckleyi* darkest, *pallidus* palest; also some difference in size.

Habitat. Extremely varied, from sea-level up to tree-line in some mountain ranges, from boreal forest and tundra to parkland with deciduous trees, shrub-steppe, moorland, open prairies and steppes. Some trees or scrubby vegetation generally preferred. Occurs in even broader range of habitats on migration, often along sea coasts.

Food and Feeding. Chiefly small birds under 50 g during breeding season; larger birds (e.g. sandpipers), bats and insects (e.g. dragonflies, locusts) after breeding and during migration; small rodents and shrews also caught, especially by young birds in first year. Usually attacks from perch, but also while flying low over ground. Prey mainly caught in mid-air; attacks less frequently directed at perched birds; often performs hot pursuit of prey in flight. Sometimes hunts in company of other raptors, e.g. Sharp-shinned Hawk (*Accipiter striatus*), and pairs hunt co-operatively, e.g. in up to 30% of hunting attempts in Iceland. Prey flushed by other raptors and other objects (e.g. automobiles, trains) is also caught. Success rates of 5-40%, depending somewhat on terrain, prey type and time of year. Food may be cached for later consumption.

Breeding. Mar-June. Solitary. Presence of nest helpers (usually yearling males) and extra-pair copulation both recorded. No nest built; heavy use of old stick nests of other species especially corvids (*Corvus*, *Pica*) in trees; also uses tree cavities, cliff ledges or stick nests on ledges; also on ground, usually in scrape made in thick vegetation cover; frequency of given nest type somewhat

dependant on region, e.g. 74% on ground in Britain, cliffs used in Iceland, but mainly trees in S Canada and forested parts of Norway; locally breeds at urban sites, e.g. in Canada. Usually 3-6 eggs; incubation 28-32 days, by both sexes, with males performing 7-15%: chicks have buffy brownish down on upperparts, grading to white underparts; fledging 28-32 days. Nest success c. 60-90% of eggs laid; fledging c. 68-80%; locally, in Norway, high success related to good vole (*Microtus*) years, with 76% fledging in good years, 38% in bad years. Breeds first at 1 year. Oldest ringed bird 10 years 7 months.

Movements. Migratory, except for populations in Iceland, British Is, locally in C Asian mountains, Pacific NW in North America, and locally in Canadian prairies. Generally moves wholly S of breeding range, with southernmost breeding populations tending to migrate shortest distances. In Eurasia moves S to Mediterranean, N Africa, Arabian Gulf, Iraq, Iran, China, Japan and Korea; in North America moves S to Venezuela, Ecuador and N Peru, and recorded S to Manaus (NC Brazil) and French Guiana; many offshore sightings, with stragglers moving across oceans as far as Philippines and Hawaii. Peak autumn migration late Aug to late Sept; peak spring migration from mid-Mar to mid-Apr.

Status and Conservation. Not globally threatened. CITES II. Status of Asian races not satisfactorily documented. Between 1960 and 1970's, significant accumulations of chlorinated hydrocarbons caused some reproductive failure; eggshells showed 13% thinning in Europe, and 23% in North America, with maximum record of 30% in Canadian prairies. Populations in Canada and Europe declined during that period; data insufficient to determine effects on Asian populations over same period. Currently (1993) chemical residues are not significant; eggshells are returning to normal thickness, and European and North American populations increasing, as indicated by breeding densities and distributions, migration counts and wintering distributions and numbers. At same time, at least in North America, alterations are reducing availability of suitable habitat; some habitat loss offset by habituation of species to humans and altered landscapes, and adaptation to urban nesting. Collision with man-made objects accounted for 43% of mortality of 88 birds in Canada. No comprehensive population estimates, but in 1980's estimated at: a few 10,000's of pairs for Eurasia, e.g. over 800 in UK, 2000 in Sweden, 1600 Finland, and 1600 in Estonia; and several thousand pairs in North America, e.g. minimum 2000 in Saskatchewan. Estimates for 1993 include 250-300 pairs in Byelorussia and possibly as many as 30,000 pairs in European Russia; by 1993 populations in UK had increased to estimated 1300 pairs.

45. Bat Falcon

Falco rufigularis

French: Faucon des chauves-souris German: Fledermausfalke Spanish: Halcón Murcielaguero

Taxonomy. *Falco rufigularis* Daudin, 1800, Cayenne.

May belong in *F. subbuteo* complex. Similarity to *F. deiroleucus* probably reflects a recent common ancestor rather than convergence. In past, alternatively labelled *F. albicularis*. Validity of race *ophryophanes* sometimes challenged. Northernmost populations sometimes awarded separate race, *petrophilus*. Three subspecies recognized.

Subspecies and Distribution.

F. r. petraensis Chubb, 1918 - N Mexico (from Sonora E to Tamaulipas) S through Central America to Colombia, and W of Andes S to Ecuador.

F. r. rufigularis Daudin, 1800 - E Colombia E to the Guianas and Trinidad, and S to S Brazil and N Argentina.

F. r. ophryophanes (Salvadori, 1895) - tableland of C Brazil (Piauí S to Mato Grosso, São Paulo and Paraná) and adjacent Bolivia, Paraguay and N Argentina.

Descriptive notes. 24-29 cm; male 108-148 g, wingspan 56-58 cm; female 177-242 g, wingspan 65-67 cm. Small version of *F. deiroleucus*, with broader black breast band more finely barred; lacks pale nape of larger *F. f. femoralis*. Head and upperparts black, with greyish edging to contour feathers from upper back to tail-coverts; throat and upper breast white, buff or cinnamon, extending to hind neck; rest of breast and underwings black, finely barred white; belly, thighs and under-tail-coverts chestnut rufous; rather long tail blackish, with several fine white or greyish bars and white or buff tip. Iris deep brown,

cere and legs bright yellow. Female much larger. Immature uniform black above; throat more buff-coloured; tawny tinge to barring on breast; undertail-coverts with black bars or spots. Races distinguished by tone of plumage coloration.

Habitat. Tropical forests, from lowlands up to montane forest at 1600 m. Fairly adaptable; inhabits unbroken forest, where hunts over canopy; sometimes reported to be more common in more broken forest (disturbed areas, forest edge, road cuts, riverbanks or cleared agricultural land with scattered trees), but this apparent predilection may be result of species being more conspicuous in such areas; observations at one nest suggest preference for foraging over intact forest rather than cleared areas.

Food and Feeding. Mainly bats, birds and large insects. Percentage of birds to bats in diet varies greatly between areas. Wide variety of birds, with 56 species caught by 1 pair in Venezuela: mostly highly aerial species, e.g. swifts, swallows and hummingbirds. Insects include dragonflies (Odonata), moths (Lepidoptera), large grasshoppers (Orthoptera), Homoptera and Hymenoptera. Mostly hunts around dawn and dusk, often well after sunset. Prey almost always taken in air, but some rats and geckos caught on ground. From high perch, will attack birds moving above canopy, through open areas, or even across road cuts through forest; more rarely hunts from high in air, chasing high-flying insects or stooping at prey below. Flies low over canopy trying to flush prey from canopy; one seen flying to canopy tree, clinging to branch while flapping wings for several seconds.

and then flying up to catch insects flushed from tree. In French Guiana, males and females employ different techniques for catching bats.

Breeding. Most data from E Mexico, with only handful of nesting attempts observed elsewhere. Season seems protracted: in Guatemala (Petén), Belize and Mexico, courtship begins in Feb-Mar (middle of dry season); in Trinidad, nesting in Feb; in Colombia, birds in breeding condition in Feb-Mar; eggs in Mar in N Venezuela, in Apr in Guyana, and in Aug (middle of dry season) in NC Brazil (Mannus). Nests in natural tree cavities or holes excavated by parrots, in old trogon nests in termite colonies, or on cliffs; also on pre-Columbian ruins, and more modern man-made structures, e.g. on sugar mill crane, in Guyana. Copulation often preceded by courtship feeding; both parents vocal and aggressive around nest tree, chasing other raptors flying as far off as 1 km from nest tree. 2-4 eggs (average 2.9, in Mexico); fledging c. 35-40 days. Male provides virtually all of food during nestling phase.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Widespread and generally not uncommon in appropriate habitat. Tolerates, and may even benefit from, patchy, small-scale deforestation (although this is uncertain). However, in Central America no longer breeds in several areas where forest extensively transformed to agriculture; this trend likely to be repeated elsewhere throughout range.

Bibliography. Beebe (1950), Blake (1977), Cade (1982), Chavez-Ramírez & Contreras *et al.* (1990), Enkerlin (1991), French (1973, 1992), Haverschmidt (1962), Hilty & Brown (1986), Inigo-Elias (1993), Kiff *et al.* (1980), Kirven (1976), Monroe (1968), Parker (1991b, 1993), de la Peña (1992), Pinto (1964), Ridgely & Gwynne (1989), Ruschi (1979), Russell (1964), Schaldach (1963), Schulenberg & Parker (1981), Sick (1985a, 1993), Slud (1964), Siles & Skutch (1989), Teixeira *et al.* (1987a), Terborgh & Weske (1975), Tostain (1986a), Voous (1969), Wetmore (1965).

46. Orange-breasted Falcon

Falco deiroleucus

French: Faucon orangé

German: Rotbrustfalke

Spanish: Halcón Pechirrojo

Taxonomy. *Falco deiroleucus* Temminck, 1825, São Francisco Island, Santa Catarina, Brazil.

Vocalizations most unusual among falcons, shared only with *F. ruficularis*, to which probably closely related; sometimes associated with *F. peregrinus* complex, but now appears clearly related to "hobbies". Monotypic.

Distribution. S Mexico S through Central America to Colombia, E to the Guianas and Trinidad, and E of Andes S through Brazil and Bolivia to Paraguay and N Argentina. Formerly thought to nest only around periphery of Amazon, but recent records of adults and juveniles in C Brazilian Amazonia suggest that species breeds throughout extensive range.

Descriptive notes. 33-40 cm; female 654 g. Toes abnormally long and mandible disproportionately large for a falcon; bright yellow feet so large as to be useful characteristic for field identification. Differs from smaller *F. ruficularis* in coarser barring on narrower breast band, and much larger feet. Very dark above, with black "helmet"; throat white, breast rufous orange; black breast band coarsely barred rufous; thighs and vent rufous orange. Female much larger; largest females weigh twice as much as smallest males. Immatures have two distinct plumages: all show dark "cummerbund" across mid-breast, barred white; in others orange with little or no white; some

birds have upper breast and throat mainly white, in others orange with little or no white; some birds have barring on thighs and undertail-coverts.

Habitat. Locally throughout lowland tropical forest, but also reported at interface of forest and open savanna; inhabits drier regions (Chaco) with gallery forest along streams and cliffs at S limit of range. E Andean slopes in subtropical forest, up to 1100 m in Cochabamba (SC Bolivia). Appears to be ecological replacement of *F. peregrinus* throughout most of Neotropics. Often seen on knoll, cliff or ridge overlooking vast expanses of unbroken rain forest or Chaco.

Food and Feeding. Highly specialized on flying prey, including pigeons, conures, parrots, swifts and martins flying above forest; bats also important, captured well after sunset and well before dawn. Enormous feet enable species to grasp large birds of canopy. Very few observations of hunting behaviour, but most attempts involve long, low flight initiated from high perch; will set off on long flight to intercept moving flocks of swifts, with sudden swing upwards into the flock. Rarely stoops from far above prey in manner of *F. peregrinus*. Adults and young cache food in epiphytes.

Breeding. Almost all available data from Ecuador, or Guatemala and Belize. In Guatemala and Belize, courtship in Feb, fledging in May-Jun (end of dry season). Nests in trees or cliffs, often near water; also in pre-Columbian ruins. Males deliver as many as 3 prey items per day when courting; copulation often preceded by courtship feeding. Clutch small, probably 1-3 eggs; incubation c. 30 days; fledging c. 40 days. Incubation and feeding of young mainly by female. Male rarely enters nest; calls female off nest for food transfer; if female does not respond, male caches prey, rather than delivering it to young in nest.

Movements. Apparently sedentary.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Sparse distribution throughout range and apparent sensitivity to deforestation suggest species requires careful attention. Generally rare, but may be more abundant locally than normally believed; in 1992, total of 10 pairs known in Belize and in and around Tikal National Park (Guatemala); in two different cases, 3 pairs nested within radius of 10 km. May be displaced from potential nest-sites by American Black Vultures (*Coragyps atratus*), which arrive in association with human occupation and deforestation; traditional nest at Tikal monuments in the Petén (Guatemala) now occupied by vultures; another traditional nest on nearby cliff no longer occupied by present species, but supports large number of vultures. Virtually all information available on breeding biology of species comes from long-term study in Ecuador and Peregrine Fund's Maya Project in Guatemala and Belize. Peregrine Fund has established captive breeding programme with small number of birds. Population of Guatemala and Belize possibly disjunct now from South American populations, and may merit special concern.

Bibliography. Baker *et al.* (1992), Baker & Whitmore (1993), Blake (1977), Boyce (1980), Boyce & Kiff (1981), Cabot & Serrano (1986), Collar & Andrew (1988), Contreras *et al.* (1990), Field & Krabbe (1990), Freemann (1950), Giescom (1932), Hardy *et al.* (1975), Haverschmidt (1968, 1980), Herman & Hedsorn (1990), Hilty & Brown (1986), Howell (1992), Jenny (1989), Jenny & Cade (1986), Jenny & Barnham (1987), Kiff (1988), Land (1970), Meyburg (1986), Monroe (1968), Ofreg (1985), de la Peña (1992), Pinto (1964), Remsen & Ridgely (1980), Ridgely & Gwynne (1989), Remsen & Hedges (1984), Short (1975), Sick (1985a, 1993), Slud (1964), Smith (1966), Smith & Paynter (1963), Stiles & Skutch (1989), Thiollay (1989a), Weick (1989), Wetmore (1965), Whitacre & Jenny (1991).

47. Eurasian Hobby

Falco subbuteo

French: Faucon hobereau

German: Baumfalke

Spanish: Alcotán Europeo

Taxonomy. *Falco Subbuteo* Linnaeus, 1758, Sweden.

Forms superspecies with *F. cuvierii*, and possibly also *F. severus* and *F. longipennis*; sometimes considered conspecific with *F. cuvierii*. Two subspecies recognized.

Subspecies and Distribution.

F. s. subbuteo Linnaeus, 1758 - NW Africa and Europe E through C Asia and N China to Kamchatka, Sakhalin and N Japan; winters in C & S Africa and S Asia.

F. s. streichi Hartert & Neumann, 1907 - S & E China, S from Qin Ling Mts (S Shaanxi); possibly also N & E Burma and N Indochina.

Descriptive notes. 28-36 cm; male 131-232 g, female 141-340 g; wingspan 69-84 cm. Red thighs and undertail-coverts; pale throat and cheeks contrast with densely streaked whitish or buff underparts. Female slightly larger. Juvenile browner and with pale feather edges above; buff undertail-coverts and thighs, pale crown.

Habitat. Open wooded areas: wooded steppe, pastures, cultivation or scrub with clumps of trees, scattered trees or copses; fields with hedges, edges of woods, etc. From semi-arid areas to boreal forests. Mainly at low altitudes in plains or foothills, but also in mountains,

up to 4000 m in India. Occasionally in cities or suburbs. In winter, occurs in woodland, especially *Brachystegia*, and savanna.

Food and Feeding. Mainly insects, especially flying insects which are eaten on the wing, e.g. dragonflies, beetles, moths, grasshoppers, locusts, crickets, ants. Also many small birds, especially in breeding season, when takes advantage of abundance of fledglings; birds include swallows, martins and swifts, as well as less aerial species of open areas, e.g. sparrows, finches, starlings, larks and pipits. Few other vertebrates, although bats and lizards locally important; some individuals specialize in certain prey type. In winter quarters in Africa, takes flying insects, particularly swarming alate termites, and also birds. Captures prey mainly in air; able to catch very agile birds due to fast, acrobatic flight; very active at dawn and dusk; visits colonies or roosts of prey species, sometimes in cities and their suburbs; follows fires or farm vehicles which flush prey.

Breeding. Lays late, mainly in Jun-Jul; late May in some areas. Solitary; uses unoccupied nests of corvids (e.g. crows, magpies) or other raptors; almost always in trees, preferring pines, but also in other conifers and broad-leaved trees; exceptionally on cliffs. Nest-site may be reused each year, not necessarily by same pair. Normally 3 eggs (2-4), laid at interval of 2-3 days; replacement laying occurs; incubation 28-33 days, mainly by female; chicks have pale creamy buff first down, greyer second down; fledging 28-34 days; juveniles dependent on adults c. 5 weeks more. Fledging success in Germany, 1-4 chicks per breeding pair, 2-4 chicks per successful pair; can be much lower. Sexual maturity normally at 2 years, sometimes 1. Oldest recorded bird 10 years old.

Movements. Mostly migratory, but *streichi* sedentary; wintering generally rare in Palearctic, e.g. small numbers in S Japan. Mainly winters in Africa, with bulk of numbers in S third of continent, arriving mainly in Nov; E birds in S & SE Asia, especially Indian Subcontinent; also in S China, alongside resident population; recorded S to Java and Timor. Normally returns to breeding areas in late Apr and May, mostly leaving in Aug-Sept. Migrates on broad fronts.

Status and Conservation. Not globally threatened. CITES II. Population levels and trends not well known; local fluctuations can be considerable, but overall possibly stable in long term; no recent declines noted in winter quarters. Difficult to estimate numbers accurately; in 1980's, European population (excluding former USSR) possibly 11,000-14,000 pairs, but perhaps up to 20,000; preliminary estimate for European Russia of 70,000 pairs in early 1990's; 1100-1600 pairs in Byelorussia; 150-200 pairs in Azerbaijan; still fairly common in Ukraine, but declining due to cutting down of old forest patches. Estimates of 500-1000 pairs in Morocco and in Turkey in 1980's. Little information available for Asia, although Asian population of former USSR may be less dense than European.

48. African Hobby

Falco cuvierii

French: Faucon de Cuvier

German: Afrikanischer Baumfalke

Spanish: Alcotán Africano

Taxonomy. *Falco Cuvierii* A. Smith, 1830, South Africa.

Forms superspecies with *F. subbuteo* and possibly also *F. severus* and *F. longipennis*; sometimes considered conspecific with *F. subbuteo*. Monotypic.

Distribution. Senegambia E to Ethiopia and S to SE South Africa.

Descriptive notes. 28-30 cm; male 125-178 g, female 186-224 g. Small dark falcon with long, slender wings and rich chestnut underparts. Juvenile has underparts more heavily streaked and upperparts edged with brown. Migrant long-winged *F. subbuteo* has chestnut restricted to thighs and undertail-coverts; similarly built juvenile *F. concolor* lacks chestnut tones on underparts, while adult grey all over.

Habitat. Moist woodland and tree savanna, including palm savanna and forest edge, up to over 2500 m.

Food and feeding. Outside breeding season, mainly insects, especially termite alates; when breeding, mainly small birds, up to the size of doves. Most prey taken high in the air using fast and dextrous flight, with high success (95% for insects, 72% for birds); up to 30 individuals gathering at insect emergences. Roosts in tall trees and spends much of the day at rest there. Hunts mainly at dawn and dusk.

Breeding. Laying Dec-Apr in W and NE Africa; Aug-Nov in SE and S Africa. Nests in tall trees, at height of up to 30 m, in old structure of crow or other raptor, or in epiphyte. Often evicts owners, and very defensive of nest area. Usually 3 eggs (2-4); incubation c. 30 days; chicks have first down cream.

second down grey; fledging c. 30 days. Male feeds female during incubation or caches food near nest; later, female catches some insects herself in vicinity of nest.

Movements. Resident as pairs in many areas, but may be locally migratory in parts of W Africa. A wet season vagrant, sometimes breeding, to the periphery of its range in NE Kenya and S Africa. No details of movements available.

Status and Conservation. Not globally threatened. CITES II. Widespread, but generally uncommon to rare; common along forest-savanna ecotone in parts of W Africa and L

Victoria basin of E Africa. Common in several densely populated areas, even within cities. Territory of 160-200 ha, hunting range over 600 ha. Not known to be affected by pesticide use.

Bibliography. Brooke & Howells (1971), Brown *et al.* (1982), Cade (1982), Forbes-Watson (1963), Ginn *et al.* (1989), Gore (1990), Irwin (1981), Lewis & Pomeroy (1989), Mackworth-Præd & Grant (1957-1973), Maclean (1993), Pakenham (1979), Pickford *et al.* (1989), Pinto (1983), Pitman (1966), Steyn (1965b, 1982), Thiollay (1975a, 1976b, 1977c, 1978c).

49. Oriental Hobby

Falco severus

French: Faucon aldovandin **German:** Maleienbaumfalke

Spanish: Alcotán Filipino

Other common names: Indian Hobby

Taxonomy. *Falco severus* Horsfield, 1821, Java.

Forms superspecies with *F. longipennis*, and perhaps also with *F. subbuteo* and *F. cuvierii*. Variation of present species in size and plumage slight and clinal; insufficient for racial differentiation. Monotypic.

Distribution. NW India and Nepal E to Yunnan, Guangdong and Hainan (S China), and S through Burma, Thailand and Indochina to Philippines, Java and Sulawesi, whence E through New Guinea to Solomon Is. Himalayan birds winter S to S India and Sri Lanka.

Descriptive notes. 24-30 cm; 168-249 g; wingspan 66 cm. Small, short-tailed, black and rufous falcon; solid rufous underparts separate from other hobbies. Juvenile similar, but heavily streaked on rufous underparts. Clinal variation in plumage tone, from paler birds in W to darker ones in E.

Habitat. Forest with clearings, from mangroves at sea-level to deciduous and evergreen forest in foothills and mountains up to 2500 m; also seen hunting over scrub.

Food and Feeding. Insects, small birds and bats. Hunts from exposed perch on tall tree; when sights prey, launches direct, rapid,

strong flight to capture prey in the air; captured prey taken back to perch where eaten. Also hawks dragonflies over water. Hunts most often at dawn and dusk. Often gathers in loose flocks; joins flocks of wood-swallows (*Artamus*) hawking insects.

Breeding. Season varies regionally: Apr-Jul in India and Burma; Jun in Java; Mar in Philippines. Stick nest in tree, usually on slope; uses nests constructed by other birds, mostly other raptors or corvids. Display flights involve series of undulations, with shallow, rapid, fluttering wingbeats on upsweeps, and gliding descent, accompanied by vocalizations. Usually 3-4 eggs; incubation 28-30 days, by both sexes; fledging 30+ days. Period of chick dependency unrecorded.

Movements. Populations of Himalayas migratory, moving S for winter; others apparently sedentary. Vagrant to Borneo and probably to Malay Peninsula.

Status and Conservation. Not globally threatened. CITES II. Generally rare and local; in Philippines, uncommon but regularly recorded. No threats known at present; surveys required over much of range, in order to clarify status. Alleged occurrence in Pakistan has been challenged; status in Sumatra uncertain, with no definite records; recently recorded on Seram.

Bibliography. Ali & Ripley (1978), Beehler *et al.* (1986), Bishop *et al.* (1994), Bowler & Taylor (1989), Cade (1982), Coates (1985), Cheng Tso-hin (1987), Deignan (1945), Diamond (1972), Dickinson *et al.* (1991), DuPont & Rabor (1973), Hadden (1981), Inskipp & Inskipp (1985), King *et al.* (1975), Lekagul & Round (1991), MacKinnon (1988), MacKinnon & Phillips (1993), van Marle & Voous (1988), Medway & Wells (1976), Meyer de Schauensee (1984), Rand & Rabor (1960), Roberts (1991), Smythies (1981, 1986), Sresemann (1940a), White & Bruce (1986).

50. Australian Hobby

Falco longipennis

French: Petit Faucon

German: Australischer Baumfalke

Spanish: Alcotán Australiano

Other common names: Little Falcon

Taxonomy. *Falco longipennis* Swainson, 1837, Tasmania.

Forms superspecies with *F. severus*, and perhaps also with *F. subbuteo* and *F. cuvierii*. Pale race *marchisonianus* of inland and N Australia commonly recognized, but probably invalid because intergradation occurs with dark birds of S humid areas. Population on Lesser Sunda Is apparently a distinct race, although very limited information available. Two subspecies recognized.

Subspecies and Distribution.

F. l. hanieli Hellmayr, 1914 - Lesser Sundas, from Lombok to Timor.

F. l. longipennis Swainson, 1837 - Australia and Tasmania; outside breeding season occurs N to New Guinea, New Britain and Moluccas.

Descriptive notes. 30-35 cm; male 132-280 g, larger female 190-365 g; wingspan 66-87 cm. Small *Falco*, resembling other hobbies. Distinguished from *F. peregrinus* by smaller size, slighter build, longer and narrower wings and tail. Juvenile has upperparts tinged brown, richer rufous underparts. Regional variation in colour within Australia; race *hanieli* slightly smaller and paler below.

Habitat. Open forest, woodland, savanna and adjacent treeless habitats, wooded farmland and urban areas with plenty of trees; from sea-level to 2000 m. Nests in trees.

Food and Feeding. Small birds, small insectivorous bats and flying insects. Mostly terrestrial flocking birds, such as larks, pipits, grassfinches (Ploceidae), doves and small parrots; also aerial birds, such as swallows. Commonly takes introduced sparrows (*Passer*) and starlings (*Stumus*) in

farmland and towns. Most prey of under 100 g, rarely over 200 g. Diurnal, crepuscular and sometimes nocturnal, using artificial light. Forages by low, fast flight, still-hunting on prominent perch, or high quartering. Seizes prey in flight by shallow stoop or direct flying attack that may become vigorous chase; hawks flying insects; occasionally steals mice from *F. cenchroides*.

Breeding. Aug-Jan. Solitary. Uses old or usurped large stick nest of other species, typically *Corvus*, high (over 10 m) above ground, in top of tree or electricity pylon. Usually 2-3 eggs (2-4); incubation c. 28-35 days; chicks post-fledging dependence of up to 6 weeks.

have cream-coloured down; fledging 34-38 days; Success 2-75 young per year, for a pair over 4 years; successful broods commonly of 2-3 young. Oldest ringed bird 7 years.

Movements. Resident and partly migratory populations. Birds breeding at high latitudes and altitudes winter in coastal and lowland areas; many migrate N, some (mostly females) reaching New Guinea, New Britain and E Indonesia.

Status and Conservation. Not globally threatened. CITES II. Fairly common and widespread, even in cities and towns. Population probably stable; has benefited from introduced prey. Eggshell thickness significantly reduced by DDT use (now ceased); local breeding depression likely in S agricultural areas. Seldom shot.

Bibliography. Beehler *et al.* (1986), Coates (1985), Copper & Copper (1981), Czechura & Czechura (1988), Czechura & Debus (1986), Debus *et al.* (1991), Hollands (1984), Marchant & Higgins (1993), Metcalf (1989), Newgrain *et al.* (1993a), Olsen & Marples (1993), Olsen & Olsen (1980a, 1987a), Olsen, Crome & Olsen (1993), Olsen, Fuller & Marples (1993), Schodde & Tidemann (1988), Tarburton (1991), Veerman (1991), White & Bruce (1986).

51. New Zealand Falcon

Falco novaeseelandiae

French: Faucon de Nouvelle-Zélande

German: Maorifalke

Spanish: Halcón Maorí

Other common names: New Zealand Hobby

Taxonomy. *Falco novae-Seelandiae* Gmelin, 1788, Queen Charlotte Sound, New Zealand.

Has been placed in separate genus, *Nesierax*, or in *Hieracidea* with *F. berigora*, to which most closely related, but also related to other Australasian and Gondwanan hobbies. Two forms, *no-vaeseelandiae* and *pottsii*, previously regarded as races or separate species on size and plumage differences, but confusion with age and sex differences. Three morphologically and ecologically distinct populations, with separate distributions, not formally recognized as races. Monotypic.

Distribution. New Zealand, Stewart I, Auckland Is.

Descriptive notes. 41-48 cm; male 252-500 g, larger female 420-594 g; wingspan 66-91 cm. Medium-sized *Falco*, distinctively short-winged for genus. Unmistakable in New Zealand, where is only dark *Falco*. Juvenile has more uniform upperparts, darker and less heavily marked underparts. "Bush form" in forest on North I and NW of South I, small and dark; "eastern form" of open habitats on South I, large and pale; "southern form" in forest on Stewart I and Auckland Is and SW coast of South I, intermediate, but closer to "bush form".

Habitat. Forest and adjacent grassland, typically in mosaic of forest remnants and cleared rangeland in hills and mountains; from sea-level to 2100 m. Nests in forest, cliffs and steep broken hillsides remote from humans.

Food and Feeding. Mainly birds, now mostly introduced species; sometimes small mammals, insects and lizards, rarely carrion. Commonly passerines, but mammals and birds ranging up to size of young rabbits and hares, stoats, herons and waterfowl. Forages by low, fast flight, quartering and high soaring, or still-hunting from perch. Seizes or strikes prey in flight by stoop or direct flying attack, which may become vigorous chase; takes prey on ground by glide from perch. Also flushes prey from cover, stalks on ground, robs nests; pairs hunt co-operatively.

Breeding. Sept-Nov, sometimes Dec. Solitary. Nest is simple scrape or depression in grassy soil of cliff face or steep hillside, or in humus of epiphyte growing on tree; rarely in tree hollow; sites on ground protected by rock overhang, vegetation or log. 2-4 eggs; incubation 29-35 days; chicks have white first down, grey second down; fledging c. 32-35 days; post-fledging dependence 70-90 days. Success 1-9 young fledged per attempt, 2-6 per successful nest; higher at cliff sites than at ground sites. Sexual maturity at 2 years; unsuccessful breeding attempts sometimes at 1 year.

Movements. Adult pairs sedentary; juveniles dispersive, sometimes moving N or to lowlands.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Population declined through habitat destruction, persecution and effects of DDT, but now stable at c. 3000-4500 breeding pairs. Uncommon and generally confined to rough and remote areas, but has benefited from fragmentation of dense forest and establishment of introduced birds and mammals.

Bibliography. Chambers (1989), Falla *et al.* (1981), Fox (1977a, 1977b, 1977c, 1978, 1979, 1985, 1988), Hedley & Hedley (1982), Lawrence & Gay (1991), Marchant & Higgins (1993), Read (1985), Soper (1976), Taylor (1977)

52. Brown Falcon

Falco berigora

French: Faucon berigora

German: Habichtfalke

Spanish: Halcón Berigora

Taxonomy. *Falco Berigora* Vigors and Horsfield, 1827, New South Wales.

Has been separated in genus *Ieracidea* or *Hieracidea*, but a typical *Falco* in most respects and closely related to *F. novaeseelandiae*. Up to seven races described, but much confusion owing to complexity of colour morphs, and recent studies suggest that most are invalid. Three subspecies now recognized.

Subspecies and Distribution.

F. b. novaeguineae (A. B. Meyer, 1894) - C & E New Guinea and coastal N Australia.

F. b. berigora Vigors & Horsfield, 1827 - E. C & N Australia and Tasmania.

F. b. occidentalis (Gould, 1844) - SW & CW Australia.

Descriptive notes. 41-51 cm; male 316-590 g, larger female 430-860 g; wingspan 89-109 cm. Medium-sized *Falco*; long legs unique in genus. Extremely variable in colour, ranging from pale almost like *F. cenchroides* but with rufous thighs, to dark like *F. subniger* but with barred underwings and tail. Distinguished from *F. subniger* by long legs. Juvenile brown with buff forehead, throat and vent. Regional variation in size and colour: resident tropical race small and rufous or dark; SW birds small and rufous.

Habitat. Open woodland, savanna, grassland, farmland and deserts; from sea-level to 2000

m in Australia, rarely to 3000 m in New Guinea. Nests in trees.

Food and Feeding. Mammals, birds, reptiles (commonly snakes), amphibians, arthropods and carrion; rarely fish. Some seasonal variation in diet (see page 232). Forages mostly by still-hunting from exposed perch; also by quartering and hovering, by low fast flight or by soaring. Seizes prey on ground by glide, dive or direct flying attack that may become short chase. Pursues insects on foot; robs other raptors. Follows fires, livestock and other animals and farm machinery for flushed prey; pairs hunt co-operatively.

Breeding. Apr-Sept in N, Aug-Oct in S. Solitary. Uses old stick nest of other raptor or *Corvus* in tree; rarely on tree-fern, shrub, vines, artificial structure, cliff or termitarium; 4-30 m above ground. Usually 2-3 eggs (1-5); incubation 31-36 days; chicks have pale rufous first down, grey second down; fledging 36-42 days; post-fledging dependence 2-6 weeks. Success variously measured as 69% fledging success (of eggs laid), 1-77 young fledged per nest, and 2-39 per successful nest; 2-2 young raised per clutch laid, 2-3-2-4 per successful nest, and 1-7 young per territorial pair. Age at first breeding 3 years for males, 2 years for females. Oldest ringed bird 11 years; longevity 16 years in captivity.

Movements. Adults generally sedentary, or with local movements to winter territories. Juveniles dispersive or partly migratory within Australia; S birds winter to N, some reaching tropical Australia and New Guinea. Some irruptive movements to sites of abundant prey.

Status and Conservation. Not globally threatened. CITES II. Common and widespread; benefits from most agricultural activities, but sometimes shot or trapped. Eggshell thickness not significantly reduced by DDT in Australia.

Bibliography. Baker-Gabb (1982a, 1984a, 1984b), Beehler *et al.* (1986), Bollen (1993), Cade (1982), Coates (1985), Cupper & Cupper (1981), Czechura & Debus (1985a), Haddon (1976), Hodder (1993), Hollands (1984), Hull (1991, 1993), Klapste (1990), Marchant & Higgins (1993), Mooney (1976, 1988, 1989), Newgrain *et al.* (1993b), Olsen & Marples (1993), Olsen & Olsen (1980a), Olsen, Crome & Olsen (1993), Olsen, Ross & Olsen (1987), Reymond (1987), Schodde & Tidemann (1988), Sonter & Debus (1985), Weatherly *et al.* (1985).

53. Grey Falcon

Falco hypoleucos

French: Faucon gris

German: Silberfalke

Spanish: Halcón Gris

Taxonomy. *Falco hypoleucos* Gould, 1841, York, Western Australia. Monotypic.

Distribution. C & NW Australia.

Descriptive notes. 33-43 cm; male 335 g, larger female 500-624 g; wingspan 86-97 cm. Medium-sized *Falco*. Paler than *F. peregrinus* and *F. longipennis*. Juvenile has darker upperparts, heavier streaks on underparts.

Habitat. Woodland, scrub, savanna and plains in arid and semi-arid zones; from sea-level to at least 500 m, but seldom near coast. Nests in riparian woodland in arid zone.

Food and Feeding. Birds, small mammals, lizards and large insects; mostly pigeons and parrots. Forages by low fast flight, quartering and high soaring, or still-hunting from perch. Seizes or strikes prey in flight by stoop or direct flying attack; glides from perch to take prey on ground.

Breeding. Jun-Nov. Solitary, though sometimes near raptors of other species. Uses large stick nests of other birds, typically *Corvus*, in top of emergent living tree, 9-25 m above ground. Usually 2-3 eggs (2-4); incubation c. 35 days; chicks have white down; fledging c. 41-52 days. Success of 1-9 young fledged per successful nest.

Movements. Poorly understood; resident and partly migratory or dispersive populations. Some pairs resident except during drought, when may disperse to coast or inland refugia in summer; some birds, possibly mainly juveniles, migrate to winter in N Australia.

Status and Conservation. RARE. CITES II. Scarce and possibly declining; breeding range has contracted to arid zone. Total population estimated at c. 1000 breeding pairs. Affected by habitat degradation; possibly being replaced in semi-arid agricultural zone by *F. peregrinus*, which is favoured by increase in numbers of Galah (*Cacatua roseicapilla*) and introduced feral pigeon *Columba livia*. Eggshell thickness significantly reduced by DDT use (now ceased), with local breeding decline likely to have occurred in S of range. Subject to illegal egg-collection and possibly taking of nestlings for falconry. Conservation

measures required include population survey and research into biology and ecology of species.

Bibliography. Beehler *et al.* (1986), Blakers *et al.* (1984), Cade (1982), Collar & Andrew (1988), Cupper & Cupper (1980, 1981), Czechura & Debus (1985b), Garnett (1992), Hermes (1980), Hollands (1984), Ley (1991), Marchant & Higgins (1993), Olsen & Marples (1993), Olsen & Olsen (1980a, 1986), Olsen, Crome & Olsen (1993), Olsen, Fuller & Marples (1993), Schodde & Tidemann (1988), Silveira (1988).

54. Black Falcon

Falco subniger

French: Faucon noir

German: Rußfalke

Spanish: Halcón Negro

Taxonomy. *Falco subniger* G. R. Gray, 1843, Victoria.

Monotypic.

Distribution. C & E Australia.

Descriptive notes. 45-56 cm; male 510-710 g, larger female 610-1000 g; wingspan 97-115 cm. Medium-large *Falco*, distinctively broader-winged than most congeners. Distinguished from dark *F. berigora* by dark underwing, short legs and large feet. Juvenile similar to adult.

Habitat. Woodland, savanna, grassland and farmland; from sea-level to 1000 m, but seldom near coast. Nests in woodland and isolated trees.

Food and Feeding. Mammals, birds, large insects and carrion; rarely reptiles. Commonly young rabbits and rats; birds such as parrots,

button-quails (*Turnix*), quails, larks and pipits, rarely up to size of herons, waterfowl and smaller raptors. Forages by low, fast flight, quartering and high soaring, or still-hunting from perch. Seizes or strikes prey in flight by stoop or direct flying attack, which may become vigorous chase; hawks flying insects; glides from perch to snatch prey from ground. Sometimes hunts co-operatively in pairs. Follows grass fires, farm machinery, livestock, shooters and other raptors to seize flushed prey; robs other raptors.

Breeding. May-Nov, usually July-Sept. Solitary, though may nest near raptors of other species. Uses large stick nests of other raptors or *Corvus*, in top of living or dead tree, or rarely on electricity pylon; nests 4-14 m above ground. Usually 3-4 eggs (1-5); incubation c. 34 days; chicks have white down; fledging 38-49 days. Success 0-79 young fledged per egg laid. Oldest ringed bird 12 years.

Movements. Poorly understood. Partly migratory and dispersive; apparently some regular movement N for winter and S for summer, with irruptive occurrences related to drought or good rains in arid and semi-arid zones, local abundance of quails or plagues of other prey species.

Status and Conservation. Not globally threatened. CITES II. Generally uncommon but widespread; may be locally common in arid zone in wet years. Population fluctuates but apparently stable or may have increased in agricultural areas, where benefits from increased prey including introduced species. Eggshell thickness not significantly reduced by DDT. May be subject to limited illegal egg-collecting, and perhaps to taking of nestlings for falconry.

Bibliography. Baker-Gabb (1984a, 1989), Bedgood (1979), Cupper & Cupper (1981), Czechura & Debus (1985a), Fraser (1985), Haddon (1976), Hollands (1984), Marchant & Higgins (1993), Olsen & Marples (1993), Olsen & Olsen (1980a), Olsen, Crome & Olsen (1993), Schodde & Tidemann (1988), Whelan (1992).

55. Lanner Falcon

Falco biarmicus

French: Faucon lanier

German: Lannerfalk

Spanish: Halcón Borne

Taxonomy. *Falco biarmicus* Temminck, 1825, Cape of Good Hope.

Forms superspecies with *F. jugger*, and possibly with *F. cherrug*, *F. rusticolus* and *F. mexicanus*. Five subspecies recognized.

Subspecies and Distribution.

F. b. feldeggii Schlegel, 1843 - S Italy and Sicily E to Armenia and Azerbaijan, then S to Lebanon.

F. b. erlangeri Kleinschmidt, 1901 - NW Africa, from Mauritania to Morocco and Tunisia.

F. b. tanypterus Schlegel, 1843 - NE Africa, including Egypt and N Sudan, to Arabia, Israel and Iraq.

F. b. abyssinicus Neumann, 1904 - Senegal and Ghana E to Ethiopia and Somalia, and S to Uganda and N Zaire.

F. b. biarmicus Temminck, 1825 - Angola, S Zaire and Kenya S to South Africa.

Descriptive notes. 35-50 cm; male 500-600 g, female 700-900 g; wingspan 90-110 cm. Smaller *F. chicquera* has chestnut extending to neck and mantle, and underparts barred. Female larger and often darker than male. Juvenile brown above, underparts heavily streaked with dark grey; facial skin pale blue, not yellow. N races have underparts finely spotted with black, whereas almost unmarked in S populations; races also differ in size and intensity of coloration.

Habitat. Very variable, from dry, flat, open desert to wet, often forested mountains up to 5000 m. Usually with open or lightly wooded

hunting areas nearby. Overlaps with *F. peregrinus* in all but most arid areas.

Food and feeding. Mainly small birds, especially quails and columbids, augmented by rodents (*Arvicanthus* rats in Ethiopia), bats, lizards (*Uromastix* in W African deserts), insects (termite alates and locusts), and, in deserts, spiders and scorpions. Hunts mainly by fast aerial pursuit from a stoop or horizontal chase, often around a water-hole and often with a pair combining in attack; also hawks flying termites in leisurely fashion, pounces from a perch on terrestrial prey, or raids birds' nests. Catches prey. Up to 20 birds may gather at prey concentrations. Learns to use human hunters as beaters; obtains some prey by piracy; takes some carrion; often crepuscular, possibly even nocturnal.

Breeding. Rarely polyandrous. Laying Feb-May in S Europe and N Africa; Jan-Mar in Sahara, W and NE Africa, coinciding with northward passage of migrant small birds; Jun-Nov (peak Jul-Aug) in E, C and S Africa. Nests in old structures of corvids, other raptors or herons, in trees or on electricity pylons; alternatively in scrapes on cliffs, the ground, quarries or buildings. Usually 3-4 eggs (2-5), rarely double-brooded; incubation 32 days; chick with white first and second down; fledging 35-47 days. Female assists in hunting for chicks late in nestling period and during fledgling period of 1-3 months. Some interchange of, and possible competition for, nest-sites with *F. peregrinus minor*.

Movements. Resident in areas of more stable climate; local N-S migrant in W Africa; extensive movements in Africa indicated by ringing recoveries of up to 1528 km and annual surplus, especially of juveniles and non-breeding adults, in arid areas of E and SW Africa. May move into desert areas after rain, and out of forested areas during mist and heavy rain; gathers at food concentrations, e.g. breeding colonies of Red-billed Quelea (*Quelea quelea*) or emergences of locusts or termite alates.

Status and Conservation. Not globally threatened. CITES II. Widespread and generally common in Africa, even in populated areas. In Transvaal (South Africa): estimated total of 1400 pairs; nests average 9-10 km apart on farmland, or 2-5 km apart on cliffs; outnumbered *F. peregrinus* about 36:1. In Zambian savanna, mean inter-pair distance for 13 pairs was 1.8-3.5 km, and for 23 pairs on Namibian cliffs was 4 km. Apparently less common in E and W Africa. Some local declines in S Africa, possibly associated with seed dressings. In many areas of Africa benefits from bush clearance, use of grain crops by crows (providing nests) and from increased availability of prey species, including free-range poultry. Drastic decline in Europe and Israel by 1970, mainly through poisoning, falconry and shooting, e.g. formerly bred in SW Spain; however, population stable in Sicily with c. 100 pairs; 60-70 pairs in mainland Italy, and c. 100 pairs in rest of Europe, e.g. c. 30 pairs in Greece (1983). Overall effects of pesticides unknown but some high levels of contamination and local declines recorded.

Bibliography. Bergier (1987), Bijleveld (1974), Bonora & Chiavetta (1975), Brown, C.J. & Cooper (1987), Brown, L.H. *et al.* (1982), Cade (1982), Ciacco *et al.* (1987), Craib (1977, 1981), Cramp & Simmons (1980), Dalling (1975), Flint & Sorokin (1994), Flint *et al.* (1984), Gensbol (1986), Ginn *et al.* (1989), Goodman & Haynes (1989, 1992), Handrinos & Demetropoulos (1983), Juny (1960), Kemp (1972, 1975, 1993), Leonardi (1994), Leonardi *et al.* (1992), Lewis & Pomeroy (1989), Liversidge (1984), Mackworth-Praed & Grant (1962), Maclean (1993), Manzi & Perna (1994), Massa *et al.* (1991), McGowan & Massa (1990), Mendelsohn (1988b), Osborne & Colebrook-Robjent (1984), Pakenham (1979), Patincev (1993), Paz (1987), Simeonov *et al.* (1990), Sinclair & Walters (1976), Smeenk (1974), Sley (1982), Tarboton & Allan (1984), Tarboton *et al.* (1987), Yosef (1991), van Zyl (1991).

56. Laggar Falcon

Falco jugger

French: Faucon laggar

German: Laggarfalk

Spanish: Halcón Yággar

Taxonomy. *Falco jugger* J. E. Gray, 1834, India.

Sometimes considered race of *F. biarmicus*, with which forms superspecies, possibly along with *F. cherrug*, *F. rusticolus* and perhaps even *F. mexicanus*. Monotypic.

Distribution. Pakistan E throughout most of India and Nepal to Assam and N Burma; absent from extreme S India. Also occurs locally in S Afghanistan and possibly SE Iran.

Descriptive notes. 38-46 cm; 525-850 g; wingspan 95-115 cm. Large, slender falcon with long, narrow dark moustachial streak, similar to *F. biarmicus* in plumage and behaviour, but usually somewhat darker and browner, greyish brown above, white below with some dark flank markings. Juvenile almost uniform blackish brown on underparts; first year birds have intermediate plumage.

operative hunting of pair reported.

Breeding. Laying Jan-Apr. Nests in variety of sites: old stick nests of other birds, especially corvids and other raptors; in trees; often near humans, on buildings, spires, towers, or even castles; on cliffs or rocky outcrops, sometimes on bare ledges; even in holes in earth banks; reports of present species constructing nests are certainly erroneous. Spectacular display flights include mutual soaring, rapid pursuit of female by male, and male diving on female. Usually 3-4 eggs (rarely 2 or 5); both sexes incubate; incubation and fledging periods unrecorded. Both parents hunt, female only when chicks older; female alone feeds chicks.

Movements. Sedentary.

Status and Conservation. Not globally threatened. CITES I. Uncommon to rare and local. Population declines noted in Pakistan and W India probably due to reduction of prey availability as result of extensive cultivation.

Bibliography. Ali & Ripley (1978), Brown & Amadon (1968), Cade (1982), Hue & Eichécopat (1970), Inskipp & Inskipp (1985), King *et al.* (1975), Lowther (1949), Paludan (1959), Ripley (1982), Roberts (1991), Smythies (1986).

57. Saker Falcon

Falco cherrug

French: Faucon sacre

German: Würgfalk

Spanish: Halcón Sacre

Other common names: Altai Falcon ("altaicus")

Taxonomy. *Falco cherrug* J. E. Gray, 1834, India.

Closely related to *F. rusticolus*, with which forms superspecies, perhaps also including *F. biarmicus*, *F. jugger* and possibly even *F. mexicanus*. Internal taxonomy very complicated and uncertain, especially with reference to populations of C Asia. Status of form "altaicus" controversial (see page 218); has been considered separate species, or race of *F. rusticolus* or of present species; now usually reckoned to be morph of present species; nevertheless, breeds significantly earlier than other nearby populations of present species. Possible races *coarsi* (from Uzbekistan) and *progressus* (EC Asia) apparently rather distinctive; several other races may be valid, including perhaps *cyanopus* (C & E Europe), and unnamed population from deserts E of Caspian Sea. Two subspecies currently recognized.

Subspecies and Distribution.

F. c. cherrug J. E. Gray, 1834 - C Europe E through SW Russia, Ukraine and Iran to R Yenisey and foothills of Altai; winters from Europe and NE Africa E to NW India.

F. c. milvipes Jerdon, 1871 - SE Siberia, N Mongolia and N China S to W & C China; winters from Iran E to Nepal and NW India, Tibet and C China.

Descriptive notes. 45-55 cm; male 730-990 g, female 970-1300 g; wingspan 102-129 cm. Plumage very variable; crown whitish to brown, streaked dark. Rather similar to slightly larger, stockier *F. rusticolus*, but generally browner, especially on upperparts; larger and more heavily built than *F. biarmicus* and *F. jugger*. Juvenile generally darker and more heavily streaked. Considerable geographical variation in plumage, but not well known; probably includes some morphs; form "altaicus" variable, but generally larger, more heavily spotted below, and darker, more blackish brown above, sometimes with rufous barring.

Habitat. Steppe, sometimes wooded, and even open woodland; abrupt rocky areas, e.g. cliffs and canyons. Occurs from plains and foothills to mountains and high plateaux, up to 4700 m. Wider range of habitats outside breeding season, but also essentially in open areas; sometimes along coast, over marshes or near lakes; hunting area can be some distance from nest or roost.

Food and Feeding. Mainly small mammals, particularly rodents and lagomorphs. In many areas susliks (*Citellus*) predominate; also gerbils, jerboas, hamsters, voles, lemmings and other rodents; young marmots and pikas in mountainous areas. Birds generally less important, mainly medium-sized and ground-dwelling birds, especially sandgrouse, gamebirds (partridges, quails, pheasants), corvids, pigeons and larks; lizards (e.g. *Uromastix*) locally important; Coleoptera also reported. Swoops on birds in air, but most prey caught on ground; watches for prey from vantage points, where may perch for hours. Also performs low foraging flights, looking for prey on ground; occasionally hovers.

Breeding. Laying in Apr-May. Nests on cliff ledges and crags; also nests in tall trees, particularly in W of range, occupying abandoned nests of other raptors, corvids or other birds; locally has switched from trees to pylons; can reuse same nest or move between various nests from year to year. Normally 3-5 eggs (2-6); replacement laying occurs; incubation over 30 days, mainly by female; male brings most of food, as female does not hunt until second half of nestling period; chicks have yellowish white first down, greyish white second down, fledging 45-50 days; young remain dependent on adults for another 30-45 days. Sexual maturity at 2-3 years, unusually at 1 year.

Movements. Mainly migratory or partially migratory; sedentary or dispersive in S of breeding range. Only occurs in winter in N Pakistan, Arabia, Africa (Sudan, Ethiopia, and N Kenya), and parts of Middle East and China. Leaves most areas of former USSR in Sept-Oct, although some pairs stay over winter, even in N regions, e.g. Khakasia; returns Mar-Apr; absence from warmer areas is shorter.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Despite apparent rarity, world population might number 35,000-40,000 pairs. Numbers and population trends not well known, particularly over extensive Asian breeding range, where bulk of population occurs; migrant populations in Asia may be declining, whilst resident populations perhaps stable or increasing. In first half of 20th century was locally abundant in both European and Asian sectors of USSR; in some areas of SC Siberia, relatively high densities of 5-7 pairs/100 km². Formerly more abundant in SE Europe: following fairly steady decline, moderate recovery in 1980's, particularly in Hungary, as result of protection efforts. Estimates include (early 1990's): 120-150 pairs in Ukraine, where decreasing due to deforestation and decrease in suslik populations; c. 100 pairs in European Russia; c. 20 pairs in Moldavia; c. 20 pairs in Romania; c. 50 pairs in Bulgaria; 20-40 pairs in former Yugoslavia; 90-150 pairs in Hungary (only 20 pairs in 1960's); 15-20 pairs in Czechoslovakia; and 1-5 pairs in Austria. Highly sought after by falconers, particularly in Arabia; resultant excessive trade may affect populations, through capture of birds, particularly females, and theft of chicks.

Bibliography. Bagura *et al.* (1994a, 1994b), Baumgart (1991b), Brown *et al.* (1982), Cheng Tso-hin (1987), Cramp & Simmons (1980), Dementiev & Gladkov (1951), Etchecopar & Hùe (1978), Flint & Sorokin (1994), Flint *et al.* (1984), Génsbel (1986), Goodman *et al.* (1989), Hadjichristou & Demetropoulos (1983), Kemp & Crowe (1993), Knyshtaus (1993), Kustov (1980), Mackworth-Præd & Grant (1957-1973), Meyer de Schauensee (1984), Paz (1987), Polushkin (1988), Popov & Verzhutskii (1990), Richardson (1990), Riddle & Remple (1994), Roberts (1991), Rogacheva (1992), Simeonov *et al.* (1990), Thiollay (1989c).

58. Gyr Falcon

Falco rusticolus

French: Faucon gerfaut

German: Gerfalk

Spanish: Halcón Gerifalte

Other common names: Gyr, Jerfalcon

Taxonomy. *Falco rusticolus* Linnaeus, 1758, Sweden.

Forms superspecies with *F. cherrug*, and perhaps also *F. biarmicus* and *F. jugger* and possibly even *F. mexicanus*. Taxonomy very complicated; usually considered monotypic, but highly polymorphic. Sometimes considered polytypic, normally with four races, based mainly on colour frequencies: *rusticolus* (Europe); *obsolens* (Asia, parts of North America); *candicans* (high Arctic of North America, Greenland); and finally *islandus* (Iceland), the most isolated, uniform and distinctive of these forms, which would probably be most valid race. Morph "*altaicus*" of *F. cherrug* has been listed as race of present species; also considered to form link between these two species. Monotypic.

Distribution. Circumpolar, occupying Arctic regions of Eurasia, North America, Greenland and Iceland; some birds move farther S for winter.

Descriptive notes. 48-60 cm; male 961-1321 g, female 1262-2100 g; wingspan 120-135 cm. The largest *Falco*. Extreme polymorphism in coloration, with three main colours, white, grey and blackish brown. Streaked or barred on underparts; white birds with some dark markings on upperparts and underparts. Legs and feet yellow. Female larger, sometimes darker. Juvenile generally darker, browner and more heavily streaked below; legs and feet pale grey. The three main colour morphs vary and grade into one another, sometimes along clines, or at any rate with colour morph ratios differing regionally: birds

in high Arctic of Greenland usually white; in Labrador, preponderance is dark brown or even blackish; in Iceland, normally various shades of grey; clinal W to E across Russia and Siberia, with 90% grey drifting into 47% white; also slight variation in size, with larger birds in N of range.

Habitat. Three basic habitats for breeding are maritime, riverine and montane. Occurs widely over tundra and taiga, from sea-level to at least 1400 m. In winter, migrants moving S frequent farm and agricultural land and native steppe habitat.

Food and Feeding. Mainly birds and mammals. Frequently a major reliance on ptarmigan/grouse (*Lagopus*) and ground squirrels (*Spermophilus*) for breeding; in coastal areas, seabirds may be major food; lemmings (*Lemmus*, *Dicrostonyx*) can be mainstay in some areas depending on season. During winter food may be more restricted, where species resident, but more varied for those migrating S, where prey as large as Sage Grouse (*Centrocercus*) is killed. Most hunting by fast flight low over ground, often rising to make rapid stoop; sometimes forages by flying along high up, or perches to scan. Prey taken on ground or water more often than in air, but sometimes after hot pursuit.

Breeding. Mar-Jul, but territories may be held all winter so breeding essentially starts Jan-Feb. Solitary. Eggs laid in scrape or depression in cliff ledge, disused stick nest of another species on cliff, or occasionally stick nest in tree or on man-made structure, e.g. gold dredger or oil pipeline. Usually 3-4 eggs (2-7 in years of food extremes); incubation 34-36 days; chicks have white down; fledging 46-53 days. Nest success varies widely in response to cyclical food sources: 1.3-4.0 young per successful nest, but generally c. 2.5-3.1 over many years; occupation of c. 31-88% of total territories available; 38-73% of occupied territories produce young. Usually first breeds in second or third year; in Iceland, some breed by end of first year. Oldest wild birds c. 13 years old.

Movements. Many adults sedentary; juveniles generally more dispersive and move farthest S. Patterns complicated by cyclical food availability, which may cause irruptive movements, but some very clear movements, e.g. white morph birds from Greenland to Iceland. Some move from North America to Siberia (see page 237). May winter around edge of sea ice or near open water (polynyas). Most birds winter N of 52° N; in North America has reached S to 35° N, in Eurasia c. 46° N.

Status and Conservation. Not globally threatened. CITES I. Currently considered near-threatened. Widespread; rare in some regions, locally common in others but status confounded by cyclical nature of numbers. Densities vary regionally with rather wide ranging estimates of total population from c. 5000-7000 to 15,000-17,000 pairs. Some estimates are: Alaska (USA) 375-635 pairs; Yukon Territory (Canada) 750 pairs; Northwest Territories (Canada) 1300 pairs; Greenland c. 750 pairs; Iceland c. 350 pairs; Scandinavia c. 120-150 pairs; 50 pairs in European Russia, with only 10-15 pairs over area of 14,000 km² in extreme NE; no survey results for Siberia. Not affected by organochlorines during 1960's and 1970's, as were other *Falco*. Recent mortality at hands of trappers in Siberia (e.g. Yakutsk, Indigirka R) suggests that c. 1000-2000 killed annually throughout Arctic Russia. Highly prized in falconry, with unknown number taken annually; probably not enough to affect breeding population. Now bred in captivity for falconry and research in North America, Europe and Russia.

59. Prairie Falcon

Falco mexicanus

French: Faucon des prairies

German: Präriefalke

Spanish: Halcón Mejicano

Taxonomy. *Falco mexicanus* Schlegel, 1851, Monterey, Mexico = California.

Formerly placed in *Gennaia* or *Hierofalco*. May form superspecies with *F. jugger* and *F. biarmicus*, and perhaps also with *F. cherrug* and *F. rusticolus*; but probably closer to *F. peregrinus*. Monotypic. **Distribution.** SW Canada through W & WC USA to N Mexico; winters to EC USA and NC Mexico.

Descriptive notes. 37-47 cm; male 500-650 g, larger female 700-975 g; wingspan 95-105 cm. A typical rather large falcon; in flight, dark axillaries distinctive. Cere and legs yellow. Juvenile often darker brown, with underparts more buff-coloured; cere and legs pale bluish grey.

Habitat. Mainly arid hilly and mountainous grasslands and shrub-steppe, including vast desert valleys and farmlands, from sea-level up to 4000 m. Usually avoids urban areas and interior of forest.

Food and Feeding. Primarily mammals, particularly ground squirrels (e.g. *Citellus*, *Spermophilus*), and birds, particularly those of open habitats or flocking passerines, e.g. larks (*Eremophila*), longspurs (*Calcarius*), meadowlarks (*Sturnella*), starlings (*Sturnus*) and columbids; also reptiles, small lizards, and insects. Tends to forage by flying along at medium height; birds usually caught on or near ground after low angle stoop; sometimes after hot pursuit.

Breeding. Sometimes arrives at eyries in Feb, but normally Mar-Jul, depending on altitude and latitude. Solitary. Achieves high densities in Idaho (NW USA), where 200 pairs occur at 1 pair/0.65 km². Nests on cliffs, in pothole-like sites; also on rocky outcrops, or high riverbanks of earth and gravel; few, exceptional records on buildings (Canada), trees (USA, in Utah and Wyoming) and electric power pylons (USA, in Nevada). Eggs laid in depression or scrape or unused stick nest of raven (*Corvus*) or eagle. 3-5 eggs, rarely 6; incubation c. 31 days; chicks have white down, with dark feathers showing by 14 days old; fledging 36-41 days. Nesting success variable, with young produced in 64-93% of attempts, normally 71%; c. 2-75 young fledge per attempt; c. 31% of young die within average 44 days of having fledged. Sexual maturity usually at 2 years, but some females breed in 1st year. Oldest ringed bird 14 years.

Movements. Variable: disperses widely with general N to S movement from N breeding locations; movements in all directions from mid-latitude breeding locations; some sedentary tendency in S, but in general follows food supplies; some movements in response to aestivation, and hence inaccessibility, of ground squirrels; most birds breeding at altitudes above 2500 m move to lower ground in winter. Post-breeding vagrants wander outside breeding range more commonly in mid-continent plains region than elsewhere.

Status and Conservation. Not globally threatened. CITES II. Widespread and common within breeding range. Eggshell thinning as result of DDT caused only minor local reductions, although greater thinning at lower DDT levels than in *F. peregrinus*. Total breeding population estimated at 5000-6000 pairs, with greatest density in Idaho. Widely used in falconry, with no apparent effect on population.

60. Peregrine Falcon

Falco peregrinus

French: Faucon pèlerin

German: Wanderfalke

Spanish: Halcón Peregrino

Other common names: Barbary Falcon (*peregrinoides*); Kleinschmidt's Falcon ("*kreyenbergi*")

Taxonomy. *Falco peregrinus* Tunstall, 1771, Great Britain.

Formerly placed in separate genus, *Rhynchodon*. Race *peregrinoides* often considered separate species, usually incorporating race *babylonicus*, although latter has, in turn, been considered independent species; hybrids between *peregrinoides* and other forms of present species are infertile. Kleinschmidt's Falcon named as separate species, "*F. kreyenbergi*", but is actually colour morph of race *cassini*. Nineteen subspecies normally recognized.

Subspecies and Distribution.

F. p. tundrius C. M. White, 1968 - Arctic tundra of North America, from Alaska to Greenland.
F. p. anatum Bonaparte, 1838 - North America S of tundra to N Mexico, except NW Pacific Coast.
F. p. pealei Ridgway, 1873 - coastal W North America from Washington N to W Alaska, and W through Aleutian and Commander Is; possibly also coastal Kamchatka and Kuril Is.
F. p. cassini Sharpe, 1873 - W South America, from Ecuador (locally) S through Bolivia and N Argentina to S Chile, Tierra del Fuego and Falkland Is.
F. p. japonensis Gmelin, 1788 - NE Siberia S to Kamchatka and Japan (may not be race of coastal Kamchatka).

F. p. furutitii Momiyama, 1927 - Volcano Is and possibly Bonin Is.

F. p. calidus Latham, 1790 - tundra of Eurasia, from Lapland E to NE Siberia, roughly to region of R Yana and R Indigirka.

F. p. peregrinus Tunstall, 1771 - Eurasia S of tundra and N of Pyrenees, Balkans and Himalayas, from British Is E to Amurland and Ussurland in Russian Far East.

- F. p. brookei* Sharpe, 1873 - S France, Spain and coastal N Africa E through Mediterranean to Caucasus.
F. p. babylonicus P. L. Sclater, 1861 - Asia, from E Iran to Mongolia.
F. p. peregrinoides Temminck, 1829 - Canary Is E through inland N Africa to Iraq, and probably Iran.
F. p. madens Ripley & Watson, 1963 - Cape Verde Is.
F. p. minor Bonaparte, 1850 - Africa S of Sahara, and N into extreme S Morocco.
F. p. radama Hartlaub, 1861 - Madagascar and Comoro Is.
F. p. peregrinator Sundevall, 1837 - Pakistan, India and Sri Lanka E to SE China.
F. p. ernesti Sharpe, 1894 - Indonesia and Philippines E to New Guinea and Bismarck Archipelago.
F. p. nesiotis Mayr, 1941 - Vanuatu and New Caledonia (race uncertain) E to Fiji.
F. p. macropus Swainson, 1837 - Australia (except SW).
F. p. submelanogenys Mathews, 1912 - SW Australia.

Descriptive notes. 34-50 cm; c. 550-1500 g; wingspan 80-120 cm. Large, stocky falcon, with relatively short tail; prominent moustache usually evident in all ages. Rather variable, with upperparts various tones of blue, grey or black; underparts white to rufous crossed with variable bars. Noticeable size dimorphism, with female 15%-20% larger than male. Juvenile has upperparts with tones of black to pale brown; underparts streaked. Races separated on size and colour: smallest, palest (tannish) forms in deserts of Eurasia and African region; largest in Pacific NW North America and Aleutian Is; darkest (deep

red and black) in Old World tropics and extreme S South America.

Habitat. Extremely variable: breeds from hot tropics to cold, wet marine habitat; arid hot or cold deserts; from sea-level to c. 4000 m. Found almost anywhere during migration, even landing on ships in C Pacific Ocean. Unexpected gaps in breeding distribution, e.g. Iceland, Newfoundland, tropical Central and South America, and New Zealand.

Food and Feeding. Chiefly birds; occasionally mammals, including bats (both Megachiroptera and Microchiroptera), rats, rabbits and voles; also insects (Orthoptera, Odonata), reptiles (lizards) and exceptionally fish; two reports of carrion feeding. More than 300 bird species known to have been taken in N Hemisphere; locally or regionally specializes on certain groups, notably pigeons and doves (Columbiformes), parrots (Psittaciformes), auks (Alcidae) and petrels (Procellariiformes) or on particular species, e.g. European Starling (*Sturnus vulgaris*); overall, Columbiformes seem to be principal prey group. Avian prey range 10-2000 g; males tend to catch birds of 20-300 g, and females of 100-1000 g. During breeding season, males normally catch prey c. 20% of their own body weight. Birds taken mainly in flight: when searching for prey, often flies high or perches at prominent site; prey once located, typically pursued at great speed, frequently culminating in very rapid stoop; prey normally killed in mid-air, but sometimes on ground or water. Many other techniques recorded, including hawking for insects, hovering and quartering.

Breeding. Laying Feb-Mar in N temperate zone, Apr-May at N high latitudes; Aug-Oct in S Hemisphere; recorded Jun-Dec at equator. Pairs maintain breeding territories, with eyries usually more than 1-2 km apart, but sometimes only a few hundred metres apart in British Columbia (Canada). No nest built; eggs laid in scrape or depression on cliff, occasionally in disused stick nest of another species, in tree hollow (e.g. in Australia), or on ground (e.g. Baltic area); nests on buildings in urban areas, or on other man-made structures, e.g. bridges. Clutch size larger in N Hemisphere, averaging 3-40 in *tundrius* of Arctic, but 2-81 in *macropus* of Australia; incubation 29-32 days; in middle to low latitudes, replacement of lost clutch may occur within 2 weeks; chicks have white down, later replaced with second, greyer down; fledging 35-42 days; chicks may remain dependent on parents for 2 months. Adult male provides most of food during first half of nesting period. Success: 1-74 young per attempt in Arctic (*tundrius*); 1-63 young per attempt in S Hemisphere (*macropus*). First breeding normally at 2 years old or more; females typically start at younger age than males, and yearling breeders mainly females; at least one record of successful breeding of yearling pair (9-10 months old).

Movements. Highly migratory in N temperate and Arctic zones: N American races *anatum* and *tundrius* moving to C Argentina and Chile for austral summer; common around Manaus during boreal winter; Eurasian races *peregrinus*, *calidus*, and *japonensis* migrate to C Africa, S Asia and Indonesia; birds may spend 6-7 months in S non-breeding latitudes. In middle latitudes and S Hemisphere, mainly resident and sedentary. Resident at some N latitudes, e.g. Aleutian Is. Pairs may remain together throughout year. Dispersal from natal or breeding areas is greater in first year birds; females disperse farther than males, and, once adult, males have higher nest-site fidelity.

Status and Conservation. Not globally threatened. CITES I. Total breeding population worldwide conservatively placed at c. 12,000-18,000 pairs in 1980's, with main concentrations in Australia, islands of N Pacific and Bering Sea, Spain and British Is; populations have certainly increased since then. Currently c. 700 pairs in European Russia, with only 20-25 pairs over area of 14,000 km² in extreme NE; 20-30 pairs in Azerbaijan; in 1989 in Scotland, 373+ young raised to fledging at 375 known occupied nests. Historically, populations very stable, and wide fluctuations were unknown. Serious declines occurred from mid-1960's to mid-1970's (see page 246), as a result of eggshell breakage, mortality of embryos and some mortality of adults from chlorinated hydrocarbon contamination. Chemicals were banned in most countries, and numbers currently returning, or have already returned, to pre-chemical levels, even overshooting historical population numbers (see page 247). Race *madens* thought to number only 6-8 pairs; *furuittii* local and rare, thought to breed only on one island, and may be threatened. Race *nesiotis* very uncommon, with probably less than 100

pairs scattered over 51,610 km² of land, and much larger area of ocean. By 1972, races *anatum*, *tundrius* and *peregrinus* listed as endangered. Because of similarity of appearance, entire species still listed as endangered by CITES in 1990. Bred extensively in captivity worldwide; as many as 5000 captive-bred birds released to wild. Used extensively in falconry; impacts continuously and heatedly debated, on meager data. Extinct in Byelorussia since 1974.

61. Taita Falcon

Falco fasciinucha

French: Faucon taita

German: Taitafalke

Spanish: Halcón Taita

Other common names: Teita Falcon

Taxonomy. *Falco fasciinucha* Reichenow and Neumann, 1895, Taita Hills, Kenya.

Most similar to *F. severus*, with which might form superspecies. Monotypic.

Distribution. S Ethiopia through Kenya, Uganda, Tanzania, Malawi, E Zambia, SW Mozambique and Zimbabwe to NE South Africa.

Descriptive notes. 25-28 cm; male 212 g, female 306 g. Small, stocky, short-tailed falcon with pale grey rump, white throat and rufous patches on nape. Smaller than *F. peregrinus*, which has dark rump and no rufous neck patches (in most races), and is heavily marked below; also smaller than *F. biarmicus*, which has paler underparts and chestnut confined to the crown. Female less strongly coloured than male. Juvenile has upperparts edged with buff, flanks more heavily streaked, nape patches paler, and rump as dark as back.

Habitat. Favours high cliffs and gorges up to 3800 m for roosting and nest-sites, but hunts

widely over surrounding dry woodland and savanna.

Food and feeding. Mainly small birds of 80-120 g, especially swallows and swifts, but including Purple-crested Turaco (*Tauraco porphyreolophus*) of 270 g; also takes a few large insects. Takes all prey aerially, by a fast stoop with rapid, shallow wingbeats, from a perch or from high, soaring flight; pairs may hunt co-operatively. Spends long periods perched inactive on cliff face, where also caches some prey.

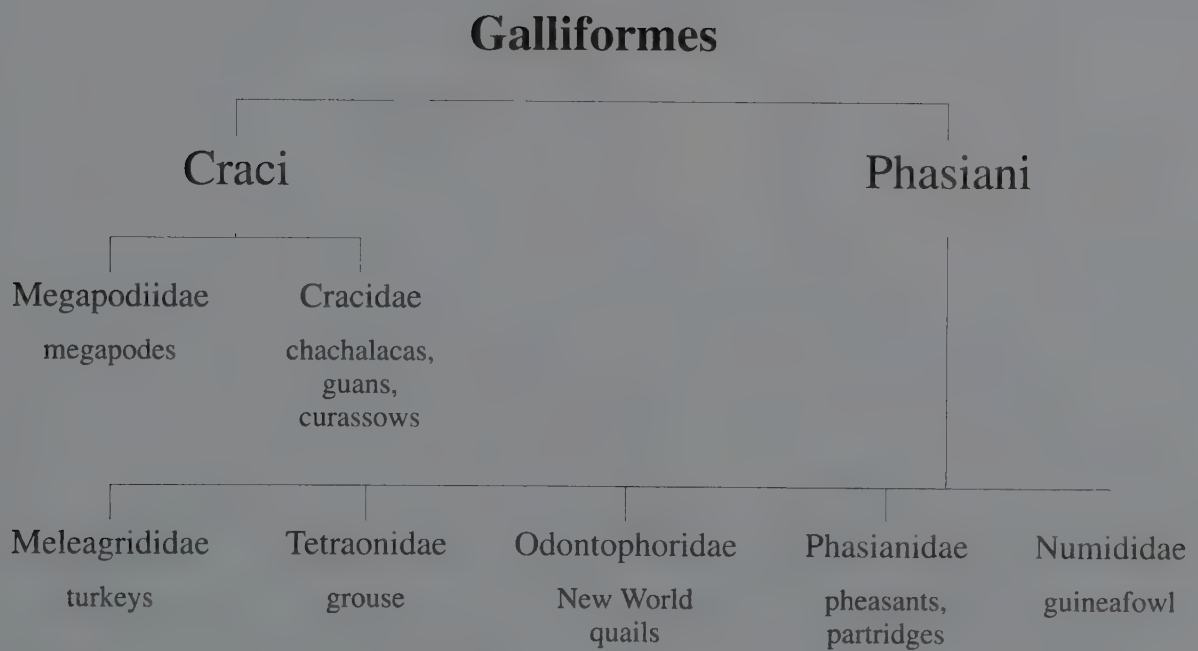

Breeding. Laying Apr-Jul in E Africa; Aug-Oct in S Africa. Favours a scrape or old stick nest at the back of a shaded hole, usually high on a cliff above a gorge, or on a mesa. Very defensive at nest; shares similar site requirements with *F. peregrinus*. 2-4 eggs; incubation 31-33 days; chicks have grey down, paler at first; fledging 42 days; female assists in feeding of chicks during fledging period of at least 3 weeks. Productivity of 0-88 chicks per pair per year, over 9 pair-years in Zimbabwe.

Movements. Pair usually resident within territory, but some sites occupied sporadically and records far from known breeding sites suggest some local movement.

Status and Conservation. Not globally threatened. CITES II. Currently considered near-threatened. Extremely localized and easily overlooked throughout most of its wide range, e.g. in Kenya, where not recently recorded from Taita (Teita) Hills, where originally collected. Only known to be relatively common on Mt Elgon in Uganda (4 pairs) and along the Batoka Gorges of the R Zambezi (8-10 pairs in 60 km) on the Zambia-Zimbabwe border, where may be threatened by proposed dam. Estimated 20-50 pairs in Zimbabwe, and recently found breeding further S in South Africa. Effects of pesticide use unknown but currently being monitored.

Bibliography. Order GALLIFORMES

Class AVES
Order GALLIFORMES
Suborder CRACI
Family MEGAPODIIDAE (MEGAPODES)

- Medium-sized to large terrestrial birds with large, powerful legs and feet and sharp claws.
- 28-70 cm.

- Australasian Region, with greatest diversity in Australo-Papuan Subregion; lone outpost in Oriental Region.
- Tropical forest, mostly in lowlands; one species occupies semi-arid woodland and scrub.
- 7 genera, 19 species, 35 taxa.
- 8 species threatened; none extinct since 1600.

Systematics

The Megapodiidae are the most distinctive members of the Galliformes, and they are often considered to be the most primitive. They form a well defined, rather homogeneous group of some nineteen species, which are closely united not only by morphology, but also by their unique breeding habits and their distribution.

The megapodes are found almost exclusively in the Australasian Region, mainly in the Australo-Papuan Subregion, and there is little reason to suppose that they were ever much more widespread, although their Pacific range has certainly been reduced (see Relationship with Man). A claim that fossil remains found in France belonged to a megapode led to a series of conjectures about possible implications, but after closer scrutiny it appears that the claim was unfounded.

There are two main theories about the origins of the megapodes, which are to a large extent dependent on opinions regarding the origins of the order. The cracids are thought to have originated in North and Central America, before colonizing South America (see page 310), their current focus of diversity, and this has been used as the basis for suggesting that megapodes may have reached their present range by moving down from North America through south-east Asia. However, the dubious authenticity of the supposed fossil megapode from France has removed a major stumbling block for those who argue instead that the order arose in Gondwanaland, the ancient austral super-continent that was in the process of breaking up about 100 million years ago, in the Cretaceous. If the theory of a Gondwanan origin is accepted, then the megapodes' occupation of Australia and subsequent colonization in the outlying islands are simple steps. In any case, it is generally agreed that the megapodes must have been isolated in Australasia since the Miocene, a period during which Australia was covered in tropical forest and so offered ideal conditions for the mound-building habit to develop.

Diversification within this family seems to have been centered in the area around New Guinea. Indications of this are the large number of species present, but more importantly the two endemic genera, *Aepyodius* and *Talegalla*, respectively containing two and three species. Australia too has two endemic genera, *Alectura* and *Leipoa*, but both of these are monotypic, while *Leipoa* is the least typical of all megapodes, a specialized form that may well have evolved from forest-dwelling ances-

tors. These factors together suggest that Australia is less likely to have been the main scene of megapode diversification.

Moving away from this focal area, the genera are rapidly reduced merely to the wide-ranging *Megapodius* and the very closely related, possibly congeneric *Eulipoo*, which occurs only to the west. Across into the Pacific, megapodes appear to follow the general trend of other families in the zone, whereby species richness decreases steadily as one moves eastwards. Nevertheless, over the centuries the activities of man have contributed to mask the original distribution of megapodes at both its eastern and western limits (see Relationship with Man).

The limited fossil evidence available so far for the family serves to indicate a more extensive Pacific range, with extinct species known from New Caledonia, Fiji and Tonga, as well as from south-east Australia. Interestingly, *Sylviornis neocaledoniae*, a huge, flightless Holocene species from New Caledonia, was originally thought to have been a ratite, but was then classed as an outsize megapode, possibly measuring about 165 cm from bill tip to tail tip. With much more material now available, it is not actually clear that it was a megapode, but it probably does represent some kind of primitive galliform. As other galliform families are virtually absent from the Australasian Region, this bird could have been one of the primitive forerunners of the Megapodiidae, although its relationship with the family remains to be proved. The earliest fossil material of megapodes discovered to date comes only from the Upper Pleistocene of Australia.

The extraordinary incubation strategies of the megapodes, in particular their use of the heat that is generated as plant matter decays (see Breeding), have led to much debate as to the origins of the family, and the postulation of direct links with the reptiles, which use a similar system for incubating their eggs. However, the apparently close relationship of megapodes with other Galliformes, together with the almost universally accepted premise that the Palaeognathae, comprising the ratites and the tinamous, constitute the most primitive extant element of the class Aves (see Volume 1, page 76), indicates that it is extremely unlikely that the megapodes' incubation strategy was inherited directly from reptiles, and rather that it is probably a case of parallel, or convergent, evolution. The alternative, that the megapodes branched off from the main line of avian evolution before all other birds, has almost the entire weight of centuries of ornithological investigation against it.

Brightly coloured bare facial skin is found in many megapodes, but it reaches its maximum expression in the Australian Brush-turkey, which has the entire head and neck bare, apart from a rather sparse covering of bristle-like feathers; it also sports an inflatable yellow pouch at the base of the neck. These features are particularly colourful in the male, especially during the breeding season, when they play an important part in display.

Bruce Coleman]

The Cracidae, the next most clearly defined galliform family, may constitute the sister group of the megapodes, an idea supported by studies of the musculature of the wing and DNA-DNA hybridization among others. In classifications, this is usually reflected by the order being divided into two suborders, with one for the megapodes and cracids and the other for all the remaining Galliformes, which are frequently lumped together into an enlarged version of the family Phasianidae (see page 434). A conflicting view proposes three suborders, with one each for megapodes and cracids, and the third for the remainder. To add to the confusion, studies of osteology, feather microstructure, eggshell structure, egg-white proteins, uropygial gland secretions and feather lice in turn suggest that the megapodes should be treated as the sister group of all other Galliformes, so for the time being the debate continues, as the evidence accumulates.

In recent years, partly as a result of an upsurge of interest in the megapodes, the internal structure of the family has undergone a series of changes. Nevertheless, the majority of the different forms remain very poorly known, so the classification of the family as a whole is still, to some extent, in a state of flux.

The family may be subdivided into three natural groups: the first, the brush-turkeys, comprises the genera *Alectura*, *Aepyodius* and *Talegalla*; the second is made up of the rather distinctive monotypic *Leipoa*; while the third, the scrubfowl, contains the widespread polytypic *Megapodius*, the apparently very closely related monotypic *Eulipoa*, and the also monotypic *Macrocephalon* of Sulawesi. All members of the first group have a naked oil-gland, are eutaxic and are mound-builders; *Leipoa* is similarly eutaxic and a mound-builder; members of the third group have a tufted oil-gland, are diastataxic, and use a variety of incubation systems. The usefulness of the oil-gland as a taxonomic feature may be limited in this family, as it can be difficult to draw the line between the states "slightly feathered" and "unfeathered"; for this reason it has not yet been established which of these character states is applicable to *Leipoa*.

One matter that is increasingly attributed taxonomic significance is the variety of different incubation strategies followed, and this has led to a series of conjectures about the relative

ages of various genera (see Breeding). Another feature with taxonomic value is the different feather lice species present, as these tend to be highly host-specific, parasitizing only one or a few closely related species. The evidence from feather lice, although incomplete, also supports the clear separation of *Megapodius* from the three brush-turkey genera. More extensive data may provide further clues about all generic relationships. However, conflicting opinions regarding the taxonomy of the lice themselves make the situation much more complicated.

Most of the genus and species limits are fairly clearly defined and agreed upon, but the genus *Megapodius* has been extensively rearranged on several occasions. A version put forward by E. Mayr in the late 1930's, whereby the genus was reduced to merely three species, remained prevalent for many years. Mayr recognized the two rather distinctive Pacific species, the Micronesian Scrubfowl (*Megapodius laperouse*) and the Polynesian Scrubfowl (*Megapodius pritchardii*), but lumped all the other forms within the Dusky Scrubfowl (*Megapodius freycinet*). In the meanwhile, the Moluccan Scrubfowl (*Eulipoa wallacei*) was retained in its own separate genus, mainly on the grounds of its more distinctively marked plumage.

A reappraisal of the genus *Megapodius* in the mid-1980's by C. M. N. White and M. D. Bruce led to its redistribution into eleven species, with *Eulipoa* incorporated. However, the latest thinking suggests that it may be best to recognize a further three species of *Megapodius*, with the promotion of the forms *tenimberensis* and *forstenii*, hitherto included in the Orange-footed Scrubfowl (*Megapodius reinwardt*), and the form *geelvinkianus*, currently classified as a race of the Dusky Scrubfowl. Megapode specialists have also concluded that the Moluccan Scrubfowl is indeed sufficiently distinct to merit a separate genus. Interestingly, at the specific level evidence from feather lice emphasizes that, in the absence of material for the Polynesian Scrubfowl, the Micronesian Scrubfowl is clearly the most distinctive form within the genus *Megapodius*.

However, the last word has not been said on the systematics of this confusing genus. As most of the different forms are separated from their congeners by stretches of open sea, and as these are birds of relatively limited mobility (see Move-

ments), in many cases it is largely a matter of personal preference whether or not any particular form should be classed as a different species. For instance, White and Bruce state that the splitting off of the Philippine Scrubfowl (*Megapodius cumingi*) as a separate species from the Nicobar Scrubfowl (*Megapodius nicobariensis*) is essentially a matter of geographical convenience, and that, were their ranges contiguous, there would be only very weak grounds for their division into two species.

Morphological Aspects

In general, the Megapodiidae are rather similar in morphology to most other Galliformes. This standardized design was apparently perfected for a terrestrial way of life at an early stage and has undergone only relatively limited modifications since.

Megapodes are medium-sized to large terrestrial birds. The largest members of the family are those of the genera *Alectura* and *Talegalla*, and the Australian Brush-turkey (*Alectura lathami*) can measure up to 70 cm long and weigh about 2450 g. Amongst the smallest species are the Moluccan Scrubfowl, which measures only about 30 cm, and the diminutive Micronesian Scrubfowl, which can be only 28 cm in length or less. Adults of these smaller scrubfowl species almost certainly weigh under 500 g.

Megapodes have the plump body that is so typical of the Galliformes and has led to many members of the order becoming the standard gamebirds of hunters in various different regions. This shape seems to be closely allied to a fairly terrestrial way of life, as heavily built birds are not well designed for flying. It may also suggest a diet based primarily on plant matter, as this is more difficult to assimilate than animal food, so herbivores usually have to eat greater quantities than carnivores, and, as a direct result, have more voluminous bodies.

The head is relatively small, and the bill fairly short, stout and unspecialized, as in most other Galliformes. It is thought that either on the tongue or in some other part of the mouth there are some highly sensitive areas. Both when preparing the mound for egg-laying and during the lengthy incubation period, a bird will dig a small hole in the mound, into which it sticks

its head. It is suggested that sensitive parts in the mouth may well enable the bird to gauge the temperature of its mound with a remarkable degree of accuracy. An indication of this implied ability is the fact that mound temperatures remain surprisingly constant for months on end (see Breeding). In most megapodes, the nostrils are large, oval and longitudinally elongated. However, the apparently closely related genera *Alectura* and *Aepyodius* have round nostrils, an unusual feature in the Galliformes.

Many species have bare facial skin, although it varies greatly in extent between the species. The Polynesian Scrubfowl, for example, has reddish facial skin which just shows through between the feathers in places. In contrast, the Australian Brush-turkey has the whole of the head and most of the neck bare apart from a sparse covering of bristles, and these bare areas take on particularly bright shades of scarlet and yellow during the height of courtship, especially in the male when he is advertising his ownership of the mound and attempting to attract females. Part of the bare skin in this species covers a bulky throat pouch, again considerably more prominent in the male, and this is spectacularly inflated during booming (see Voice).

In Bruijn's Brush-turkey (*Aepyodius bruijnii*) the bare skin of the face and neck is embellished with long, pendant wattles, and the Wattled Brush-turkey (*Aepyodius arfakianus*) is similarly, though perhaps less spectacularly, decorated, the bluish white facial skin offsetting its otherwise dark appearance. Both species also sport a reddish comb, which is particularly prominent in the male during the breeding season. The three species of the genus *Talegalla* are almost identical in plumage, but differ in the extent and colouring of their bare parts: the face varies from black to reddish brown to yellowish green, and the legs and feet from reddish to yellowish.

Perhaps the most unusual adornment of the head is that found in both sexes of the Maleo (*Macrocephalon maleo*). It consists of a black bony knob projected backwards in the form of a skullcap, and reaching forwards down the forehead towards the juncture with the bill. This knob is mainly hollow, with a pneumatized spongy filling, producing a tough, but rather lightweight crown. The arrangement is strikingly offset by the reddish pink and yellow of the bill and eye-ring. The function

Although megapodes are almost exclusively terrestrial, several species react to potential dangers by flying up into nearby trees, and, in addition, some are known to have regular communal roosts in trees. The scrubfowl (*Megapodius*) seem to be the ablest fliers in the family, which ties in with their smaller body size. Note the powerful legs of this Orange-footed Scrubfowl, and the long, sharp claws, well designed for grasping quantities of nesting material and hurling them backwards onto a mound.

[*Megapodius reinwardt*.

Like other megapodes, the Malleefowl lives almost all of its life at ground level, but it is unique in many ways. Whereas other megapodes most typically occur in tropical rain forest, this species is found much further south in semi-arid woodland and scrub, most notably in areas of mallee, a dwarf form of Eucalyptus. In connection with this different habitat, the Malleefowl presents a beautifully marbled plumage, in marked contrast with the rather drab colours seen in other members of the family.

Bruce Coleman]

of the Maleo's peculiar knob is unknown, but it has been suggested that, as in some rather similarly equipped woodpeckers, it might act as a kind of shock absorber, when the bird is pecking forcefully at hard-shelled nuts.

Many species show some form of a feathered crest, and this may be highly conspicuous and pointed, as in the Orange-footed Scrubfowl. In contrast, it is scarcely visible in its congener the Philippine Scrubfowl, or in the Malleefowl (*Leipoa ocellata*).

The wings are large and rounded. Flying abilities vary within the family, but without ever reaching great levels of proficiency, as is the norm in the other members of the order. Generally, megapodes are better equipped for a fast take-off, in order to escape predators, than for flying long distances. Typically, when disturbed, a bird flies a fairly short distance up into the trees. However, inter-island movements within archipelagos are apparently carried out with some regularity, although perhaps only by scrubfowl, the smallest megapodes (see Movements). The larger members of the family, such as the Australian Brush-turkey, find it difficult enough to get off the ground, and rarely manage more than to flutter laboriously up into a tree, and then perhaps move on from one tree to another.

The form of the tail varies considerably between the different genera. In *Megapodius* it is particularly short, and is presumably of limited use. At the other extreme, the large brush-turkeys of the genera *Alectura*, *Aepyodius* and *Talegalla* have longish, rounded, rather bulky tails, which at any rate in some species can be opened and raised or tilted vertically during displays, making the bird appear noticeably larger; in contrast, the Wattled Brush-turkey's display involves concealing the tail under an outspread wing. The tail consists of twelve rectrices.

Perhaps the outstanding physical features of the family are the very strong legs and feet that all of the species possess. This is recalled in the very name "Megapode", which comes from the Greek for "big foot". The strength of the legs, and indeed of the birds in general, is amply demonstrated by their ability to shift large, heavy objects, such as dead branches, and the Orange-footed Scrubfowl, a species weighing about 550-1200 g, has been recorded digging up a stone that weighed 6920 g, and shifting it over a distance of 70 cm.

The evolutionary function behind the development of the legs and feet was presumably the nesting habits of the family. There are two different types of activity connected respectively with mound-building and the digging of burrows. The first system involves the bird grasping handfuls of material and hurling them backwards onto the mound or off it, as the moment requires. The second is rather a question of digging burrows in sand or soil, merely scraping the sand backwards and out, and subsequently scraping some of it in again. The Maleo has a small amount of basal webbing to the toes and rather short claws, which suggest that its feet are well developed for digging in the sand, as it habitually does for the purpose of laying its eggs. In contrast, all scrubfowl have long, sharp claws, which are useful for picking up material to throw onto a mound, but are less appropriate for digging in sand; this is true even of the Melanesian Scrubfowl (*Megapodius eremita*) and the Moluccan Scrubfowl, which are both habitual burrow-nesters, rather than mound-builders. With the support of this evidence it has been postulated that mound-building was the earlier form of incubation to develop (see Breeding).

The hallux, or hind toe, is on the same level as the front toes, and over the years this characteristic, which is shared with the Cracidae, has been one of the strong reasons for separating these two groups off from the other families of the order Galliformes, in which the hallux is raised above the level of the other toes.

As already stated, megapodes are clearly adapted to a largely terrestrial way of life, and all species spend most of their time wandering about on the ground. It is said that the Nicobar Scrubfowl, for instance, is a strong runner, and that it prefers to run away rather than to fly to safety, although when necessary it is capable of strong flight. The Black-billed Brush-turkey (*Talegalla fuscirostris*) too normally escapes from danger by dashing away in zig-zags through the undergrowth.

In general, the plumage found in this family is a very drab combination of brown, black and grey. This is in keeping with the birds' occupation of areas of dense undergrowth and particularly shady parts of the forest floor, where bright, conspicuous colouring could be hazardous, especially in terms of making it easier for potential predators to determine the whereabouts of an incubation mound. The only major exception

proves the rule: the Malleefowl has much more handsome plumage, with an attractive scaled pattern on the upperparts, and its colour scheme ties in very suitably with the fact that, unlike any other megapodes, it is found primarily in semi-arid woodland and scrub (see Habitat).

The sexes are generally very similar or even identical, although males tend to average slightly larger, are often more brightly coloured, and may have more prominent wattles. In this aspect megapodes would appear to obey the rule in Galliformes, whereby the species with the least dimorphism in size and colour are normally monogamous (see page 440); the slightly more marked dimorphism in the Australian Brush-turkey is thus in accordance with its polygamous tendencies (see Breeding). Again as a consequence of the megapode breeding strategy, the highly precocial juveniles, on emerging from the mound or the egg-burrow, are already clothed in a plumage similar to that of their parents, and they are soon, in effect, like miniature adults.

At present, little is known about moult in this family, and this is one of the many areas in which studies are at present being directed. So far most of the investigation carried out has been on skins in museum collections. Primary moult is serially descendant, and, as in other Galliformes and also in tinamous, touracos and the Hoatzin (*Opisthocomus hoazin*), the two outermost primaries, which first appear rather late in juveniles, are not replaced during the post-juvenile moult, and in fact remain in position until all the other primaries have been moulted for the second time. To date, the sequence of moult in the secondaries and the tail feathers has not been established. Further work in the whole of this field is likely to have useful implications for the external and possibly also internal taxonomy of the megapodes. The Australian Brush-turkey moults during March and April, between the end of one breeding season and the start of the next.

Males of both the Australian Brush-turkey and the Malleefowl have a form of penis, whereas the limited evidence available suggests that this is not the case in *Megapodius* scrubfowl.

Habitat

The typical habitat of the Megapodiidae is the floor of tropical rain forest. Almost all species use this as their foraging habitat, and for most it also serves as breeding habitat, but some species have learnt to take advantage of solar or volcanic heat and go to sandy beaches to lay their eggs (see Breeding).

In fact, a variety of forest types and wooded areas can provide suitable habitat. For instance, on the small island of Komodo, in the Lesser Sundas, the Orange-footed Scrubfowl lives and breeds in fairly dry open woodland and thickets, sometimes building its mounds only about 100 metres from villages; elsewhere, the same species can even occur in areas as damp as mangrove swamps.

It is generally thought that optimum habitat for most megapodes, at any rate mound-building species, implies an area with suitable plant material for the building and maintenance of the mound, and perhaps below a closed canopy, to avoid the mound overheating or drying out. Material is always added to the mound from the immediate vicinity, and never brought in from further afield, so there must be a plentiful supply of fresh material throughout the breeding season. An adequate food supply is also a major necessity, particularly as the male or the pair often stay very close to the mound for most of the year, and in some scrubfowl the pair may maintain a well defined feeding territory (see General Habits). The female, in particular, requires considerable resources in order to be able to carry out successful egg production throughout the appropriate period.

The precise requirements of burrow-nesters are much less clear, partly because these species are less visible most of the time, so their ecology is probably more difficult to study. For breeding, they require a suitable naturally warm site, which can range from a beach of black sand to areas influenced by geothermal heat sources, perhaps in the vicinity of hot springs,

mudpots, steaming fissures or even volcanic heat vents. One of the fundamental requisites of such sites is that they be free from excessive disturbance and exploitation, and the steady encroachment of growing human populations is rapidly eliminating many, if not most, of such sites. As these species do not have to tend and regulate a mound, they are theoretically able to forage over much larger areas, and so would not require the same sort of concentrated area of optimum feeding habitat as the mound-builders. On the other hand, the extent of suitable breeding habitat available to these species is a good deal more limited, so birds often congregate in large numbers to lay at the best sites, with the result that there are greater densities in the surrounding forest and more intense pressure from foraging competition than in the mound-building species. In this sense, it may be relevant that the Polynesian Scrubfowl, a burrow-nester, is one of those species suspected of holding feeding territories.

The Malleefowl differs from all other megapodes in that it inhabits semi-arid areas of mallee shrubland and woodland, which are dominated in particular by dwarf *Eucalyptus*, as well as other plants including *Acacia*. As this species lives and breeds further south than other megapodes, in cooler, drier, more open areas, the temperature and moisture regimes of its mounds are rather different too, as are the associated maintenance activities (see Breeding). The male in particular is tied extremely closely to his mound for up to eleven months of the year, so a rich and reliable food supply is essential to the success of the lengthy breeding attempt. Areas of optimum habitat for the Malleefowl have been seriously damaged and fragmented, and they are now few and far between; this constitutes the major threat facing this species at present.

In some areas, particularly in New Guinea, where several species are sympatric, there is often a degree of altitudinal segregation. This seems to be the case of the three species of the genus *Talegalla*. The Black-billed Brush-turkey occupies the lowlands of southern New Guinea. In the west it overlaps with the Red-billed Brush-turkey (*Talegalla cuvieri*) over a front of at least some 240 km, while in the east there is a similar zone of sympatry with the Brown-collared Brush-turkey (*Talegalla jobiensis*) covering a distance of 80-400 km. In both of these zones it appears that the Black-billed Brush-turkey is the lowland species, while its two congeners are forced uphill by competition. In contrast, where both of these species occur unaccompanied by the Black-billed Brush-turkey, they occupy areas of suitable habitat down to sea-level.

Nevertheless, in most parts of New Guinea, three different species of megapode can frequently be found in the same forests, with the occurrence of the Wattled Brush-turkey and a representative of each of the genera *Talegalla* and *Megapodius*. Indeed, an active nest mound of a scrubfowl species, probably the Orange-footed, was found within 200 m of an active mound of the Black-billed Brush-turkey. In the Southern Highlands of New Guinea, eggs belonging to each of these three genera were collected in the same area, including some eggs of both *Talegalla* and *Megapodius* from the same mound, probably indicating parasitic laying by the smaller scrubfowl (see Breeding). To date, so little is known about the ecology and the exact distribution of the species involved that it is impossible to assess the extent of competition that occurs between them, or possible segregating mechanisms.

The family is confined to the tropics, except in Australia, where the Australian Brush-turkey occurs south into temperate zone, and the Malleefowl occurs exclusively in this zone. Due to their unique incubation systems relying on asomatic heat sources, it seems highly unlikely that the mound-building members of the family could occur much further south, and this system is thought to have been the original method in megapodes, from which the uses of solar and volcanic heat are derived (see Breeding). Also, in the same way that latitude is a limiting factor, there are presumably altitudinal limits, above which the heat necessary for incubation can not be derived from decomposition; this fits in with a tendency of most species to occur, or at any rate breed, primarily in lowlands, although the Wattled Brush-turkey inhabits montane forest up to 2800 metres.

The Wattled Brush-turkey is one of many megapode species about which very little is known. This is partly due to the fact that its habitat is often rather remote, in the montane forest of New Guinea. Much of what is known about the species comes from a study of captive birds, but this is one of the few individuals to have been observed in some detail in the wild. Here, on his mound, this male is performing a curious display, in which he tucks his tail round under a wing, with the result that he appears to have lost it!

The reasons why the family has not spread any further north or west are surely quite different. Megapodes occur north to the Philippines and the Marianas, and west through most of the Lesser Sundas to the Kangean Archipelago, off north-east Java. They are not found in Java or Sumatra, and in Borneo occur only at the extreme northern tip; indeed, there is no evidence to suggest that they ever had more than this tiny foothold in the Greater Sundas. However, there is an isolated population in the Nicobar Islands (see Relationship with Man).

There are two main theories as to the causes of this pattern of distribution. The first suggests that the megapodes have been kept from colonizing south-east Asia and most of the Greater Sundas due to competition with their ecologically similar relatives the Phasianidae. That family occurs very sparingly east and south of the Greater Sundas, and of the few species that have reached New Guinea and Australia there are no forest dwellers. It is proposed that the Phasianidae, with their very limited ability to cross over water, have not been able to spread beyond the edge of the Sunda Shelf, which marks the limit of the land-bridge that formerly linked the Greater Sundas to south-east Asia.

An alternative view put forward remarks on the well delimited, and almost complete, allopatry of megapodes and potential mammalian predators. Such predators occur throughout the Greater Sundas, but are absent from the Nicobars, the Lesser Sundas, except Bali (where megapodes do not occur), the Moluccas and New Guinea. What is even more notable is that in the areas of overlap, at the extreme north of Borneo, in parts of the Philippines and in Sulawesi, all megapodes are burrow-nesters, rather than mound-builders. It is convincingly suggested that burrow-nesters are probably less susceptible to predation than are mound-builders, due to the much less frequent, and often shorter, visits to the nesting site, and also due to their communal nesting (see Breeding), which through sheer numbers increases the chances of detecting any approaching predator. Remarkable support for the proposal is to be found in the tiny Kangean Archipelago, where the Orange-footed Scrubfowl builds mounds on several of the smaller islands, but is absent from the main island, precisely where leopards and civets occur.

General Habits

Little is known about the habits of most megapode species when they are away from their breeding sites. They tend to be inconspicuous and rather shy, so they are usually difficult to observe.

Scrubfowl go about in pairs most of the time, and it has been suggested that lone individuals may more often than not be immature birds. In the case of the Orange-footed Scrubfowl, pairs have been found to hold territories, which may be defended against intruders. These territories can, but need not, contain an incubation mound. However, they do not appear to be related to breeding rights, as the female of one pair can lay in a mound that is in the territory of another pair. Thus, if there is enough suitable feeding habitat, the same mound can be used by two separate established pairs.

Research on the Polynesian Scrubfowl suggests that it may use a similar territorial system, although as yet hard evidence is lacking. This species lays its eggs in volcanically heated sites, for instance on exposed slopes of loose ash. Birds seem to spend the vast majority of their time foraging in forest or thickets and only visit these incubation sites for the purpose of laying, with the result that territories again appear to be independent of laying sites. In this species, as perhaps in others, food is thought to be a limiting factor, and it would thus seem quite plausible that each pair defends its own feeding territory. Apparently a pair advertises its ownership of a territory by means of a whistled duet, to which neighbours promptly reply. Neighbouring pairs that intrude are driven from the territory by the male: generally there is a short chase, after which the pairs call at each other repeatedly for five to ten minutes, until peace is once again restored. The size of these presumed territories was calculated in two areas to be in the region of 1-1.5 ha. An interesting possible corroboration is the fact that the female on her way to or from laying sites sometimes emits a soft bubbling trill, which may be a form of appeasement call to the owners of the territories that she is passing through.

Malleefowl tend to be solitary for about nine months of the year, when involved in breeding (see Breeding), and, although the pair-bond is strong, male and female tend to forage and roost apart, coming together only at the mound for nest main-

The Maleo, endemic to Sulawesi, is a burrow-nester that typically uses large communal laying grounds, often on beaches. Where a site suffers a certain amount of disturbance, the birds tend to arrive and lay their eggs only around dusk or dawn or at night. Large numbers of Maleos may gather in the vicinity of the laying grounds in the late afternoon, where they will wait in the trees, calling repeatedly, until they feel confident enough to emerge into the open. It is only in and around the laying grounds that the birds are at all conspicuous.

[*Macrocephalon maleo*, Sulawesi.

Ardea]

tenance, copulation and egg-laying. However, once breeding is over, and during the short respite in late autumn, before the next breeding attempt is undertaken, several pairs may be encountered foraging together.

The Australian Brush-turkey is now one of the best known species, largely as a result of the extensive research carried out by D. N. Jones in recent years in south-east Queensland. This species tends to be solitary in most of its activities, for instance when foraging, but at artificially provided feeding sites, especially rubbish dumps, loose flocks of up to 22 birds sometimes congregate, and some shows of aggression may occur, although these groups are normally dissolved within a few minutes.

Males of this species are strongly territorial, defending their mounds by means of a progression of increasingly aggressive displays. These may start with a short charge at the intruder with the neck raised, and sometimes with the wings spread open. If the contest continues, the aggressor is likely to start booming (see Voice), and the fight often continues with a chase up into the trees. Another high intensity interaction is the Cock-fight, which recalls the typical battles of domestic or trained fighting cocks, the birds leaping at each other and striking out with their powerful feet. Such disputes are of considerable importance, as a male may see his mound, built with many hours of hard labour, usurped by another during a brief interaction.

Australian Brush-turkeys form communal roosts, with as many as 15-30 birds gathering in tall trees at the principal roosting site in the area. Other, smaller roosts may also be formed on a regular basis, but most of the mound-owning males in the area collect at the main roost. There are also regular sites used by several birds for resting during the day, but mound-owning males invariably stay close to their mounds for such day-time resting.

Several other species are also known to form communal roosts, at least during part of the year. For example, a roost of Brown-collared Brush-turkeys was located about eight metres up in a large forest tree. The copious droppings on the ground below suggested that this was a regular roosting site.

However, despite such communal roosting, it seems that megapodes generally seem to lead a fairly solitary life. Very little is known about the New Guinean genera *Aepyodius* and *Talegalla*, but the Wattled and Black-billed Brush-turkeys are usually found alone or in pairs. Equally unknown in many respects are the Wallacean genera *Eulipoa* and *Macrocephalon*, but, being communal burrow-nesters, both are amongst those species that do show some gregarious tendencies, as they can gather in very large numbers at particularly favoured laying grounds.

Some species, for instance the Nicobar and Orange-footed Scrubfowl, are reported to be partially nocturnal in their activity, and this is certainly the case again of some burrow-nesters, such as the Moluccan Scrubfowl, which come down out of the forest at night to lay their eggs, when they are less liable to be detected by potential predators, both of their eggs and of themselves.

In situations of alarm, birds very often walk or run off to safety, but they sometimes fly up fairly high into trees to take shelter; the frequency of these different responses varies with the species and the intensity of the threat. For example, the Vanuatu Scrubfowl (*Megapodius layardi*) and the Sula Scrubfowl (*Megapodius bernsteinii*) are both said to be loath to fly; if pressed, they will take flight, but after covering a short distance they quickly drop back into cover. When the Orange-footed Scrubfowl suspects danger, it bobs its head and outstretched neck up and down, sometimes freezing momentarily with its head held straight out in front of its body, as it attempts to locate the source of danger. The Black-billed Brush-turkey normally walks about with its tail held high, but when alarmed or suspicious, it often lowers the tail.

Amongst the most typical predators of megapodes are monitor lizards (*Varanus*), which habitually raid the incubation mounds to pilfer eggs. In an area of dry sclerophyll woodland in southern Queensland, individual feeding Australian Brush-turkeys have on several occasions been seen to repel lace monitors (*Varanus varius*) by turning their backs on them and showering them with a barrage of sticks and stones

and general debris, one of the few recorded cases of the use of weapons by animals; one bird was even seen to peck at the tail of a retreating monitor. However, on the small Indonesian island of Komodo, there is little Orange-footed Scrubfowl can do against Komodo dragons (*Varanus komodoensis*), which on occasions grow as large as three metres long. Nevertheless, on one occasion when a dragon was seen digging its way into a scrubfowl mound, a scrubfowl was just as quickly hurling the material back onto the mound; eventually the lizard gave up and moved off.

Dusting has been recorded in the Australian Brush-turkey, in one of the drier parts of its range. Birds go to regularly used sites, where pits have been formed, and squat in these while beating their wings to throw sand and dust over the plumage, in order to help clean it. In the same area birds, almost invariably females, have been recorded sunbathing, which normally involves rolling over onto one side, raising the respective wing and sometimes fanning the tail. Once again, the main purpose of such behaviour is likely to be feather maintenance.

Voice

Like many other largely terrestrial birds, megapodes are generally rather difficult to see, presumably an adaptation to the fact that on the ground birds are more open to attack from a wider array of potential predators. To overcome the communication problems arising from such secretive behaviour, they are fairly vocal.

Several species of scrubfowl tend to call noisily and continually when foraging. This is presumably a sort of contact call, which will act to maintain the pair in contact, although it may also have a series of territorial uses and implications, for example in the Polynesian Scrubfowl (see General Habits).

The Orange-footed Scrubfowl is reported to be rather less noisy most of the time, although when approaching the borderline with the territory of another pair, birds tend to call rather incessantly. Territorial advertising calls, which can be heard up

to six kilometres away in suitable conditions, involve the male and female occupying a favoured perch in a tree usually overlooking a creek. From this perch they perform a duet. This is emitted mainly at night, and mainly during the breeding season, but can, in fact, be heard at any time of day or in any season. During breeding, the duet is normally initiated by the female, but at other times of year it is the male that tends to start, and in the early part of the year he usually calls alone. To date, the Nicobar Scrubfowl is the only scrubfowl species for which there is evidence to suggest that it does not have a duet.

Black-billed Brush-turkeys mainly seem to call when approaching their mounds and mostly in the middle of the day, but they may call at any time of day or even at night. Partners can call simultaneously, but not apparently in a formalized duet.

Voice plays an important part in supplementing territorial behaviour and defence. For instance the Australian Brush-turkey is generally rather silent, but it uses a kind of deep resonant booming for warding off and driving off other males that may attempt to usurp their mounds and copulate with females that are already bespoken (see General Habits). A bird booms with its neck tilted downwards and its throat and pouch inflated; booming can only be performed properly by a male with a sufficiently developed throat sac, and as it is poorly developed in immatures this puts them at an even greater disadvantage in confrontations. The polygamous mating system of this species may be responsible for the fact that it performs no duet. The Malleefowl too proclaims its mound ownership by means of booming, although it lacks the bare inflatable throat pouch.

The burrow-nesting Maleo utters quite different vocalizations, which serve its own particular needs. For instance, when birds gather near laying grounds, they make a series of disyllabic rolls, which are thought to act as a form of contact call. Once the birds move out onto the beach and start digging their burrows, the frequent disputes regarding burrow rights are continuously accompanied by calls, including a duck-like quacking.

The main foraging method of the megapodes involves raking around in the leaf litter, typically for invertebrates or fallen fruits. Surprisingly little is known about megapode feeding habits, and this is even true of the Australian Brush-turkey, a species that has been the object of intensive research in recent years. Note the distended pouch and the outsize legs and feet.

Food and Feeding

Surprisingly little is known about the diet of even the best known megapodes, while virtually nothing at all has ever been recorded for a good number of the species. However, it seems likely that in general terms both food and feeding habits will be fairly similar for most species.

The few species studied so far have been found to be omnivorous. The Malleefowl, the best known species in terms of feeding habits, but the least typical megapode in most respects, seems to be extensively granivorous. In this species the foraging strategy may be designed essentially for taking seeds, and the capture of small animals may be largely incidental. Observations of birds feeding showed that plant matter was taken in 87% of the cases recorded, while insects were recorded in only 13%. Indeed, even during periods when invertebrates form the bulk of the diet, the Malleefowl does not seem to seek out such prey actively, but rather takes more of them because they are more abundant at these times.

In contrast to these tendencies observed in the Malleefowl, both the Polynesian and the Sula Scrubfowl are considered to feed mostly on animal food. Both seem to be largely insectivorous, but the former has also been found to take considerable numbers of snails, as well as centipedes and worms. During extensive observations, this species was not conclusively recorded taking plant food: it was seen pecking at fruit, but might have been extracting insects.

A wide variety of different kinds of plant and animal have been recorded for the various members of the family. The commonest plant parts in the diet are seeds, buds, flowers, leaves and fruits, and many species feed on fruits that have fallen to the forest floor. Animal food recorded is very diverse, ranging from a whole host of insects to spiders, centipedes, worms, snails, perhaps small lizards and even dead rats. The Malleefowl even feeds on fungi.

The feeding habits of the Malleefowl first received serious attention during a pioneer study of the species carried out by H. J. Frith in the 1950's, in western New South Wales. He showed that this species has different food preferences at the different times of year: for instance, insects are taken mainly in spring; herbs in autumn, winter and spring; buds in winter and spring; flowers in spring and early summer; and seeds in summer and autumn; amongst plant food, the buds and fruits of *Beyeria opaca* are particularly important in spring and summer. The main food of the species has been summarized as seeds of legumes in summer, but herbs in autumn and winter. Several further studies have been carried out more recently, and these show a certain amount of regional variation, probably due to local availability, with for instance the greater importance of insects, especially lerps (Homoptera), in Victoria.

In some species, perhaps all, young chicks probably start off by feeding mostly on invertebrates, which they can take even on the day of hatching. Later, the young of several species may progress gradually onto a more herbivorous diet. Animal food is more easily assimilable and contains more nutrition, and this may well be important for the chicks. As they hatch considerably larger than the chicks of other birds of comparable size, and as they receive no help from their parents either in terms of food provision or at least the learning of foraging techniques, they may well have great difficulty finding sufficient food, and starvation has been found to be a major cause of chick mortality in the Malleefowl (see Breeding). Perhaps the chicks are poorly prepared for finding or recognizing suitable plant food, and they learn to take moving food items more quickly.

All megapode species typically forage by walking along, pecking at plants or scratching in amongst the leaf litter and soil with their feet, sometimes throwing aside a clawful of litter. When food is revealed, the bird can peck at it immediately, without having to step back first, in the typical manner of farmyard hens. As megapodes wander along scraping up the leaf litter and soil, the overturned material can provide opportunities for other species: For instance, the Australian Fernwren (*Crateroscelis gutturalis*) has been recorded feeding in association with the Orange-footed Scrubfowl.

Scrubfowl normally forage in pairs. For instance, in the Polynesian Scrubfowl the two birds almost always remain within 2-3 metres of one another, thus furnishing additional evidence that the pair-bond is very strong in this species, as it may be in other scrubfowl. An interesting practice has been noted in this species which has not yet been recorded in any other megapode. On locating food, the male frequently offers it to the female, by pointing at it with his bill, often calling her over by means of a soft piping. In cases where the food item is quite fast-moving, he will catch it in his bill and offer it to her. This food offering was recorded more than 20 times in half an hour, and in over 60% of prolonged observations of feeding. It has been interpreted that this behaviour may show that food is in short supply for the species, and that the female requires as much nourishment as possible to help in the costly process of egg formation.

Australian Brush-turkeys normally start foraging as soon as they leave the roost early in the morning, and they continue to do so right through till the evening, except for a period of repose in the middle of the day. However, when breeding, males tend to stay at their mounds in the early morning, as this is the period when most females visit mounds; during the breeding season, males normally start foraging only after about 08:00 hours.

An interesting relationship is that of the Australian Brush-turkey with the prickly pear (*Opuntia*). A bird will fly over this plant and snatch off a fruit with its feet, before landing rather clumsily beyond and consuming the fruit. At the beginning of the twentieth century, the prickly pear underwent a fairly short-lived population explosion in south Queensland and north New South Wales, and this was accompanied by a parallel expansion of the brush-turkey, as it was able to occupy habitat that was not normally suitable for it. The spread of the plant reached infestation levels and the angry farmers blamed the bird for causing the spread. However, it was found that the vast majority of the seeds were actually crushed in the bird's gizzard, and those that were not registered poor germination potential. In any case, the prickly pear was subsequently brought under control and the brush-turkey disappeared once again from the temporarily colonized zones.

Like many other birds, megapodes ingest grit in order to help break down their food. For instance, the Wattled Brush-turkey swallows pebbles, while the Malleefowl takes in large quantities of sand. No species is known to require water, but drinking has been recorded occasionally in species such as the Black-billed Brush-turkey and the Malleefowl. However, even during dry periods the Orange-footed Scrubfowl appears totally uninterested in water, and it will simply ignore any pools it comes across.

Breeding

The vast majority of what is known about megapodes is related to breeding. There are two main reasons for this. First, the fact that they do not use body heat for the incubation of their eggs is a habit unique within the bird world, and as such is naturally the aspect that has most interested scientists, from physiologists and biochemists to evolutionary biologists, taxonomists and biogeographers. Second, like many other Galliformes, they are essentially rather secretive birds, and it is only at their nest mounds or colonial laying beaches that they can be observed with relative ease and a certain degree of regularity. Nevertheless, although there has been an upsurge in interest in the Megapodiidae over the last decade or so, the habits of most species remain little known, or in the case of Bruijn's Brush-turkey totally unknown. Logically, it is the three Australian species that have received fullest attention, but other species too, such as the Maleo, have also been the objects of extensive research.

Much the most remarkable aspect of the megapodes' breeding strategy is the variety of unique incubation systems that they use. As many as five different systems can be distinguished, and the two basic modes of building mounds or digging burrows may be used as significant factors in clas-

There are very few records of megapodes drinking, and most species probably do so only rarely, if ever, instead obtaining their liquid requirements from their food. During dry spells the Black-billed Brush-turkey occasionally comes to drink at small pools in the forest, as illustrated by this bird, which was photographed in southern New Guinea. The brown patch on the hindneck shows that it is an immature.

[*Talegalla fuscirostris*, southern New Guinea. Photo: Brian J. Coates]

sifying the different groups, especially with relation to other particular features, such as foot structure or percentage yolk content of the egg.

The five identified systems are as follows: mound-building; burrow-nesting, using geothermal sites; burrow-nesting, using solar-heated beaches; burrow-nesting, using decaying tree-roots; and mound parasitism. As all three of the Australian species are mound-builders, this is much the best studied of the strategies. With the much more active participation of the birds in the preparation of the laying site, this system probably offers the greatest scope for research.

The megapode mound is one of the most remarkable constructions built by any bird, and while it may lack the architectural complexity of the nests of weavers (Ploceidae), penduline tits (Remizidae) and New World orioles (Icteridae), it makes up for this in sheer volume. The Australian Brush-turkey's mound averages almost one metre high, and three or four metres in diameter, containing an average of 2-4 tonnes of material. Indeed, the mounds on Kangaroo Island, off Victoria, contained a remarkable 6-8 tonnes on average. Admittedly, this population is not typical, as it arose from birds introduced on this island, well to the south of the present natural range of the species, in a zone where ambient temperature is correspondingly cooler, so more material is presumably required for the mound to reach the required temperature for incubation. Not surprisingly, such large agglomerations, requiring so much hard work in construction, may be used repeatedly over the years, and thus continue to grow; this happens regularly in the Orange-footed Scrubfowl, though not necessarily by the same pair, but much less frequently in the Australian Brush-turkey. One of the most impressive mounds on record, belonging to this scrubfowl species, was found in Northern Territory, Australia. It was a total of 18 metres long, five metres wide and three metres high; not surprisingly, it was active only at one end. Another mound of the same species was reported to be some eight metres in height, and another was 51 metres in circumference. Some of these largest mounds almost certainly contain well in excess of 100 m³ of material, probably weighing well over 50 tonnes.

In terms of both volume and surface area, there is a minimum size limit at which a mound is viable for incubation.

Experiments using artificial mounds have shown that a mound needs to be at least 0.75 metres high and two metres wide in order to be able to generate the necessary heat, and observations in the wild corroborate this. However, size alone is obviously not the only factor, and mounds being reused need sufficient fresh material to permit adequate heat production.

Mounds are mostly conical, bell-shaped or sometimes elongated, in the case of some older mounds; those of the genus *Talegalla* tend to be lower, flatter and more irregular and untidy than those of *Megapodius*. Mounds are basically composed of any form of leaf litter, twigs, sticks and even branches, mixed with soil or sand, depending on the local substrate. Where sand is available it tends to be incorporated in fairly sizeable quantities, notably by the Malleefowl, but where heavy soil underlies the site it is far more sparingly used, as its capacity for conducting heat is far lower.

It was traditionally thought that the heat was caused by fermentation, but recent research has demonstrated that the heat is actually generated by the respiration of micro-organisms, in particular of thermophilic fungi. Both heat and oxygen percolate throughout the mound by means of diffusion.

The temperature of the mound is remarkably constant, especially that of the section in which the eggs are laid. Thus, throughout a breeding season often lasting 7-8 months, the Australian Brush-turkey's mound remains within a very tight range of 30.8°-35.8°C without constant regulation. A similar range of 29°-38°C is found in the Malleefowl, where the temperature is actively regulated by the male every day throughout the very long breeding season. The average temperature of the mound is also surprisingly constant between the different species. For instance, both the Australian Brush-turkey and the Malleefowl remarkably show exactly the same average of 33.3°C. The mound must reach a situation of temperature equilibrium, whereby any rise or drop in the temperature for whatever reason is automatically offset by an increase or decrease in heat loss. Three features particularly enhance the temperature stability of the mound: larger mound size; higher ambient temperature; and fresher constituent material. The temperature in the core of the mound is even more constant, and in one Australian Brush-turkey mound on Kangaroo Island, where the species is introduced south of the natural distribution

Megapode mounds can reach enormous proportions. The male Australian Brush-turkey builds his mound in an average of about 37 days, raking in all the suitable material from round about, and shifting some 56 kg per day during the early stages. Material typically includes soil, leaves, twigs, sticks and even branches. Throughout the breeding season fresh material may be added, so that the mound is constantly growing. The largest mounds of this species can contain about 4 t or even 6-8 t of material.

[*Alectura lathami lathami*, Queensland, Australia. Photo: Oriol Alamany]

of the family, core temperature was found to remain at 35.5°C, even when the mound was abandoned for at least six months over the winter. As overall temperature change is normally very slow in the Australian Brush-turkey's mounds, it can be tested and regulated by the addition of extra material or by airing each time a female comes to lay, when the mound has to be opened up anyway.

The physiological characteristics of the mound are of considerable interest. It is essential that the embryo, subsequently the chick, does not suffocate, so efficient gas exchange must occur throughout the mound. Equally, the egg must not become excessively dried out, as dehydration rapidly leads to embryo death, so the moisture content of the mound must also be just right. Too much water can also be a major problem, as waterlogging of the mound quickly leads to anaerobic conditions, and even more immediately to important heat loss. Furthermore, extra moisture leads to a higher rate of heat production, with the possibility of overheating, but, while this may be balanced by greater heat loss, in the long run the higher rate of energy expenditure by the mound means that the mound owner has to put in far more time providing the necessary material to fuel the whole process, while the overall condition of the mound is far less stable. Thus, the most efficient manner involves minimum heat production with correspondingly low heat loss, at the same time safeguarding an adequate supply of both oxygen and moisture for the embryos.

The importance of the correct moisture content has been clearly demonstrated during droughts, which can cause mass mortality. Experiments have shown that, in such circumstances, hatching success can be improved markedly, if a little water is added to the mound. At the other extreme, unusually long periods of persistent heavy rain can lead to the mound becoming waterlogged. If this happens, the eggs are doomed, due to the combined effects of excessive cooling and lack of air; any embryos may effectively be suffocated or even drowned, if they have not already perished due to the cold.

Usually most of the construction and maintenance work devolves on the male, and in the polygamous Australian Brush-turkey, for instance, the female plays no part at all. This is an integral part of the whole megapode breeding strategy, as the female's production of a large number of very large, high

quality eggs means that she must devote herself uninterruptedly to the business of building up the energy necessary for the formation of these eggs. The Australian Brush-turkey builds its mound by scraping together plant litter and soil at the chosen site. This tends to involve 5-7 hours a day over some 36 days, before the mound can be considered more or less functional. While males of this species often own more than one mound, at the other extreme several pairs of Orange-footed Scrubfowl can lay in the one mound, although this species too frequently holds subsidiary mounds.

Mounds usually require substantial attention from their owners, mainly in order to maintain the temperature equilibrium. Birds will add some moist material if the temperature requires a boost, or alternatively they may open up the mound if it is becoming too hot. The addition of just a small amount of material to the mound can increase the core temperature of the mound quite considerably. Overheating is as dangerous as overcooling, and would ultimately lead to the death of the embryos. It is thought that if gas diffusion deteriorates notably in the mound, the Australian Brush-turkey, at any rate, may dig ventilation holes in an attempt to combat this problem. Daily attention of the mound also serves to prevent the material becoming too compacted, reducing aeration and heat production, and also making it more difficult later on for chicks to extract themselves from the mound.

However, in the Malleefowl the process is a good deal more complicated. This species builds a mound that is in many respects not dissimilar to those of other megapodes, but the heat necessary for incubation comes from two different sources: that produced in connection with the process of decomposition; and that coming from the sun's rays. This is connected with it being the only species adapted to living in fairly open areas, and is also probably related to its more southerly distribution. The construction of the Malleefowl's mound starts in early winter with the digging of a pit, roughly three metres wide by one metre deep, the excavated sand or soil being heaped up round the edge. The male and, to a lesser extent, the female gather together all the plant litter from round about, raking it into this pit with their feet until the heap rises about 60 cm above ground level, and then leaving it to receive a good soaking from the late winter rains. After this, in the top of the pile a small egg

The fact that the Malleefowl inhabits much more arid, open habitat than other megapodes, at a more southerly latitude, means that the processes involved in the operation of the mound as an artificial incubator are somewhat different. It is the only species that combines the use of heat produced in connection with the fermentation of plant matter and that provided by the sun's rays.

chamber is dug, in which only the more delicate material is retained, such as leaves and bark, but not large sticks. The whole heap of plant matter, now beginning to rot, is stirred and then covered over with sand or soil, which forms an insulating layer to keep in the heat and also permit the draining off of excess moisture. The birds now regularly monitor the mound temperature, and once it reaches the required temperature of about 30°C, egg-laying can begin.

Now that the female must concentrate on building up the extensive resources necessary for egg formation, the male is on his own. Every day throughout many months he laboriously tends and manipulates his mound, controlling both temperature and moisture as much as possible, but the processes vary across the seasons. At the start of his long vigil, the weather is generally fairly cool, so that most of the heat is microbially produced, and in the morning he regularly opens up his mound in order to let the excess heat escape, quickly covering it with sand again, to avoid too much heat loss. As the season progresses, the sun becomes warmer, while microbial action diminishes, and the bird now has a brief respite during which slightly less maintenance activity is required.

However, as summer arrives the problem turns to the business of trying to avert excess solar heat, as fermentation has now lessened considerably. The mound is covered with a thick layer of sand so that the eggs do not overheat, and from time to time it may be opened up in the early morning to get rid of excess heat. Towards autumn, the effects of any fermentation are waning and the sun's rays are now much weaker. The male is now rejoined in his work by the female, and daily, around mid-morning when the day is warming up, the birds open up the mound to let the sun's warmth pervade it. Now they busy themselves in heaping up sun-warmed sand over the mound, so that by the late afternoon the eggs are once again covered by a thick layer of warm sand which will keep them warm throughout the chilly night. Eventually, even this strenuous labour is not sufficient to keep the mound temperature high enough, and the nest is abandoned for the year. Sometimes it is dug out by the male, and left as a bare crater, possibly to be used again in a forthcoming season; any eggs turned up in the process are kicked out with the rest of the mound material.

Thus, while it is often asserted that megapode chicks receive no parental care, this statement requires qualification. In fact, very few other male birds invest so much energy over such a long period, to ensure the successful development of their young. The parental care of mound-building megapodes can be considered to take place before the chick leaves its egg.

The case of the burrow-nesting species is really quite different. They use naturally occurring sources of heat, which can be divided into three main types. The first encompasses a variety of geothermal sources, involving heat produced by some sort of volcanic activity, and is related to the fact that the distribution of the megapodes coincides in part with the Ring of Fire and other zones influenced by intensive volcanic activity. For example, the Polynesian Scrubfowl, which is restricted to the island of Niuafo'ou, an active volcano in the Tonga group, typically lays in beaches alongside crater lakes or in slopes of volcanic ash, sometimes in the proximity of heat vents. The second source is solar energy, which some species are able to harness for their benefit, by laying their eggs in beaches, typically those of black sand which more readily soaks up the heat of the sun's rays. This is a widespread potential source of heat, but is actually used by relatively few species; indeed, there are many apparently suitable beaches available to the several species found in New Guinea, but as yet no evidence of the practice occurring any nearer than on the Admiralty Islands. The third source of heat is that created by the decay of rotting tree roots. This system remains very poorly known at present, but it may be the normal method for the Vanuatu Scrubfowl.

For most burrow-nesters scarcity of suitable nesting sites is usually a major limiting factor, so it is normal for these species to use communal laying grounds. These can vary from just three or four pairs laying at the same site to the colossal scale of nesting recorded in the Melanesian Scrubfowl, at Pokilli in New Britain, where tens of thousands of burrows can be found, and some 53,000 birds were estimated to have been present in 1978. The largest site known for species that use solar heat is one on the island of Haruku, to the south of Seram, where up to 4000-5000 pairs of the Moluccan Scrubfowl may lay throughout the year.

Maleos lay their eggs in burrows, often in communal laying grounds. These may be on solar-heated beaches or at sites where the ground is heated by geothermal activity. Where the substrate is firm, laying grounds tend to be covered in a series of craters. Inside one of these craters, the male and female join forces to dig a subsidiary burrow, and, once this is ready, the female disappears into the burrow to lay her egg. After a while, she emerges, and the pair fill in the burrow again before departing, taking no further interest in the egg.

[*Macrocephalon maleo*, Tengkok Reserve, North Sulawesi. Photo: Alain Compost/Bruce Coleman]

Where such sites are out in the open, many birds may congregate towards evening in the forest nearby, waiting for darkness to fall and keeping a look out for potential predators. If there is no sign of any disturbance, around dusk or dawn the birds may emerge onto their laying grounds and start digging. The exact timing of laying varies with the species, the site and the levels of disturbance that prevail there. Maleos, for example, can start digging in the late afternoon, although even then they probably wait until the next morning to lay. The Melanesian Scrubfowl tends to do all its work in the early morning. The habits of the Moluccan Scrubfowl are poorly known, but it apparently performs the whole process under the cover of darkness.

Large, communal laying grounds can present a sort of lunar landscape, as the whole area may be peppered with small craters. After selecting a suitable egg-laying crater, a bird will disappear into it, and then dig a subsidiary burrow in which it lays its egg. In the Maleo, both members of the pair take active part in digging the burrow, a process which can take from half an hour to as much as three hours. Then, after a long period during which the female is under the ground laying the egg, it may take them almost as long to fill the hole in again. In scrubfowl the business of digging the burrow takes much less time and is carried out by the female alone; if undisturbed, she will often rest for an hour or so in the main burrow after laying the egg. In the Vanuatu Scrubfowl burrows can be 120-300 cm deep, 40 cm wide and up to 200 cm long. Those of the Melanesian Scrubfowl average 40 cm wide by 90 cm long, while in the Polynesian Scrubfowl they are roughly 15-20 cm wide by about 90-150 cm long. On beaches the sand is obviously far less stable and quickly caves in, so that the effects of burrowing are rarely obvious long after the moment of laying. However, for the very same reason, the whole process of excavating a suitable hole is much harder work.

Like mound-builders, burrow-nesters also lay their eggs at sites with very regular temperatures, but they do not need to regulate the temperature, and, in fact, are unable to do so. Nevertheless, the limited evidence available to date suggests that they use sites where they have learnt by experience that the temperature remains fairly constant at the required level. Interestingly, the Maleo and the Polynesian Scrubfowl tend to

lay at sites showing rather similar temperatures to those recorded for the mounds of the Australian species. Once the egg has been laid, the subsidiary burrow is filled in again with whatever material is available, in some areas including fresh vegetation which may actually contribute to the heat in the way it does in mounds. After this stage has been completed, the egg is totally abandoned to its fate; thus it might be said that burrow-nesting megapodes are the only birds, apart from brood parasites, in which all parental care ceases immediately after the laying of the egg.

The case of those burrow-nesters that use rotting tree roots as their source of heat differs somewhat from the two main types. This form of burrow-nesting depends on microbial heat produced by the decaying roots of live trees, and in some ways it could almost be considered a form of mound-building that does not require any kind of construction or maintenance. On the other hand, the processes involved and the type of burrow made are entirely comparable with those used by other burrow-nesters. As a consequence of the reduced area available for laying, such sites do not seem to be used communally, or at any rate by a large number of pairs.

Mound parasitism remains the least known of the methods. In several of the few cases known, it is unclear which species are involved, and in some of these cases it is not even clear which species is parasitizing which. The Moluccan Scrubfowl, normally a burrow-nester, has often been suspected of laying in the mounds of other species, but, although it is not actually even known to build mounds, it too has been said to suffer parasitism by the Dusky Scrubfowl. It seems likely that a species of *Megapodius*, perhaps the New Guinea Scrubfowl (*Megapodius affinis*), parasitizes mounds of both the Wattled Brush-turkey and one of the *Talegalla* species, probably the Brown-collared Brush-turkey, in the southern highlands of New Guinea, where what is certain is that the eggs of two different species have been found in the same mound. This system again shows features of both of the major megapode incubation methods: incubation of the eggs logically proceeds in exactly the same manner as in the mound-builders; but the act of laying recalls the burrow-nesters, as the bird is essentially making use of an already existing heat source. Parasitism might well be derived from the practice, recorded in the Orange-footed Scrub-

fowl, of several pairs laying in the same mound, which might itself anyway be considered a form of mound parasitism.

The breeding season for megapodes is very variable, and, as in many tropical bird species, tends to be related to rainfall patterns. For instance, throughout its extensive range the Orange-footed Scrubfowl tends to avoid breeding during the rainy season, presumably to lessen the risk of its mounds becoming waterlogged. Several species, such as the Maleo, can be found breeding throughout the year. In contrast, in south-east Queensland the Australian Brush-turkey's nest building activity does not tend to get under way until the first heavy rains have arrived, in this case permitting the commencement of the fermentation process. The Malleefowl, with its more southerly distribution, can not raise sufficient heat for incubation during the winter, but its whole breeding process is so complex that it can last as much as eleven months of the year from beginning to end.

It was long assumed, for evolutionary reasons, that the remarkable investment of the male in mound-building species must imply that his parentage of the chicks is guaranteed, which in turn could only be the case in a system of monogamy. This is still thought to be the norm in most species, especially in scrubfowl. However, the Australian Brush-turkey is now known to follow a strategy of simultaneous polygyny, a male attempting to mate with each female that comes by his mound. It seems that the more time and energy he invests in building a larger, more attractive mound, or in building and maintaining two mounds, the more likely he is to be successful in attracting females with which to mate. In addition, recent research has shown that once a female has found a suitable male she tends to copulate only with him and lay only in his mound for about 3-6 weeks, thus adopting temporary monogamy; only occasionally does a temporarily paired female attempt to mate with another male.

Polygyny has also been recorded in the Malleefowl, where one male was found to own two mounds, each attended by a different female, but such cases are thought to be rather exceptional in this species. Although essentially monogamous, like the scrubfowl and the Maleo, the Malleefowl differs in that its strategy is based on defence of a mound and its immediate surroundings, whereas in the scrubfowl, the male appears to

defend his female and several pairs can lay in the same mound; in this respect, the Malleefowl's strategy is perhaps closer to that of the Australian Brush-turkey. The systems followed by the genera *Aepyptodus* and *Talegalla* are not yet known, but while certain aspects of breeding behaviour in captivity have linked the former with *Alectura*, the latter genus is tentatively grouped with the monogamous species.

Little or nothing is known of courtship, pair formation and most other basic aspects of breeding behaviour in the vast majority of species. Again it is apparently the least typical species that are the best known.

In the Australian Brush-turkey mate choice is made by the female. Throughout the breeding season, females wander about inspecting males and their mounds; this involves watching the male's behaviour at the mound and sometimes probing into the mound with the bill, taking a billful of material and manipulating it between the mandibles. As has been seen, a female apparently stays with one male for about 3-6 weeks, after which she moves on to another, fresher mound.

There are several factors that influence the female in making her decision, and one of these seems to be the ease with which she can dig into the mound: if the mound is not clogged up with large sticks and other awkward items, she can probably shift the material far more easily and quickly, with less risk of injury; equally, the same conditions probably favour her chicks when they hatch. Regular male attendance at the mound is another significant factor, as this is essential for successful hatching, and the lengthy incubation period may well be one of the reasons that females tend to choose mounds that have only recently reached suitable temperatures for incubation, as this implies that there is less danger of the male's interest in his mound ceasing before the chicks hatch.

When a female Australian Brush-turkey approaches a mound, the male presents her with a ritualized stalking display, in which he bobs his head up and down. Copulation takes place on top of the mound, and the male will not permit a female to lay in his mound, unless she first copulates with him. Egg-laying tends to last over 45 minutes, but sometimes takes less than 15 minutes, if other females are queuing up to lay. On occasions, females will squabble over the right to lay in a particularly good nest, and a waiting female may wander off.

Mound temperature tends to be surprisingly constant. This is essential for the correct development of the embryos, and too much or too little heat can result in the loss of all the eggs in the mound. The male Australian Brush-turkey efficiently regulates the temperature of his mound. If it becomes too hot, he will open vents to let the excess heat escape, whereas if it cools down excessively, he will add fresh material, and thus increase the rate of fermentation.

possibly to lay elsewhere. Mound ownership is absolutely indispensable for a male, as it is almost impossible for him to secure a copulation without a mound. For this reason, each male defends his mound or mounds vigorously against intruders and possible usurpers.

In all species, both mound-builders and burrow-nesters, the correct incubation temperature is essential for laying. A bird will "drill" test holes into the mound or burrow, in order to check that the temperature is suitable, and to find the right depth for laying, and in this process the bill or the mouth may be used as a thermometer (see Morphological Aspects). In the Malleefowl the eggs are laid in the central core area, but other mound-builders may lay more or less anywhere in the mound. Burrow-nesters sometimes find that a burrow they are in the process of digging does not meet the necessary requirements, because it is too cold, too wet or the walls too crumbly. In such cases, they will simply abandon that burrow and try again in another place.

One of the intrinsic features of the megapode breeding strategy is the prolonged period of fertility of the female. This is dictated by the high energy content of each egg, and is permitted by the lack of post-hatching chick care. One of its most obvious benefits is that, despite the high energy demands of each egg, the female can produce a large clutch, although in megapodes clutch size is normally difficult to ascertain. In captivity a female Australian Brush-turkey can lay 30 eggs over a period of several months, representing up to three times her own body weight. The Malleefowl normally lays a clutch of 15-24 eggs, whereas a female Maleo is reckoned to produce 8-12 eggs per year. At Garu, in New Britain, 20 burrows of the Melanesian Scrubfowl were taken as a sample and studied for six weeks, during which time production ranged from four to eleven eggs per burrow. However, the ratios of females per burrow, burrows per female or both were not known.

The egg itself constitutes yet another remarkable feature of megapode breeding. It is white in *Alectura* and *Aepyodius*, but in all the other genera the shell is covered in a reddish brown powder, a colour not known to occur on any other galliform eggs. It is fairly large, averaging approximately 75 x 45 mm in the Polynesian Scrubfowl to 106 x 62 mm in the Maleo, with average weights of 75 g and 231 g respectively. It generally represents roughly 10-20% of the female's body weight. However, of more significance is the extremely high yolk content. In most birds, including all other Galliformes, the yolk only very rarely constitutes as much as 50%, and in some species with notably altricial chicks, the proportion can be as little as 15%. However, there is a range of 48-55% for most brush-turkeys, 51-54% for *Leipoa*, and a remarkable 61-69% for *Macrocephalon* and *Megapodius*. The high values for these last two genera are paralleled only in the kiwis (Apterygidae), which, like megapodes, have a very long period of incubation.

The high yolk content is closely connected with the advanced stage of development at which the chick emerges from the egg. A direct result of this high yolk content is that the egg is much more elongated than in most other birds, as the yolk has to be more evenly distributed throughout the egg, rather than amassed at one end; the same is also true of reptile eggs. Another logical effect is that the initial water content is unusually low, making up an average of only about 67%, as opposed to 75% in other birds with precocial chicks and more than 84% in those with altricial chicks. The moisture content of the mound obviates the necessity of an extra water supply for the embryo, and water loss is very low, only 8% of the initial egg weight in the Australian Brush-turkey. This also means that the embryo makes the maximum use of all the energy supply of the egg in its growth and helps to advance its development; indeed, the Malleefowl embryo uses 94% more energy than do the embryos of other precocial chicks in similar-sized eggs.

The shell is very thin, measuring only 69% of the thickness expected for an egg of its size. This is a development that permits highly efficient gas exchange, so that although the egg is buried under the ground, sometimes in rather moist condi-

tions with a somewhat limited supply of oxygen, the embryo's air supply does not run out. As a result of this, the level of gas conductance of the Australian Brush-turkey's egg is more than double that of similar-sized eggs in other bird groups, which means that despite the extraordinary conditions of the egg being buried underground, the gas tension within the egg remains very close to that found in other birds' eggs.

The eggs of most birds have a small air chamber which is enlarged during the incubation period by water loss, and which provides the chick with air for its first breaths prior to hatching. However, this chamber is lacking in the megapode egg, as a result of the reduced water loss, so that the chick can not take its first breath until the shell has been broken, with the result that hatching is of necessity very rapid. Thus, instead of the normal hatching process of other birds, using the egg tooth, the megapode chick actually kicks its way out of the egg, rupturing the shell instantly, so that pulmonary respiration can begin at once; at the same time, in the moment of hatching a fair amount of water tends to be discharged from the egg. It is interesting to note that the chick does indeed grow an egg tooth during the embryo period, but loses it by the time of hatching. This is further proof that the megapode incubation system, along with the large egg, the thin shell and other features, almost certainly evolved from the typical system used by other birds, which was subsequently lost. The very thin shell again comes into play, as it facilitates the chick's rapid escape in this crucial moment. On the other hand, while undergoing incubation the egg does not generally require as thick a shell as in other birds' eggs, because there is only a limited chance of it being broken by the adults. Finally, another advantage of the thin eggshell is that it is energetically less costly for the female to produce.

The incubation period is very long, taking 71% longer in the Malleefowl than would be expected for eggs of such weight; this is directly related with the high yolk content of the egg and the highly precocial hatchling. The length of the incubation period itself varies remarkably depending on the physiological conditions of the mound. Indeed, in the Malleefowl it has been known to take as little as 50 days and as much as 96 days, probably the greatest range noted in any bird species; in different artificial conditions eggs of this species have even been hatched at 44 and 99 days. Another evident difference with the habits of other birds is that megapodes' eggs are not turned during incubation.

There is no synchronization whatsoever in hatching, which ties in with the lack of parental care, as there is no need for a brood to be cared for and raised together. Indeed, the fact that the different chicks hatch over a lengthy period would anyway make the task of parental care excessively burdensome. In line with this, chicks in captivity tend to shy off from one another or even use threat displays, rather than showing the gregarious habits of other galliform chicks.

The super-precocial chick remains in the egg as it effectively passes through the stages of the first days or even weeks after hatching of the chicks of other birds. In the first place, the chick is very large, again a direct result of the large yolk and the long incubation period. For instance, a Melanesian Scrubfowl chick that had just emerged from its nest burrow on the island of Savo, in the central Solomons, already measured 11 cm in overall length, roughly a third of adult length, and even more impressively it had a 31 cm wingspan, probably about half that of the adult.

On hatching, the chick struggles up to the surface, usually a journey of about 50 cm, which can take as little as a couple of hours or a full day, or more, and, not surprisingly, by the time it gets to the top it normally requires a rest. Clearly, in order to be capable of successfully completing such a journey, the chick needs to be in a very advanced stage already upon hatching.

The hatchling is the most precocial in all birds. It receives absolutely no parental care, and an adult Malleefowl that came across an emerging chick while tending its mound simply kicked it out as though it were another item of mound material. The chick lacks the usual coat of down, but instead already has

The Orange-footed Scrubfowl is much the best known member of *Megapodius*, due mainly to an interesting study carried out in Queensland in the early 1970's. In this species, mounds are regularly reused from one year to the next, although not necessarily by the same pair. An interesting discovery was that one mound can actually be used by two different pairs simultaneously, although the pairs remain strictly independent of one another, and are not to be seen together on the mound. Such sharing is perhaps all the more surprising, given that in this species each pair maintains a territory. The explanation is that the territories are probably related to foraging, as opposed to breeding, so, where food is sufficiently abundant, birds may allow their neighbours to use a mound that is on their property.

[*Megapodius reinwardt*.

Ardea]

The business of mound maintenance is especially arduous in the case of the Malleefowl, as the male, in particular, has to tend the mound assiduously for up to eleven months a year. The most complicated task is temperature regulation, particularly as the processes involved vary at different times of year. Nevertheless, most of the work involves removing and putting back material, especially sand. In order to shift the sand, the bird invariably faces away and scoops the sand backwards, whether it be onto the mound or off it.

[*Leipoa ocellata*, Australia. Photo: L. Robinson]

a fairly full plumage of pennaceous feathers, including all but the outermost two primaries; it is capable of flight almost straight away, in its first day of life. Indeed, a hatchling Melanesian Scrubfowl released by an egg-collector flew out over the sea and then back into forest, covering an estimated approximately 1600 metres non-stop. A newly-hatched chick is also immediately capable of regulating its own temperature within a range of at least 5°-45°C. In some species it begins to feed by itself at about one day old, normally after losing weight on its first day out of the egg.

One of the most interesting peculiarities of the megapode chick is the fact that it has no opportunity of imprinting on its parents, except very rarely in cases such as the described, when it might happen to emerge just in a moment when an adult is tending the mound or laying in a burrow. Thus, again as in the brood parasites, like cuckoos, species recognition must be innate in megapodes.

The little that is known about breeding success once again refers to the Australian species, but the pattern is likely to be similar in all species. A study of success rates in the Australian Brush-turkey over three years, involving 499 eggs, showed a high overall hatching success of almost 87%, although in one year, with a particularly wet spell that caused mound temperatures to drop by 8°-12°C, under 80% of the eggs hatched. In contrast, recruitment was very low, with 90-97% of the chicks failing to reach the subadult stage, giving an annual average of 0.8-1.7 chicks recruited per successful male. In this case it seems that much of this mortality was due to predation, mainly by cats, but probably also by dogs, dingos, snakes and raptors.

Elsewhere, predation of eggs, especially by monitor lizards but also by dingos and foxes, has been found to be a major cause of low overall success. In the 1950's, a study of hatching success in the Malleefowl in New South Wales found it to be about 50%, with 37% of the eggs taken by foxes. A study in

the same zone in the 1980's gave a similar overall result of about 50%, but in this case fox predation accounted for under 6% of the losses, whereas infertility of the eggs was the main cause of failure; it is thought that fragmentation of the population (see Status and Conservation) and resultant inbreeding may be responsible for this apparent decline in fertility, and significantly a simultaneous 1980's study in South Australia showed hatching success of over 79%.

An interesting experiment was carried out to test the survival rates of Malleefowl chicks in the absence of terrestrial predators. This involved distributing 29 artificially incubated chicks among four enclosures in natural mallee vegetation, each of which had slightly different conditions. The results showed convincingly that food availability was a major factor for chick survival, as all but one of the chicks that had access to extra food outlived the 30 days of the experiment, while not one of the birds in other enclosures survived. The fact that chicks have to learn feeding skills by themselves, instead of being taught by a parent, may well be a significant cause of mortality in all megapode species.

In looking back over the many extraordinary aspects of the megapode breeding system, it seems inevitable to ask how and why it all began. There has been much speculation as to which of the two main incubation strategies, mound-building or burrow-nesting, was the original method used by the early megapodes. On the evidence currently available, it seems that mound-building is more likely to have been the original method used, essentially as this would involve the fewest changes of habit along the way.

In effect, this would mean that somewhere along the line the Maleo's lineage lost the habit of mound-building and switched to burrow-nesting, while the scrubfowl gained the option of burrow-nesting. If burrow-nesting were taken to be the primitive method of the megapodes, this would mean that four whole genera would have to have lost the habit of bur-

row-nesting and have gained that of mound-building, while the condition of the scrubfowl remains the same. A third possibility is that both methods evolved simultaneously, but this seems highly unlikely, and would still imply that all genera except *Megapodius* had lost one or other of the traits. In the future it will be interesting to see if further taxonomic research bears out the conclusion that within the genus *Megapodius* strict mound-builders like the Nicobar Scrubfowl are more primitive, and strict burrow-nesters like the Polynesian Scrubfowl more advanced.

Evidence to support this proposal comes from the foot structure, as the Maleo's foot appears to be adapted for digging (see Morphological Aspects), while all scrubfowl, including burrow-nesters, lack this feature. If these burrow-nesting species lack this feature, it is more likely that the structure seen in the Maleo does not represent the original megapode foot, but rather a later development. Thus, the Maleo would be a more advanced species than the scrubfowl, while the brush-turkeys and perhaps the Malleefowl would be even older forms. The extremely high yolk content in the eggs of the Maleo and the scrubfowl would be a sign of the more advanced state of development of these species, rather than a relictual feature.

A further step in this analysis involves an attempt to establish which of the main burrowing strategies came first, those using solar or geothermal heat sources. While this too remains effectively a matter for speculation, it has been noted that of all the species known to use more than one system there is none that combines mound-building and nesting on sun-heated beaches; it seems that in order to adopt this strategy, a species may first have to pass through the practice of using geothermal heat.

Assuming that the incubation methods of the megapodes are not evidence of a direct link with the reptiles (see Systematics), then it must be supposed that at some stage the megapodes' ancestors incubated by means of body heat like all other birds. The mound-building habit may have evolved from incubating birds covering their eggs with leaves when they left the nest in order to keep them both warm and inconspicuous, a common practice for example in the tinamous (see Volume 1, page 120). Birds might have found that by placing more

material over the eggs, they could leave them for longer periods, and from here the step to mound-building would not appear too difficult.

Movements

The Galliformes in general show a rather limited capacity of mobility, and in the entire order true migration is limited to a handful of Old World quails (*Coturnix*). The results of this would appear to be reflected by the geographical distribution of the component families, which present a very limited degree of overlap. It seems that when members of the order occupied different zones, they were better able to diverge and adapt themselves locally to the conditions prevailing in the particular zone, rather than adopt the practice of moving back and forth between different zones to take advantage of the best moments in each. This may well be related to the fact that plants often make up an important part of the diet, and this requires relatively large body size, although this difficulty need not be unsurmountable, as notably demonstrated by some members of the Anatidae.

The megapodes are usually reckoned to be more mobile than most other Galliformes, but this epithet is really applicable only to the scrubfowl. The other species, comprising the much larger brush-turkeys, Malleefowl and Maleo, appear to be at least as poorly designed as some of the larger pheasants (Phasianidae) for movements of any great distance. However, at present very little is known at all about the movements performed by megapodes.

Some movements over water are known to occur, and these have particularly been noted on small islands where the birds quite certainly are not normally present, but where they may suddenly turn up to breed. The number of Moluccan Scrubfowl thought to breed on the small island of Haruku (see Relationship with Man) is so large that it must include at least some that fly the few kilometres separating this island from Seram to lay here, and birds have indeed been seen arriving over the sea soon after dusk. One of the most notable cases of such movements is that of the Micronesian Scrubfowl, as its island-hopping habits are particularly evident in parts of

The moisture content of the mound is just as important as the temperature, and must also be actively controlled. Too little moisture will dry out the eggs and may cause fermentation and heat production to cease. Too much moisture can lead to waterlogging of the mound, implying a slump in both gas exchange and temperature levels, and ultimately the loss of the eggs; this can, in fact, be a major cause of breeding failure in the Australian Brush-turkey.

The megapode chick is the most precocial in the bird world. It escapes from its egg by means of a sharp kick, rather than gradually pecking its way out, like other birds. It then works its way up through the soil, sticks and leaves to emerge on the surface of the mound, the moment captured in this photo. It is already all but fully feathered, and almost at once it is capable of flying, feeding itself, and regulating its own temperature. It receives no attention or assistance whatsoever from the adults.

the Palau Islands, due to the very small size of many of the islands. On occasions, birds must be capable of flying several kilometres over water, and the very presence of this species in the Palau Islands and especially in the Marianas, quite some way from the nearest landmasses begs the question as to how they arrived. It seems mostly likely that this species and also the Polynesian Scrubfowl reached their current ranges by natural means, presumably by dispersal over the sea (see Relationship with Man).

Especially in colonial nesters, it has been suggested that birds may cover great distances between regular foraging grounds and the laying site. Certainly, some such mechanism must exist at any rate at the largest colonies, such as Pokilli in New Britain (see Relationship with Man), because the huge numbers of female that use these sites could not be supported by the forest immediately surrounding the laying sites, and to these numbers must be added the males. At this particular site, flocks of over 60 Melanesian Scrubfowl have been seen flying over the sea heading apparently towards what were, at the time of a study in the mid-1970's, vast expanses of undisturbed lowland forest; it was not known if the birds remained permanently in this nearby forest, or dispersed further afield.

The three Australian species are sedentary, and each Maleefowl pair maintains a home range of 1.7-4.6 km², which may overlap with that of its neighbours. It seems very likely that most species are basically sedentary, especially mound-builders, but juveniles may regularly disperse over quite large areas. Radio-tracking has occasionally been used, although with mixed success. For instance, of six Maleos so equipped, five almost immediately disappeared from the laying site without further trace, while the other stayed around the site for 12 days. A female of this same species, wing-tagged at a laying site, was resighted five years later, some 25 km from where it was originally marked.

Relationship with Man

Like most Galliformes, megapodes have a long history of contact with the local human populations, and at various different times humans have almost certainly had important influences

on the distribution of several species, although the true extent of this may never be known.

The current distribution of the Megapodiidae has been a fertile source of speculation and discussion. The present geographical limits of the family have been explained by different hypotheses (see Habitat), but there are two populations that stand out particularly, namely the tiny isolated outposts in Tonga in the east and the Nicobars in the west, both of them separated from any other megapode populations by vast stretches of sea, and distances in excess of 1500 km and 2500 km respectively.

One possible explanation that has commonly been quoted is that the birds were transported to these islands by humans. For the eastern population, this might have been at the hands of early colonizers on their migrations into the South Pacific. Against this proposal of human transport is the fact that there is no evidence to show that any megapode species has ever been domesticated. Several species have now been found to breed well in captivity, which suggests that domestication might be feasible, but any successful domestication would surely have been very likely to lead to the rapid proliferation and spread of domestic birds, as happened with some other galliform species, most notably the junglefowl (see page 463).

However, much stronger contrary evidence is available in the case of the Polynesian Scrubfowl, a species that is found only on the small Tongan island of Niuafo'ou. This and the Micronesian Scrubfowl, also rather isolated in the Pacific, are the two forms of *Megapodius* that really differ quite notably from all the other members of the genus, and the specific status of these two forms alone is undisputed. Had these birds been transported to their respective islands by human colonizers, it seems highly unlikely that there would have been sufficient time for them to differentiate to the degree that they have done.

Human arrivals on small islands have repeatedly led to a series of extinctions amongst the local wildlife. Archaeological evidence indicates that this process occurred in the South Pacific, and in some cases the chronicles of early European explorers provide additional, though sometimes none too reliable, evidence. It now seems very probably that this was the story with megapodes too in this region. Fossil and subfossil

evidence, including leg bones found in early middens, shows that megapodes formerly had a much more extensive distribution in the South Pacific, occurring, for example, in other parts of Tonga and also in other island groups. Local tradition in Fiji talks of the now extinct Sasa, a bird which was reportedly similar to a megapode. Until recently, there were no further clues, but excavations on Lakeba Island in Fiji revealed megapode bones in a midden full of other bird bones. This find was dated to about 900 BC, which is thought to be roughly the period in which this island was first occupied, so it appears that here at any rate, and perhaps throughout much of the South Pacific, indigenous megapodes were perhaps encountered by the first human settlers. The disappearance of the megapodes from several islands in the region, and in all probability from many others as yet unproved, implies that they may well have been persecuted to extinction, quite possibly by means of intensive, systematic hunting and egg-collecting.

However, at the western extreme of the megapodes' distribution, the situation appears quite different. It has been suggested that a form of *Megapodius* spread westwards, island-hopping and gradually occupying neighbouring islands, and thus expanding its range. Theoretically it would have colonized at least as far west as the Nicobars. Subsequently the species would have disappeared from all of the intervening areas of land west of the Philippines, Sulawesi and Lombok, including the immense islands of Sumatra and Java and all but the northern tip of Borneo, leaving the isolated population in the Nicobars. The causes of this mass disappearance would presumably have to be tied in with exclusion by Phasianidae or mammalian predators (see Habitat). This whole idea seems rather unlikely, as the extinction without trace from the mass of small islands in the intervening area that would presumably have been colonized appears unrealistic, while there is no obvious reason to explain why the Nicobar population should have survived.

In this case it would seem far more reasonable to suppose that this population did indeed originate from birds imported by humans, an idea already put forward by Alfred Russel Wallace in 1876. In support of this proposal is the fact that the grounds for recognizing this form as a separate species from the slightly differentiated Philippine Scrubfowl are essentially the geographical isolation of the two (see Systematics). An interesting coincidence is that megapodes were reported to have been introduced by a sultan to a small islet in the Maldive Islands during the nineteenth century, probably with birds brought from the Nicobars.

It is also interesting to note that the local names for megapodes in widely separated areas show great similarity. That the name "Maleo" is applied to the Sula Scrubfowl on Taliabu in the Sula Islands is not particularly remarkable, as the species to which this name is normally applied in literature, *Macrocephalon maleo*, is found very close by on Sulawesi. Likewise, the Philippine Scrubfowl is known on Sulawesi as "maleo kecil", or "small Maleo". However, of greater interest is the fact that the name "malau" is the local name for the Vanuatu Scrubfowl, and even more notable is the local name for the Polynesian Scrubfowl, once again "malau". This has been suggested as proof that the birds reached Polynesia by means of human transport, but all it probably means is that when the first colonizers arrived, they were already familiar with megapodes, so they naturally retained the word that already existed in their language, a process that has repeatedly occurred during colonizations, perhaps most notably throughout the Americas.

The megapode egg, with its remarkably high yolk content, offers a very rich source of protein to local human populations, which often have to survive on impoverished, rather unnutritious diets. Over the centuries, the eggs of many, probably most, megapode species have traditionally been harvested by the local human populations. In most areas, ancestral laws or customs prevented excessive exploitation, so that collecting was carried out at sustainable levels. Nevertheless, some isolated populations on Pacific islands were almost certainly wiped out as a result of excessive exploitation. It seems likely that egg-

collecting would have been an important factor, but there was clearly some hunting too, as indicated by the bones found in the middens of early settlers. However, in some areas, at any rate until recently, birds approaching camps and huts were not killed, as the locals realized that the eggs are a much more valuable source of protein than the flesh of the birds. The combination of hunting with intensive egg-collecting is likely to lead to rapid population declines over relatively short periods.

One of the major problems is that the sites used by megapodes for egg-laying, especially mounds or communal beaches, are usually rather prominent and easy to detect. This applies particularly to humans, but also to any other large predators, notably monitor lizards and in Australia introduced European foxes (see Breeding), and this vulnerability may be behind the absence of the family from continental Asia and most of the Greater Sundas (see Habitat).

In parts of New Guinea, a megapode mound is traditionally considered to be the property of whoever finds it, and the owner is entitled to take all of the eggs for consumption, sale or barter; he may wish to despoil it completely at once, or he may prefer to harvest the eggs periodically, by which method he is presumably likely to gain more in the long run, as long as his rights are respected.

A similar system operates in many areas with nesting beaches, and each small village, and sometimes each family, may have its own particular patch to which it has all the harvesting rights. In fact, where such hereditary systems are still in operation, they can imply a most efficient form of protection for the megapodes, as the local human population has vested interests in preserving the site and avoiding overexploitation. Such a site of the Moluccan Scrubfowl was recently rediscovered on the island of Haruku, off the south coast of Seram in the southern Moluccas. The site, first reported in 1894, had not apparently been visited by any ornithologist since 1953, until R. Dekker searched it out in 1991. He feared that the site would have ceased to be operational, like so many others of this threatened species, but was delighted to find a large communal laying site, just as described, which he estimated might be used by up to 4000-5000 pairs each year. Most importantly, this site is still protected by local custom, and all harvesting strictly controlled. One tenant has the comprehensive rights for egg harvesting at the site, a privilege for which he pays on an annual basis, and which appears to be respected by the local people. In fact, the whole site is strictly protected by local custom, which even prohibits firewood collection there. The tenant states that he deliberately leaves something in the region of 20% of the eggs, in order to maintain the population. This well organized site shows that, if properly organized for sustainable harvesting, exploitation can actually provide security for individual megapode populations, as it regularly did in the past, before the widespread disruption of local traditions.

Exploitation on a most amazing scale occurs at the largest known nesting concentration of any megapode species. At Pokilli, in central New Britain, an estimated 53,000 Melanesian Scrubfowl congregate at breeding grounds that are heated by geothermal activity. This site and others in the area have been exploited by the local people certainly for several centuries and probably since long before the arrival of the first Europeans in the region. As elsewhere, each site, or portion thereof, has its traditional owner. In the past full-scale wars were fought between the various tribes regarding ownership of the burrows, with the dead often being buried in the very burrows they had died defending. Convention traditionally protected the birds and their eggs from excessive exploitation, but with the arrival of the white man and his Western values, as well as increases in the human population, many local customs have been shattered, and the tacit restrictions affecting egg-collecting have been cast aside.

At Garu, another, much smaller site about 60 km west of Pokilli, it was found in 1971 that villagers were taking some 15,000 eggs per year. Despite legal protection of this site in 1975 and the imposition of restrictions that appear to have been accepted, a reassessment of the situation showed that over

30,000 had been taken in 1979. However, this falls into insignificance when compared with the activity at Pokilli. On any one day, over 200 people can be seen working the burrows here; after digging out the eggs, they wrap them in palm leaves and load them onto lorries which transport them back to the villages for sale. A rough estimate in the mid-1970's, based on the number of eggs taken per village, the number of villages involved and the length of the breeding season, suggested that about 4,890,000 eggs were collected per year, an estimate that was thought to be conservative!

In recent years an unexpected conflict has arisen in suburban Brisbane, in south-east Queensland. The Australian Brush-turkey used to be found regularly near the city centre, but it was largely restricted to several patches of forest and wooded parkland within the city limits. However, during the 1970's the species started colonizing residential zones too, mostly those abutting on the patches of forest, and this has led to a certain amount of conflict. Birds have taken to installing themselves in private and public gardens, city parks and precincts, and in such sites they set about building their mounds. Unfortunately, this can involve raking up somebody's flowerbeds or shifting the compost heap, and not surprisingly many householders find this a considerable nuisance, particularly as on occasions the birds can cause a fair amount of damage to property. Other people find them a bother to themselves and their children and also to their pets, and they are accused of stealing food laid out for the pets. Yet other householders are delighted to have the birds around them, and may be proud of having a successful mound on their property, sometimes encouraging the birds by feeding them, which has the inconvenient side effect of making the birds tamer and more likely to pester those who do not want them.

In response to complaints, several methods have been tried in attempts to eject the birds in places where they are not wanted, but as the problem is still fairly new, it is not yet certain which of these, if any, is the appropriate one. For instance, the relocation of birds, which requires legal authorization, seems to be fairly ineffective, particularly as birds may even come back again from quite some way off.

A recent study of the dynamics of this unusual population has produced some interesting findings. The overall success of suburban nesters averages considerably lower than that of wild populations nearby. The main causes of this seems to be the different proportions of the various mound materials, disturbance, direct human interference and the lower overall brush-turkey density. It is thought that most of the birds that arrive and set up territories are probably young males that are unable to compete and establish territories in the more traditional forest patches. While males of this species tend to remain on or by the mound much of the time, females visit the mound only for copulation and egg-laying, and so are much less likely to become tame, which may be a further factor in the low success of some mounds that are exposed to particularly high levels of disturbance.

The irony of this situation now is that the species would appear to be expanding, although this may be a false impression, given the high hatching failure. However, at the same time in the Brisbane area as a whole the species is increasingly threatened, as the projected development of several forested areas is liable to mean the loss of some of the most suitable patches of habitat in the whole of Greater Brisbane.

Archaeology and ornithology recently combined to solve a long-standing mystery. In northern Australia, in Arnhem Land and the Cape York Peninsula, a series of large mounds made mainly of earth and shells can be seen. The presence of shellfish refuse and some bone and stone artifacts in these mounds led scientists to the conclusion that they had been built by Aborigines, although nobody could produce a satisfactory answer as to how they were built or why. However, a recent re-examination of the material and comparison with similar, rather more recent sites shows that they are probably very old mounds of the Orange-footed Scrubfowl. The birds had built their mounds alongside earlier Aborigine sites, and had simply incorporated their rubbish into the mounds.

Status and Conservation

In the last decade or so, extensive research has been carried out on this hitherto poorly known family, mostly by members of the Megapode Specialist Group, which operates under the auspices of BirdLife International, the World Pheasant Association and the Species Survival Commission. Studies have been performed into many aspects of the breeding biology, ecology, taxonomy and conservation status of megapodes. Although the majority of this work not surprisingly continues to concentrate on those species found in Australia, there has been a concerted effort to improve coverage of the large number of poorly known species occurring elsewhere. Nevertheless, three whole genera, *Aepyodius*, *Talegalla* and *Eulipoa*, still remain virtually unknown in most of these aspects.

As part of the recent Conservation Assessment and Management Plan (see page 472), the status of each megapode species was individually reviewed. The Megapode Specialist Group had, in fact, already been investigating many of the lesser known species for some time, but the CAMP initiative has helped to clarify the situation. The results are alarming, if not altogether surprising. Whereas the IUCN Red List includes eight species as threatened, the reappraisal, using the new Mace-Lande categories (see page 19), concluded that a total of 11 of the 19 species should currently be classified as threatened. In addition, two races that may actually merit treatment as full species are also reckoned to be at risk. This compares most unfavourably with the 1978/79 Red Data Book, which listed only the Maleo and the two races of the Micronesian Scrubfowl; all three are still threatened.

The threats are essentially the same for all megapodes, although the case of the Malleefowl is, yet again, slightly different. Given the distribution and typical habitat of the family, it comes as no surprise that reduction in the extent of suitable habitat available is one of the chief threats in most cases. In its different forms it can be classified as habitat destruction, degradation or conversion, but in the long run it all comes down to habitat loss. Most megapodes are almost exclusively forest-dwellers, so they are directly affected by the unremitting forest destruction that the whole region is suffering. If the most widespread and persistent logging is perhaps in Indonesia, this is probably only because the Philippines have already suffered even greater ravages. Of the eight species that are still considered to be secure, four occur only on New Guinea and one exclusively in Australia, while one more is found extensively on these two great landmasses. The remaining two species, the Dusky and Melanesian Scrubfowl inhabit island groups in the vicinity of New Guinea, the former occurring in the north Moluccas and West Papuan islands, and the latter in the Bismarck Archipelago and the Solomons. Thus, it is the species in the core area that are generally the most secure, while the species with more marginal distributions are amongst those most at risk: the Maleo and the Nicobar, Philippine and Sula Scrubfowl in the west; the Micronesian Scrubfowl in the north; the Polynesian and Vanuatu Scrubfowl in the east; and the Malleefowl in the south.

Nor does the situation of the "secure" species leave room for complacency. Indonesia's fast escalating population and the associated transmigration schemes, together with Japan's insatiable demand for timber, suggest that the huge tracts of forest on New Guinea that are still largely undisturbed may soon be under threat. Also, there is very little hard information regarding the abundance of these species, and large proportions of their estimated total populations are the result of tentative extrapolations. Extensive surveys of all of the species found on New Guinea would be very welcome, and would be a starting point on which to base the subsequent monitoring of populations.

The second significant threat to megapodes in general is exploitation by human populations, mainly in the form of egg-collecting. There is a very long history of such exploitation, and it has probably already caused the loss of some species on Pacific islands. Where species have managed to survive in spite of exploitation, it was often due to their protection from over-

Remarkably, the *Sula* Scrubfowl was unknown in the wild until the 1980's, with only a few specimens collected for museums as proof of its existence. Recent surveys of the *Sula* and Banggai Islands, which together make up the entire range of the species, have shown that it is still quite common in parts of the former and widespread in the latter. However, with the large-scale commercial logging operations that are going on in these islands, for the time being the future of this species can not be regarded as secure.

[*Megapodius bernsteinii*,
Sula Islands.
Photo: M. Indrawan]

exploitation by local traditions (see Relationship with Man). The breakdown of these traditions, in conjunction with rapidly increasing human populations has already led to many local extinctions and is now jeopardizing the survival of several species.

The other main threat facing many members of the family is that of introduced predators, which can, of course, be related to exploitation by humans. Megapodes, like most other animals, have a series of natural predators, including monitor lizards which excavate the eggs, and birds of prey which take chicks and, on occasion, adults, but the balance of nature generally keeps the effects of such predators in check. On the other hand, there is no such allowance for introduced predators, especially cats, dogs and foxes, but perhaps also mongooses, rats and even snakes in places. While no megapode species is known to be at risk exclusively due to this factor, it is often a secondary cause that exacerbates the effects of either or both of the other principal threats.

Sadly, the first species to be studied in detail and brought to the public attention, the Malleefowl, is now considered to be threatened, and it numbers only a few thousand pairs. It used to be widespread throughout much of southern Australia in suitable habitat, most notably in mallee scrub, and it occurred at least as far north as Alice Springs in Northern Territory. Shooting by white settlers may have caused an initial decline, and it is also reckoned that the more static lifestyle which was forced upon Aborigines may have led to more concerted exploitation and local declines.

However, the main factors in the long run have undoubtedly been those affecting the species' habitat, which has suffered extensive agricultural conversion, generalized degradation and an alarming degree of fragmentation. Over the last century or so, there has been extensive clearing of the mallee to make the land suitable for the cultivation of wheat, and optimum areas of mallee with higher rainfall have mostly been cleared. The species is now rare or absent over about 80% of its former range, and the only remaining areas of mallee extensive enough to support viable populations are in Victoria and South Australia. In New South Wales, for example, the range does not appear to have shrunk, but the population is now extremely fragmented. The situation of the

species in Western Australia is very poorly known, although the species may be widespread in a slightly different type of woodland habitat.

In tandem with agricultural development is the expansion of livestock farming. Large areas of suitable habitat are stripped down by domestic herbivores, especially sheep and to a lesser extent goats, but probably also by rabbits. These exotic species feed heavily on much the same plants that constitute the Malleefowl's diet, and by sheer weight of numbers are driving the birds back. Food availability is known to be of great importance to Malleefowl, and its scarcity is a major factor in chick mortality (see Breeding). Where sheep have been allowed to graze in undisturbed stretches of mallee, Malleefowl density has been seen to decline notably and populations have slumped by 80-90% in some areas.

Another significant threat to this species is fire, which regularly has an integral role in the regeneration process of such Mediterranean-type ecosystems as the mallee. In recent years, major bushfires have become increasingly frequent in south-eastern Australia, with the result that the habitat does not have sufficient time to recover fully. Recently, the scale of devastation that such fires can cause in many parts of Australia was amply demonstrated by one that raged uncontrollably through Sydney in late 1993. Man also puts fire to his use, and on occasions has sparked off some of the most serious of all bush fires. One of the commonest uses is "controlled" burning of an area with the aim of improving the grazing for livestock, but in many areas this has been carried too far, so that the natural habitat is very seriously damaged. Unfortunately, the prime habitat for the species is of the most inflammable type, as the birds require an ample supply of plant litter for their mounds, so such optimum areas tend to lie thick in suitable dry fuel. Research has shown that Malleefowl reach their greatest densities in stands of mallee that have not suffered the effects of fire for over 60 years. However, in one of the strongholds of the species in Victoria, almost all of the habitat has been burnt since about 1960, and more than one third of it since about 1980. In combination with the already alarming rates of habitat loss and fragmentation, fire can suddenly wipe out whole populations, which then have virtually no chance of natural recolonization.

Another major factor in the decline of the species seems to be predation. There is a degree of natural predation by birds of prey and dingoes, but nowadays there are also two significant introduced predators. European foxes raid the mounds to dig up the eggs, and they have been found to account for as much as 37% of all eggs. They have also been found to cause mortality of up to 61% of the chicks. Feral cats also take some chicks, and will even occasionally take adults at their mounds. One of the first steps towards safeguarding the Malleefowl would be the elimination, or at least drastic reduction and control, of these introduced predators.

Until fairly recently, the species was thought to be reasonably common and secure, but it now seems that this was due, at least in part, to the fact that it is rather conspicuous and it could regularly be observed at several well known sites. The extreme fragmentation of the Malleefowl's habitat has several serious consequences. Contact is lost with other populations, so that recruitment from outside is impossible, which in turn leads to inbreeding and lower fertility. At the same time there is insufficient room for young birds to establish themselves, so those that manage to survive mostly have to move off to sub-optimum habitat, where the chances of breeding success are correspondingly lower. Finally, the process increases the risk of extinction of individual populations due to catastrophes, natural or man-induced.

In response to the alarming situation, the species has been afforded full protected status. Another important step has been the creation of a series of special mallee reserves, designed to conserve not only this unique species, but also its unique habitat, and scientists are examining the best possible ways of securing such areas against fire. At the same time, a captive breeding programme is in progress, with a view to the possibility of making reintroductions in New South Wales and South Australia, when and where appropriate.

In looking over the rest of the megapodes, it is noteworthy that, despite the recent attempts to establish the status of all species, even now virtually nothing at all is known about Bruijn's Brush-turkey. This species is only known to occur on the island of Waigeo, off north-west New Guinea, although on occasion it has been suggested that it might also occur on other West Papuan islands. Recent visits to Waigeo have been frustrating, as practically the only information obtained was a limited amount of hearsay from local villagers. As the species occurs in forest in the rugged, impenetrable karst interior of the island, it has proved extremely difficult to make any progress in the knowledge of this species, as the initial problem of actually managing to observe an individual has proved unsurmountable. Indeed, with only one specimen collected during the whole of the present century, the question was even raised as to whether or not the range of the species really was Waigeo.

The mere inaccessibility of the habitat does at least imply that the species is likely to be less subject to human interference than other megapodes at present, but there is now a threat that Waigeo might be opened up to cobalt mining. Were this to take place, access would inevitably be afforded to deposits in the interior of the island, presumably resulting in habitat destruction on an unpredictable scale and exploitation of the megapodes and their eggs by mine and ancillary workers. The extremely restricted range of the species suggests that it would probably be highly vulnerable to any form of exploitation.

Several other threatened species are also very poorly known, but steps are being taken to improve the overall coverage. In order to assure the survival of any threatened species, an adequate knowledge of its life history is essential, so that the satisfaction of habitat, feeding and breeding requirements, in particular, can all be guaranteed. One of the latest species to receive attention has been the Sula Scrubfowl, a species that until recently was unknown in the wild, but which has now been the object of initial survey work. The species was found to be relatively common on the island of Taliabu in areas of selectively logged forest. However, it suffers considerable, though irregular, hunting pressure, and the surroundings of some mounds are festooned with snares. It

seems that the periods of most intensive trapping coincide on the one hand with bad weather, when fishermen can not put out to sea, and on the other with school holidays, when many small children set their snares. It is interesting to note that here the islanders do not appear to exploit the birds' eggs. This species, and others like it, require the setting up and active preservation of a series of protected areas, as well as effective enforcement of the legal protection that it has theoretically enjoyed since 1931.

The status of the Nicobar Scrubfowl was until recently a matter of some confusion, as the species was first assumed to be fairly common, and then thought to be in serious decline, probably due to habitat loss and overexploitation. There was very little information to go on, partly because the Indian authorities did not concede visas to foreigners to visit the islands. However, in early 1992 access to the islands was permitted to R. Dekker, the first foreign scientist to visit the islands at any rate since the 1940's. Dekker found that over 80% of the main island of Great Nicobar was still covered in undisturbed primary forest, while surveys showed the species to be relatively common, apparently suffering only limited exploitation. Most importantly, over 500 km², roughly a quarter of the island, was designated for two national parks. Further surveys will indicate whether or not this species could be removed from the threatened list.

Although the Moluccan Scrubfowl overlaps extensively with the Dusky and Orange-footed Scrubfowl, and has a total range of comparable size with that of the former, it might be the most threatened of all megapodes, whereas the latter two species are considered to be secure. Perhaps even more surprising is the fact that in areas of overlap it is the Moluccan Scrubfowl that tends to occur at higher altitudes than the *Megapodius* species. While the lowland forest is invariably the first to be logged or disturbed, it seems that for some unknown reason the *Megapodius* species are both better able to withstand a certain degree of habitat disturbance, perhaps simply because they have a longer history of closer contact with humans. Nevertheless, it seems more likely that the key to the difference in status may lie in the fact that the Moluccan Scrubfowl is mainly a communal burrow-nester on sandy beaches, whereas the other two are habitually mound-builders. Once a communal laying site has been discovered by man, it can apparently be wiped out in a very short time by intensive egg-collecting. Although the status of this species is imperfectly known, and current opinion is perhaps based less on negative data than on the absence of positive data, along with the Maleo it should serve as a warning for the case of the still abundant Melanesian Scrubfowl, which is locally suffering very high levels of egg-collecting (see Relationship with Man).

The presence of megapodes in the Pacific was indicated by an egg purchased in Samoa in 1847, but it was not until 1864 that the Polynesian Scrubfowl was described, from the Tongan island of Niuafo'ou to which it is endemic. Only 40 years later, the species was nearly wiped out by the last steam blast eruption that rocked the island in 1886. It has been suggested that the megapode incubation system with the eggs buried under the ground for some two months before hatching might have been an important factor in the survival of the species, as it might have enabled the eggs to remain relatively unaffected by the heat and poisonous gases. However, the population had been greatly diminished, and around this time local chiefs imposed a ban on the collection of eggs and hatchlings, until the species recovered.

The actual size of the current population is not well known, but while one estimate put it as low as about 200 birds, another suggested at least 800; the latest estimate is of some 200 pairs. The species suffers regular egg-collecting and also predation by cats, which lie in wait for the females as they emerge from their laying burrows, but the inaccessibility of many nesting sites, at any rate to humans, acts as some kind of a safeguard. The most serious threat is probably the fact that the entire population of the species is restricted to a single volcanically active island; another eruption could exterminate it. With this in mind, in 1968 a few birds were released on Tafahi, another

Egg-collecting is one of the chief threats facing several megapode species, in particular all those that lay at communal sites. The Maleo has suffered more than most, with almost all of its known laying sites either abandoned or threatened. In response to this serious decline, major conservation work has been undertaken in recent years, including a series of measures designed to promote public awareness and involve local human populations actively in the conservation of this unique species.

[*Macrocephalon maleo*,

island in the Tonga group, which is formed of a steep volcanic cone. However, subsequent visits indicate that the scrubfowl apparently failed to establish itself. A further threat loomed in 1991, when the Tongan government was considering a project to build a crude oil depot on Niufo'ou. It was considered that the approval of these plans would almost inevitably lead to the extinction of the Polynesian Scrubfowl. Fortunately, however, the plans seem likely to be dropped.

One of the most distinctive, and also one of the most threatened, megapode species is the Maleo, a representative of the peculiar endemic fauna of Sulawesi. The species is still fairly widespread, mainly in the north of the island, but it suffers greatly at the hands of egg-collectors. Maleos lay communally on beaches or in areas influenced by geothermal heat. Surveys over recent years have come across several new laying sites, but as fast as these sites are discovered others are being deserted by the birds, and some of the newly located sites are already overexploited. In 1992, a total of 85 sites were known, of which 22 had already been abandoned and 51 were active, while the status of the remaining 12 was unknown. However, of the active sites all but one or two were severely threatened. The largest known concentrations were recorded in the early 1980's at Bakiriang in east Sulawesi, where up to 100 birds were seen on a single morning. Subsequently this laying site was thought to have been abandoned due to habitat destruction, related to a nearby transmigration settlement, but birds were present again by 1991, when some 40 were seen together.

Although the collection of Maleo eggs is illegal, the law is not enforced. At the same time, other factors are known to be having a significant negative impact on the species, including logging, disturbance, predation by village dogs and trapping. Many steps have already been taken to combat the rapid decline of the Maleo, and the species is now the object of a major conservation programme. This involves a good deal of survey work and research, but perhaps most importantly a public awareness campaign, designed to reach people through posters, leaflets and newspaper articles, and even publicity of the project on television. Another conservation move made in recent years is the setting up of artificial hatcheries. Megapode eggs can be incubated fairly easily, especially at hatcheries alongside

laying sites, and as the chicks require no parental care, this is a relatively easy way of bolstering natural populations, in which recruitment has presumably decreased notably.

Another measure could prove to have important implications for this and other megapode species. Communal laying grounds might be suitable sites for the promotion of wildlife tourism, with small parties of tourists being accompanied to a position at a prudent distance, from which to watch and possibly photograph the birds excavating their burrows prior to laying. However, any such initiatives must be carefully planned and co-ordinated, with strict control and vigilance. Ecotourism is potentially one of the few ways of using wildlife to boost local economies without necessarily causing harm or undue disturbance to the wildlife itself. However, unless it is properly planned and managed it can often be just as damaging as many forms of direct exploitation, as has been seen at seabird colonies and the laying beaches of marine turtles. Equally, the system is most unlikely to succeed if it does not actively involve members of the local human population, and all too often such concerns are set up and run by incomers in search of quick profits. Another important consideration is that there would be little use in preserving a laying beach if the appropriate foraging habitat of the hinterland were not integrated into the same conservation measures. Notwithstanding these strict limitations, this projected scheme may have the potential to provide security for several species.

Genus *ALECTURA* Latham, 1824

1. Australian Brush-turkey

Alectura lathamii

French: Talégalle de Latham **German:** Buschhuhn **Spanish:** Talégalo Cabecirrojo
Other common names: Australian Scrub-turkey/Bush-turkey, Wild Turkey(!); Purple-pouched Brush-turkey (*purpureicollis*); Yellow-pouched Brush-turkey (*lathamii*)

Taxonomy. *Alectura lathamii* J. E. Gray, 1831, near Sydney, New South Wales. May be most closely related to *Aepyodius*, as suggested by some similarities in behaviour at mound, extensive brightly coloured bare skin with adornments on neck, round nostrils and white eggshell. Two subspecies recognized.

Subspecies and Distribution.

A. l. purpureicollis (Le Souëf, 1898) - N Queensland.

A. l. lathamii J. E. Gray, 1831 - C & S Queensland, NE New South Wales.

Introduced to Kangaroo I (off South Australia), where still survives; also to Dunk I (off EC Queensland), where may persist; in past, released at Kaipara in N North Island (New Zealand), but species failed to become established.

Descriptive notes. 60-70 cm; male averages 2450 g, female 2210 g. Unmistakable within range, due to large size, brightly coloured bare skin and mostly black plumage with whitish scaling on most of underparts. Largest megapode: considerable size variation, perhaps clinal or individual, with largest birds in S. Colour of head and neck can be much brighter during courtship, generally much duller outside breeding season, when pouch shrinks. Iris pale brown to yellow or cream. Female averages slightly smaller; has very small neck pouch. Race *purpureicollis* has pouch pink to purple; iris tends to be paler.

Habitat. Typically occurs in closed areas of rain forest along coast, in tropical and warm temperate zones; also found in wide variety of other habitats, including dry sclerophyll woodland, gallery forest, eucalypt forest and swamp woodland. Main preference may be for dense understorey, as frequently occurs in areas with extensive growth of introduced lantana (*Lantana camara*); often found along dry creeks; tends to build mounds in areas with closed canopy and sufficient supply of leaf litter (not normally *Eucalyptus*). Increasingly occupies disturbed habitats and even city suburbs, where will build mounds in public and private gardens (see page 298); forms feeding flocks at rubbish dumps.

Food and Feeding. Very poorly known. Omnivorous, with apparent preference for plant food, but no quantitative analyses performed. Seeds, grain, shoots, roots, fruit and berries of many species recorded. Animal food includes gastropods, worms, insects and their larvae; carrion also recorded. Normally scratches for food in leaf litter; takes fruit of prickly pear (*Opuntia*) in flight (see page 286); excavates and feeds on roots of *Aracaria cunninghamii*, causing damage to plantations; also recorded digging termites out of rotten wood. Young chicks feed mainly on invertebrates at first, before progressing onto seeds.

Breeding. Mound-building starts May-Jun (winter) in SE Queensland; mounds abandoned Jan-Feb. Males simultaneously polygynous, females serially polyandrous; females tend to be loyal to single male for several weeks. Mound-builder. Mound built by male in c. 37 days (14-77); typically contains damp leaf litter and earth, sometimes with other debris; average 85 cm high x 300-400 cm across, containing 2-4 t of material, although average 6-8 t on Kangaroo I, where species introduced; mound temperature relatively stable at c. 31°-36°C (average 33-3°C), with limited regulation. Several females may lay in any one mound, which is property of single male; males may tend two active mounds; up to 58 eggs (average 12) laid in single mound per season. Each female can lay 15-27 eggs in a season. Incubation 47-52 days (in captivity). Chick has soft brown down and well developed wing feathers; weight at hatching c. 120 g, at 20 days 200 g, at 50 days 460 g, at 100 days 1300 g, at 200 days 2100 g. Hatching success of 86-6% recorded (499 eggs), but only 3-10% survived to subadult stage.

Movements. Sedentary. Males remain within home range all year round and in successive years; home range considerably larger during breeding. Sporadic records outside normal range probably refer mostly to escapes or (illegal) translocations.

Status and Conservation. Not globally threatened. Mace-Lande: Safe. Total population reckoned to be stable at over 100,000 individuals. Main problem is clearing of forested areas, which has reduced distribution, especially W of Great Dividing Range; also fragmentation of habitat, and in past hunting, which have caused some local extinctions; around 1902, almost exterminated by shooting from Murphy's Creek area (SE Queensland), where previously common. Early in present century, when prickly pear spread far inland, present species expanded range correspondingly, as used succulent parts of fruit for mound material in arid areas; with control and eventual removal of plant, birds retreated into traditional range. During same period, significant contractions in southern parts of range. Recently expanding into suburban parts of Brisbane, SE Queensland, where frequently comes into conflict with human population (see page 298). Predators include cats, foxes, dogs and dingoes; probably some disturbance of mounds and predation of eggs and chicks by pigs and perhaps also snakes and lace monitors (*Varanus varius*). In 1936 single pair introduced to Kangaroo I (off South Australia), where species continues to flourish. Captive population numbers c. 250 birds.

Bibliography. Balun (1969), Birks (1990, 1991, 1992), Booth (1985, 1989b), Brookes (1919), Coles (1937), Delacour (1935), Dow (1980, 1988a, 1988b), Fleay (1937), Jacobs (1970), Jones (1979, 1985, 1987a, 1987b, 1988a, 1988b, 1988c, 1989b, 1991a, 1990b), Jones & Everding (1991), Kaveney (1958), Keys (1990), Marchant & Higgins (1993), Schodde & Tidemann (1988), Seymour (1991), Seymour & Bradford (1992), Seymour & Rahn (1978), Suttie (1965), Troy & Elgar (1991), Vleck *et al.* (1984).

Genus *AEPYPODIUS* Oustalet, 1880

2. Wattled Brush-turkey

Aepyodius arfakianus

French: Talégalle des Arfak **German:** Kammtalegalla **Spanish:** Talégalo Carunculado
Other common names: Wattled Scrub-turkey

Taxonomy. *Talegallus arfakianus* Salvadori, 1877, Arfak Mountains.

Wattles of bare skin on neck and solitary behaviour at nesting mound may imply species is more closely related to *Alectura* than to *Talegalla*, although breeding habits of latter virtually unknown. Two subspecies recognized.

Subspecies and Distribution.

A. a. arfakianus (Salvadori, 1877) - mountains of New Guinea.

A. a. misolensis Ripley, 1957 - Misool I (off NW New Guinea).

Descriptive notes. 38-46 cm; male 1600 g, female 1200 g. Dark reddish brown rump and uppertail-coverts; legs and feet bluish grey to olive brown. Bright reddish comb and neck wattle of male duller outside breeding season. Female smaller, with duller colouring on head and smaller wattles. Race *misolensis* smaller, with thinner bill.

Habitat. Montane forests at 750-2800 m. Race *misolensis* occurs at much lower altitudes, around 300 m.

Food and Feeding. Fallen fruits and seeds; probably also insects. Ingests large amounts of small stones to help break down food.

Breeding. Apparently during most of year, with eggs from all months except Jul, Aug and Nov. Mound-builder. Mound is usually fairly steep-sided heap of leaves and twigs, c. 300 cm wide and 150-180 cm high; mound may be property of male. In captivity: mound built by male; 20 eggs laid by single female in c. 4 months, at intervals of c. 6 days; eggs laid in mounds with temperature of 29.4°-34.3°C. Mounds parasitized by *Megapodius* (?affinis) in SC New Guinea. Chick weighs 115-125 g at hatching.

Movements. Presumably sedentary. Normally solitary or in pairs. When disturbed, tends to fly up into tree.

Status and Conservation. Not globally threatened. Mace-Lande: Safe; *misolensis* possibly vulnerable. Total population of species possibly numbers 10,000-1,000,000 individuals; thought to be stable, and no significant threats known. In Irian Jaya (W New Guinea), widespread and fairly common, but thinly distributed and little known; uncommon in Papua New Guinea; may occur on Yapen I. Regularly encountered in suitable habitat, although inconspicuous. Suffers from intensive egg-collecting, and casual hunting of adults, but thought to be secure in areas where human population is sparse. Legally protected in Indonesia. Captive population numbers c. 10 birds. Race *misolensis* suffering from habitat destruction; may number 100-10,000 birds at present, but extensive survey work required in order to gain more accurate idea of population size and extent of threats.

Bibliography. Anon (1986), Bechler *et al.* (1986), Coates (1985), Diamond (1972), Dwyer (1981), Flieg (1970), Holmes (1989), Kloska (1986), Kloska & Nicolai (1988), Mayr (1930), Parker (1967), Ripley (1960, 1964), Rohlf *et al.* (1985).

3. Bruijn's Brush-turkey

Aepyodius bruijnii

French: Talégalle de Bruijn **German:** Braunbrustalegalla **Spanish:** Talégalo de la Waigoe
Other common names: Waigoe Brush-/Scrub-turkey

Taxonomy. *Talegallus Bruijnii* Oustalet, 1880, Waigoe. Monotypic.

Distribution. Waigoe I, to NW of New Guinea.

Descriptive notes. 41-46 cm. Male has three pendant wattles on neck. Brown underparts; legs and feet very heavy. Female and immature lack neck wattles.

Habitat. Evergreen forest in rugged karst interior of island.

Food and Feeding. No information available.

Breeding. No information available. Thought to be mound-builder.

Movements. No information available. Presumably sedentary.

Status and Conservation. RARE. Mace-Lande: possibly Endangered. Total population possibly numbers as few as 100-2500 individuals.

ails; trends and potential threats unknown. Virtually no information available; extensive survey required, and preservation of habitat must be guaranteed. Only one bird collected during present century; in past, absence of records led to considerable doubt as to whether or not range of species was really Waigoe I. Recent opinion suggests species may be less seriously threatened than usually suspected, as interior of Waigoe is extremely inaccessible to humans. Habitat apparently remains intact, but very little solid proof, and considerable damage caused by forest fires in 1982; c. 153,000 ha (almost half of Waigoe I) currently included in nature reserve. Threats of logging and interference by visiting fishermen thought to be of minor consequence; cobalt reserves on Waigoe could be

source of problems in future. Possible record from nearby Batanta I (to S) in 1986. No birds known to be held in captivity.

Bibliography Bechler *et al.* (1986), Collar & Andrew (1988), Holmes (1989), Mayr (1930), Meyer de Schauensee (1940), Rand & Gillard (1967).

Genus *TALEGALLA* Lesson, 1828

4. Red-billed Brush-turkey

Talegalla cuvieri

French: Talégalle de Cuvier **German:** Rotschnabeltalegalla **Spanish:** Talégalo de Cuvier
Other common names: Red-billed Scrub-turkey

Taxonomy. *Talegalla Cuvieri* Lesson, 1828, forests of New Guinea = Manokwari.

Genus sometimes misspelt *Talegallus*. Monotypic.

Distribution. Salawati I, Misool I and NW New Guinea E to Mimika R and Geelvink (Cenderawasih) Bay.

Descriptive notes. 45-56 cm. Black all over, with orangish red bill and pale orange legs and feet; bare skin on face pale greenish yellow; iris yellow.

Habitat. Forested areas in lowlands and hills, occurring up to 1600 m. In zones of overlap with *T. fuscirostris*, present species occupies higher ground.

Food and Feeding. No information available.

Breeding. Female in breeding condition collected in Nov on Misool I. Mound-builder. Chick dark brown, with chestnut collar.

Movements. Presumably sedentary. Flies heavily into trees when disturbed.

Status and Conservation. Not globally threatened. Mace-Lande: possibly Vulnerable. Total population might number 1000-100,000 individuals; currently thought to be in decline. Until recently regularly encountered in suitable habitat, and species was thought to be secure in areas where human population was sparse. Suffers from intensive egg-collecting, and casual hunting of adults, but main threat now is degradation of habitat. Extensive surveys required. No birds known to be held in captivity. Protected by Indonesian law.

Bibliography Bechler *et al.* (1986), Bergman (1963), Dekker (1991b), Diamond (1972), Holmes (1989), Mayr (1930), Ripley (1960, 1964).

5. Black-billed Brush-turkey

Talegalla fuscirostris

French: Talégalle à bec foncé **German:** Schwarzschnabeltalegalla **Spanish:** Talégalo Piquinegro
Other common names: Yellow-legged Brush-turkey, Black-billed Scrub-turkey

Taxonomy. *Talegallus fuscirostris* Salvadori, 1877, Epa and Hall Sound, New Guinea. Two subspecies recognized.

Subspecies and Distribution.

T. f. occidentis C. M. N. White, 1938 - Aru Is: SW New Guinea.

T. f. fuscirostris Salvadori, 1877 - SE New Guinea.

Descriptive notes. 51-53 cm; 1275-1330 g. Greyish black bare skin on side of head; iris brown to reddish brown; bill ranges from very dark brown to black; pale greenish yellow legs and feet. Juvenile is smaller, duller version of adult, with brownish patch on hindneck. Race *occidentis* smaller.

Habitat. Rain forest, monsoon forest and sometimes gallery forest, mostly in lowlands but up to 800 m or possibly higher in places; known to occur in areas of disturbed forest. Altitudinal segregation apparently operates in areas of overlap with *T. cuvieri* in W of range and with *T. jobiensis* in E, present species occurring at lower altitudes. In many areas sympatric with *Megapodius reinwardi*, sometimes breeding in close proximity. Normally breeds on dry, level ground.

Food and Feeding. Insects, grubs and fallen fruits; may take small lizards. Occasionally drinks from forest pools during dry weather.

Breeding. Laying apparently all year round; evidence suggests possible peaks in wet season in lowlands, but in dry season at higher altitudes of 700-800 m. Mound-builder. Mound consists mainly of dead leaves, as well as some sticks, usually placed at base of large tree; mounds fairly flat, measuring up to c. 700 cm x 540 cm and 60-100 cm high. Mound thought to be used for few years, and then abandoned. Chick uniform dark brown, with yellowish ochre throat and centre of belly.

Movements. Presumably sedentary. Mostly seen singly or in pairs; usually runs away, but occasionally flies off high through trees. In one area of rain forest in lowlands, density of 3 birds/10 ha recorded, though no evidence of breeding.

Status and Conservation. Not globally threatened. Mace-Lande: Safe. Total population might number 10,000-1,000,000 individuals, but declining. Widespread and common in Irian Jaya (W New Guinea), widespread and fairly common in Papua New Guinea; regularly encountered in suitable habitat. Main threats are conversion and degradation of habitat; suffers from intensive egg-collecting, and casual hunting of adults, but species thought to be secure in areas where human population is sparse. In Papua New Guinea, wherever human population sizeable, species rapidly exterminated by hunters. Legally protected in Indonesia. No birds known to be held in captivity.

Bibliography Bechler *et al.* (1986), Bergman (1963), Coates (1985), Dekker (1991b), Diamond (1972), Holmes (1989), Mayr (1930), Ripley (1964).

6. Brown-collared Brush-turkey

Talegalla jobiensis

French: Talégalle de Jobi **German:** Halsbandtalegalla **Spanish:** Talégalo Patiritojo
Other common names: Collared/Red-legged/Brown-billed Brush-turkey

Taxonomy. *Talegallus jobiensis* A. B. Meyer, 1874, Jobi (Yapen) Island.

Two subspecies recognized.

Subspecies and Distribution.

T. j. jobiensis A. B. Meyer, 1874 - Yapen I; NC New Guinea.

T. j. longicauda A. B. Meyer, 1891 - E New Guinea, W to R Sepik and possibly R Aroa.

Exact limits of range uncertain in many areas. Several records of *Talegalla* in CE New Guinea; identity uncertain, but may well refer to present species.

Descriptive notes. 53-61 cm. Dark reddish tinge on bare skin of face and neck; legs and feet orange to dull red; reddish brown collar; iris brown; bill brown. Race *longicauda* slightly larger.

Habitat. Forested zones from sea-level up to 1800 m; seems to prefer dry ground, and tends to avoid areas of swamp forest; in higher parts of range, often found in ravines. In area of R Aroa (SE New Guinea) assumed to occur at higher altitudes than *T. fuscirostris*. Roost recorded c. 8 m up in large forest tree; copious droppings on ground below.

Food and Feeding. No information available.

Breeding. Female in breeding condition collected in Sept in NC New Guinea. Mound-builder; also said to be parasitic. Mound flat and wide, sited between large trees; alternatively, very large heap of humus measuring 100-450 cm wide x 150 cm high; mound temperature c. 32°-36°C. Usually used by pair, once by 3 birds. Said to parasitize mounds of *Megapodius affinis* in NC New Guinea, but inverse seems far more likely, and probably recorded in SC New Guinea (see page 290). Much predation of eggs by monitor lizards (*Varanus*). Chick weighs 125 g at hatching, 292 g at 6 weeks old.

Movements. No information available. Presumably sedentary.

Status and Conservation. Not globally threatened. Mace-Lande: Safe. Total population might number 10,000-1,000,000 individuals, but declining. Regularly encountered in suitable habitat; common and widespread in Irian Jaya (W New Guinea). Main threats are conversion and degradation of habitat; some protected areas should be designated; suffers from intensive egg-collecting, and casual hunting of adults, but species thought to be secure in areas where human population is sparse. In Papua New Guinea, wherever human population sizeable, species rapidly exterminated by hunters. Legally protected in Indonesia.

Bibliography Bechler *et al.* (1986), Bergman (1963), Coates (1985), Dekker (1991b), Diamond (1972), Dwyer (1981), Holmes (1989), Mayr (1930), Ripley (1964).

Genus *LEIPOA* Gould, 1840

7. Malleefowl

Leipoa ocellata

French: Léipoa ocellé **German:** Thermometerhuhn **Spanish:** Talégalo Leipoa
Other common names: Lowan

Taxonomy. *Leipoa ocellata* Gould, 1840, Swan River, Western Australia.

E populations sometimes split off into separate race, *rosinae*. Monotypic.

Distribution. SW & S Australia E to NW Victoria and EC New South Wales. Introduced to Kangaroo I (off South Australia), where probably now extinct.

Descriptive notes. c. 60 cm; male 2020-2050 g, female 1520-2050 g. Most distinctive megapode, with pale, patterned plumage; flattened crest. Female averages slightly smaller and lighter than male. Immature similar to adult but smaller.

Habitat. Woodland and scrub of semi-arid areas in temperate zone, especially areas dominated by dwarf mallee (*Eucalyptus*), where annual rainfall totals 300-430 mm; less abundant in mallee with lower rainfall of 220-300 mm. Common in areas of mulga (*Acacia aneura*); also found in areas with other *Acacia* and *Callitris*, and in places occurs in dry

coastal heath. Optimum habitat apparently has near-complete canopy and often rich layer of shrubs, but is fairly clear at ground level. In NE Victoria, favours patches of tall broombush (*Melaleuca uncinata*) more than 30 years old. Abundant food required in immediate environs of mound, as male's attention to mound is almost perpetual during certain periods of year (see page 289).

Food and Feeding. Omnivorous, but probably mainly granivorous. Buds, flowers, fruits and seeds of shrubs, especially legumes; also seeds, flowers and leaves of herbs, especially seedlings. Other items recorded include fungi and wide variety of invertebrates, e.g. beetles, cockroaches, dragonflies, bees, ants, spiders; birds do not apparently search actively for invertebrates, which are simply taken whenever encountered. Observations in W New South Wales showed that birds fed on: buds, fruits and seeds (during 73% of observations), especially *Cassia eremophila*, *Acacia* and *Beyeria opaca* (58%); herbs (10%); and insects (17%). In Victoria, observed targets of pecks: 49% herbs; 37% lerps (*Glycyaspis*); 7% fungi (mostly *Myceana*); and 4% assorted invertebrates. In South Australia, dry weight of crop and gizzard contents gave: 53% seeds of *Dodonaea bursarifolia*; 41% seeds of *Cassia melanantha*; and 22% sand (ingested to help break down food). Considerable seasonal variation in diet: insects mainly in spring; herbs (autumn/winter/spring); buds (winter/spring); flowers (spring/early summer); and seeds (summer/autumn); buds and berries of

Beyeria opaca particularly important in spring and summer. Main food types are seeds of legumes in summer, but herbs in autumn and winter. Adults reckoned to require c. 37 g of seeds (300-2200 seeds) per day. Hatchlings can feed on insects on same day as hatching. See page 286.

Breeding. Mound-building starts Apr/May; laying starts mid-Sept/mid-Oct in W New South Wales. Generally monogamous, with strong pair-bond, but one record of polygyny. Mound-builder. Mound built mainly by male, using leaves, sticks, bark, debris and sand; foundation crater of mound c. 300 cm wide x 90 cm deep; mound temperature relatively constant at c. 29°-38°C (average 33°C), regulated mostly by male. Mound tended by male for 9-11 months per year; old mounds (of same or different pair) often dug out and reused, but normally after being left unused for 1 year or more. Single female normally lays 15-24 eggs (2-34) per season; eggs laid at average interval of 6-4 days (4-17); incubation averages 62-64 days (49-96). Chick has down above dark brown barred pale buff, below pale brown, with wing feathers well developed; weight at hatching c. 107 g, at 20 days 146 g, at 60 days 300 g, at 100 days 450 g, at 200 days 800 g, at 500 days 1580 g. Hatching success: 79% (for 289 eggs) in zone where no predation of eggs by foxes, though several adults eaten; 49.5% (for 1094 eggs) in area with heavy predation by foxes (37%); 51% (for 530 eggs) in area with limited predation by foxes (5.6%), but many eggs lost in saturated mounds (11%), and many infertile (14%); chick mortality assumed to be very high. Sexual maturity at 4 years old, in captivity.

Movements. Sedentary; male tends mound for 9-11 months of year, at times returning at hourly intervals. In area of low rainfall in South Australia: home range of c. 4 km²; density of 1-1 pairs/km². In area of higher rainfall (300-400 mm/year), in New South Wales, during breeding season: males remained within 100 m of mound, females within 250 m. Territory and mound normally abandoned by Apr, but often for little more than 1 month. Mounds rarely placed on same site during two successive years, but usually within radius of c. 500 m.

Status and Conservation. VULNERABLE. Mace-Land: Vulnerable. Total population numbers only 1000-10,000 individuals, and declining. Estimated populations: New South Wales c. 745 pairs; Victoria under 1000 pairs; no figures available for South Australia, but population reckoned to be small; Western Australia may have largest population, but little known. Formerly widespread in suitable habitat from Western Australia to New South Wales and NW Victoria; in 1920's and 1930's also bred as far N as Alice Springs (Northern Territory), and perhaps even further N; now absent or rare in 80% of range: population of SW Northern Territory probably now extinct; still declining in New South Wales; Victoria and South Australia contain only remaining areas of mallee extensive enough to support viable populations. Precarious status long ignored, because species locally conspicuous. In New South Wales, range has not apparently shrunk, but population now extremely fragmented; small remnants of mallee in wheatbelt, where species occurs at high densities; larger numbers, at much lower densities, in more intact areas to W, including contiguous reserves of Yathong, Round Hill and Nombinnie, totalling c. 250,000 ha, but most of this is suboptimal habitat; surveys at Round Hill Nature Reserve in 1979-1982 revealed population density of 0.03 pairs/km², as opposed to estimate from 1950's of 0.15-1.54 pairs/km². Main threats are destruction and fragmentation of habitat, effects of grazing livestock, fire and introduced predators. In second half of present century much loss of habitat due to conversion for agriculture; extensive clearing of mallee for wheatlands over last century or so; optimum areas of mallee with higher rainfall have mostly been cleared; large areas used for grazing by sheep, and in such areas population of present species found to drop by 80-90%; goats and rabbits also contribute to habitat deterioration. In NE Victoria, cyclical cutting of broombush for fencing material removes a favoured habitat of species; such patches also particularly threatened by periodical bush fires; excessive controlled burning of habitat to improve grazing. Many eggs taken by introduced European foxes (*Vulpes vulpes*) and significant predation by feral cats. Fragmentation of habitat leads to inbreeding, and increases risk of extinction of individual local populations due to catastrophes, natural or man-induced. Several special mallee reserves created; captive breeding in progress, with a view to reintroduction in New South Wales and South Australia. Extensive survey required, along with constant monitoring of populations; preservation and management of habitat necessary, especially with respect to fire risk; competing grazers should be controlled and, in places, removed; introduced predators should be eradicated. See page 299.

Genus MACROCEPHALON S. Müller, 1846

8. Maleo

Macrocephalon maleo

French: Mégapode maléo **German:** Hammerhuhn **Spanish:** Talégalo Maleo
Other common names: Maleofowl, Gray's Brush-turkey

Taxonomy. *Macrocephalon maleo* S. Müller, 1846, Sulawesi. Alternative genus name, *Megacephalon*, obsolete. Monotypic.

Distribution. N, C & SE Sulawesi, probably also Buton (Butung) I, off SE Sulawesi. Populations, probably introduced, formerly occurred off NE Sulawesi on Lembeh and perhaps Bangka, and also on several of Sangihe Is.

Descriptive notes. 55 cm. Unmistakable. Prominent dark bony casque. Salmon pink wash on lower breast and belly of variable intensity; thighs black, but sometimes obscured by belly feathers.

Habitat. Lowland and hill forest, with records up to 1200 m; descends to breed on beaches along coast or in forest clearings with sandy substrate; sometimes breeds on beaches backed by mangroves. Recently found laying eggs in black sand along shores of lakes. Of 85 laying sites known historically by 1992, 48 were on coast and 37 inland.

Food and Feeding. Known to feed on fallen fruits, insects and invertebrates. No further information available.

Breeding. Laying throughout year, with peak Oct-Apr in N Sulawesi; eggs May-Jul and Nov-Jan in SE Sulawesi. Apparently monogamous, maintaining pair-bond throughout year. Communal burrow-nester, using geothermal sites and also solar-heated beaches. Burrows up to 300 cm wide, and often over 100 cm deep; eggs typically buried 20-60 cm below surface; incubation 60-80 days, in soil

Status and Conservation. VULNERABLE. CITES I. Mace-Land: Vulnerable/Endangered. Total population probably numbers only 1000-10,000 individuals, and declining. Main body of population on Minahasa Peninsula (N Sulawesi); estimate from 1970's gave 3000 adults using 13 known breeding grounds; in mid-1980's, estimated 150-200 pairs each at Tambun and Tumokang in Dumoga-Bone National Park, where nine further laying sites known; by 1991 population at former had increased slightly. Some colonies known to have been exterminated during 1980's; several colonies recently discovered in C Sulawesi, but some threatened by habitat loss to agricultural development in association with transmigration, and two already being exploited, one for 40 years; new sites also found in S Sulawesi in 1989/90, but some already being exploited by villagers. In 1990/91, total of 34 sites surveyed, of which 25 previously unrecorded; most sites already abandoned or severely threatened by excessive egg-collecting, often by unauthorized persons. In 1992, total number of sites known 85, of which 22 abandoned, 51 active, and 12 unknown; 19 of the 22 sites abandoned were coastal; all but one or two of active sites severely threatened. Largest known concentrations at Bakirang (E Sulawesi) in early 1980's, with up to 100 birds recorded on single morning; this site subsequently thought to have been abandoned, due to habitat disturbance and destruction, but birds returned by mid-1991, and c. 40 seen together in Dec 1991; conservation initiatives here include artificial hatchery and protection of breeding grounds; colony may well manage to survive, and may be suitable as site for ecotourism. Throughout range, egg-collecting carried out by villagers, in many cases on excessive scale; intensive illegal egg-collecting by workers of rattan company, illegally working in protected forest of Dumoga-Bone National Park; habitat loss and fragmentation, overexploitation of eggs and general human population pressure all increasing; some predation by village dogs. Species is subject of major conservation project, with backing of ICBP, WWF, PHPA (Indonesian Nature Conservation Department) and University of Amsterdam; tasks include surveys of old and new sites and major public awareness campaign. Survey work should be continued and augmented; many populations require active management, with involvement of local people, and public campaigns of environmental education; preservation and management of habitat also necessary; more artificial hatcheries should be developed. Species protected by Indonesian law. Successfully bred in captivity at New York Zoological Society's Wildlife Survival Center (Georgia, USA) in 1988 and 1990.

Bibliography. Andrew & Holmes (1990), Argeloo (1992a, 1992b, 1992c), Baltzer (1990), van den Berg & Bosman (1986), Collar & Andrew (1988), Dekker (1988b, 1990b, 1993), Dekker & Argeloo (1992), Dekker & Brom (1990), Dekker & Wattel (1987), Holmes (1989), Indrawan (1992), King (1978/79), Kobayashi & Gurnaya (1993), MacKinnon (1978, 1981), Pramono (1991), Rifai & Soehjar (1976), Rozendaal & Dekker (1989), Sasaki *et al.* (1982), Stark (1988), Tarmudji (1978), Watling (1983), White & Bruce (1986), Winn (1992), Zieren (1985).

Genus EULIPOA Ogilvie-Grant, 1893

9. Moluccan Scrubfowl

Eulipoa wallacei

French: Mégapode de Wallace **German:** Molukkenhuhn **Spanish:** Talégalo de Wallace
Other common names: Wallace's Scrubfowl

Taxonomy. *Megapodius wallacei* G. R. Gray, 1860, east Halmahera.

Often included in genus *Megapodius*, but plumage fairly different from that of rather uniform members of that genus; secondaries said to be shorter than primaries in present species, but of equal length in *Megapodius*; breeding habits differ from those of most members of *Megapodius*. Monotypic.

Distribution. Moluccas, from Halmahera S to Buru and Seram; Misool I (off NW New Guinea).

Descriptive notes. c. 30 cm. Small size; has median and greater upperwing-coverts and feathers of mantle reddish tipped grey; greyish underparts contrast with white undertail-coverts; bill bluish grey to whitish, legs and feet dark olive.

Habitat. Forested areas in hills and mountains at 700-1950 m, occasionally inhabiting lowland forest, e.g. on Misool; comes down to coast to lay eggs in sandy beaches. In areas of sympatry, occurs at higher altitudes than *M. freycineti* or *M. reinwardti*. May be largely restricted to limestone habitats on Halmahera. On Seram occurs in undisturbed forest, but

recorded in coastal scrub; thought to be less tolerant of disturbance than *M. reinwardti*.

Food and Feeding. No information available.

Breeding. Laying Sept-Dec on Buru; Oct-Apr on Haruku. Communal burrow-nester, using solar-heated beaches; also thought to be parasitic, and even said to build mounds. Comes down by night to lay eggs in communal laying beaches.

Movements. Large communal nesting grounds on Haruku receive many birds flying in over sea at night, probably from nearby S Seram. Recorded only once on Misool I (off NW New Guinea), when two birds collected; some suggestions that these might have been vagrants.

Status and Conservation. RARE. Mace-Land: Endangered/Critical. Total population may number c. 10,000 individuals; declining. Main threat is overexploitation of communal laying sites, and

any colony could be wiped out by lone collector in single season; also suffering degradation and conversion of habitat throughout range. Large communal laying site on Haruku (off S Seram) estimated in 1991 to be used by as many as 4000-5000 pairs yearly; still protected by local tradition, with strictly controlled harvesting (see page 297). In contrast, communal laying site at Amahai (S Seram) used by increasingly fewer birds, as villagers take eggs indiscriminately; also habitat destruction here, with removal of gravel and sand for roads. Only one bird seen in two month survey of Manusela National Park, C Seram, in 1987. Said still to be common on Buru, but confirmation of this required. Rare on Halmahera; probably extinct on Ambon and Ternate. Extensive surveys required, along with monitoring of populations and intensive general research on species; public campaigns of environmental education also highly desirable. Protected by Indonesian law. Eggs successfully hatched at Jakarta Zoo, Java.

Bibliography. Bowler & Taylor (1989), Collar & Andrew (1988), Dekker (1991a), Holmes (1989), Ripley (1960, 1964), Wallace (1860), West *et al.* (1981), White & Bruce (1986).

Genus *MEGAPODIUS* Gaimard, 1823

10. Polynesian Scrubfowl

Megapodius pritchardii

French: Mégapode de Pritchard **German:** Pritcharduhn **Spanish:** Talégalo de las Tonga
Other common names: Niufo'ou/Pritchard's/Tongan Scrubfowl/Megapode

Taxonomy. *Megapodius Pritchardii* G. R. Gray, 1864, Niufo'ou, Tonga.
Monotypic.

Distribution. Niufo'ou I (NW Tonga). Introduced to Tafahi I (NE Tonga), but this population has apparently died out; recently introduced to Late I and Fonualei I (NC Tonga).

Descriptive notes. c. 30-35 cm. Generally dark slaty grey, with short whitish crest; lower back, rump and wings washed reddish brown; white patch at base of primaries and white uppertail-coverts, both individually variable, and usually concealed; underparts grey, generally paler on belly. Bill yellow, iris brown, legs and feet bright yellow. Female has slightly paler legs. Juvenile generally duller, with brown and black barring; lacks white wing patch; has brownish iris and brownish orange legs and feet.

Habitat. Forages mainly in forested areas or thickets. Lays on beaches of crater lakes, in open patches of volcanic ash near vents or in dense forest along crater rim; prefers steeply sloping wooded areas, especially inner slopes of caldera, with large amounts of loose volcanic ash, perhaps because most of flat ground more subject to human disturbance and has less substantial vegetation cover; also rather bare cinder slopes on inside of caldera, and even on large island in centre of crater lake; small numbers said to breed on shores of SW coast of Niufo'ou, but this report has been challenged.

Food and Feeding. Mainly animal food. Prey identified by field observation included 53% insects, 25% land snails, 13% centipedes and 9% worms; most of prey much smaller, and so unidentified; also seen feeding on small amounts of fallen *Syzygium* fruit, though possibly only removing insects. Much time spent searching for food by scratching around in fallen leaves and other plant litter, or throwing it aside to reveal food. Often forages in pairs, both birds remaining fairly close together; male frequently offers food to female (see page 286).

Breeding. Apparently all year round, with peak in Apr-May. Burrow-nester, using geothermal sites. Egg burrows c. 90-150 cm long, c. 15-20 cm wide; information from local people suggests that up to 12 eggs can be laid in same burrow during c. 2 weeks. Incubation 47-51 days, in soil temperature of 29°-38°C. Newly-hatched chicks measured 12-13.5 cm in overall length, and weighed 40-51 g. Captive chicks did not try to find food until 4-5 days after hatching; at 6 days old, recognized ants, small insects and worms, and pecked at them.

Movements. Presumably sedentary. Only evidence of displacement is presence of birds breeding on island in midst of crater lake. Niufo'ou lies c. 200 km from nearest land, and c. 1500 km from nearest extant population of megapodes, in Vanuatu; huge distances involved and absence otherwise of megapodes from Vanuatu in historical times suggest species not equipped to perform successfully any movements away from Niufo'ou.

Status and Conservation. VULNERABLE. Mace-Lande: Endangered. Total population numbers only 400-800 individuals; considered to be stable. In 1976, estimated 820 birds in study area of 500 ha; extrapolated for total area of suitable habitat (c. 1500 ha) to give carrying capacity for whole island of c. 2500 individuals; still quite common in undisturbed forest, of which under 10 km² remain; some previous estimates as low as c. 200 birds. Niufo'ou is active volcanic island of c. 55 km², of which crater lakes comprise c. 18 km²; apparently species almost wiped out by volcanic eruption in 1886. Main threats are intensive egg-collecting and predation by feral cats. Legally protected, but in practice no enforcement; over 100 eggs can be taken annually at each breeding site; roughly one third of all sites surveyed in 1976 abandoned by 1990; most laying sites survive due to inaccessibility; very limited hunting of adults. Cats ambush females when they emerge from laying burrows, and remains of 7 birds found around one burrow; introduced rats and pigs may also pose serious threats; some natural predation by Barn Owls (*Nyctale*). Niufo'ou recently chosen by government of Tonga as potential site for crude oil storage depot; such a development would almost certainly lead to extermination of species, but project now likely to be abandoned. Current research concerns behaviour, habitat requirements and population size. Conservation measures proposed include attempts to establish additional populations on other islands in Tonga, as insurance against extermination or decimation of Niufo'ou population; attempts initiated on Late and Fonualei in 1993, with some initial success; introduced to Tafahi I (NE Tonga) in 1968, but apparently died out. Population requires monitoring; introduced predators should be eradicated; intensive general research on species necessary; public campaigns of environmental education also highly desirable. Only 2 birds known to be **found in captivity.**

Bibliography. Collar & Andrew (1988), Curio (1992), DuPont (1976), Friedländer (1899), Hay (1986), Lister (1911), Mayr (1938), Pratt *et al.* (1987), Rinke (1986a, 1986b, 1991), Steadman (1991, 1992a, 1993), Todd (1983), Watling (1982), Wei (1973), White & Bruce (1986), Ziswiler (1970).

11. Micronesian Scrubfowl

Megapodius laperouse

French: Mégapode de La Pérouse **German:** Lapérousehuhn **Spanish:** Talégalo de las Marianas
Other common names: Palau Scrubfowl (*senex*); Mariana Scrubfowl/Scrubhen (*laperouse*)

Taxonomy. *Megapodius La Pérouse* Gaimard, 1823, Tinian Island, Mariana Islands.

Linked with *M. layardi* in past. Race *senex* sometimes considered full species, mainly due to geographical isolation and differences in size and normal breeding habits. Two subspecies recognized.

Subspecies and Distribution.

M. l. laperouse Gaimard, 1823 - N Mariana Is.

M. l. senex Hartlaub, 1867 - Palau Is.

Descriptive notes. c. 28-30 cm. Smallest megapode. Short pale grey crest; iris brown, chestnut or golden yellow; legs yellow to brownish yellow. Gular skin may be brighter red in male than in female. Race *senex* smaller.

Habitat. Race *laperouse* occupies mainly forest in limestone areas, sometimes in hills, but also commonly found in coconut groves; other habitats include coastal scrub and thickets fringing beaches. Race *senex* found inland on large islands, affecting forest on deep soil or sharp rocky ridges with little soil; also in habitats small, raised limestone islands; breeds in strand forest behind sandy beaches; has

been recorded in limestone forest, at c. 50 m above sea-level.

Food and Feeding. Forages in soil and leaf litter on forest floor; usually in pairs.

Breeding. Burrow-nester and mound-builder, depending on race. Burrow-nester (*laperouse*), using geothermal and solar-heated sites, with burrows dug in cinder soil; on Agrihan I, said to scratch up fairly large mounds of volcanic soil 300-400 cm wide x c. 67 cm high, into which it digs egg burrows; nominate race may be mound-builder too, especially on large coral islands of S, where geothermal heat unavailable. Mound-builder (*senex*), making mounds from leaf litter and sometimes sand. On some small islands, pairs apparently territorial, at least for part of year. Chick dark sepia brown.

Movements. Irregular, but relatively frequent, presence of birds on small, barren volcanic islands indicates that colonization occurs, either naturally or due to intervention of people. In Palau Is, known to fly between islands, sometimes crossing several kilometres of sea; probably capable of flying between neighbouring islands fairly regularly, particularly for purposes of egg-laying.

Status and Conservation. RARE. Mace-Lande: *laperouse* endangered; *senex* vulnerable. Total population of *laperouse* numbers only 1000-2500 individuals; that of *senex* probably numbers c. 1000-10,000 individuals; both thought to be stable, although populations require monitoring. Race *laperouse* formerly abundant, at any rate on larger islands; during 19th century extirpated from Guam, Tinian and Rota. Largest numbers survived on Saipan (Marianas), but extirpated by 1930's, due to intensive hunting; reintroduced in 1960's, and small numbers survive, but apparently declining. Survives on small, uninhabited coral island of Aguijan; also thought to survive on all or most of the nine small, remote volcanic islands further N, most of which are also uninhabited, but some have very little suitable habitat; Guguan I may hold up to 2000 birds, and Sarigan I a few 100's. Populations on uninhabited islands thought to be relatively safe, but habitat preservation, control of introduced predators and strict enforcement of laws essential. This race has suffered from egg-collecting, loss of habitat to urban development, and also introduced predators; problems caused by feral pigs and monitor lizards on Saipan, and goats on Aguijan, although extent of impact unknown; extensive habitat destruction on larger islands of S for sugar cane plantations. Legally protected, but traditional exploitation of birds and eggs by indigenous people permitted. Four small islands of N (Guguan, Asuncion, Maug and Farallon de Pajaros) are Wildlife Sanctuaries. Much work needed on ecology of species; possible conservation initiatives include creation of artificial breeding grounds on some of larger islands of S. Race *senex* locally common on limestone islands and outlying islands, e.g. Kayangel Is; rare on larger, volcanic islands, and already exterminated from three. Egg-collecting more intensive and far-reaching in recent years, as facilitated by use of speed boats from 1970's. Habitat damaged by growing human population in some areas, but in mid-1970's reported still to be relatively intact on many islands. Effects of introduced predators uncertain: e.g. crab-eating macaque (*Macaca irus*) numerous on Angaur I, as is wild pig (*Sus scrofa*) on Babelthup I. Legal protection, but little enforcement, if any. Species occurs on some of Ngerukewid Is, very small islands which have been wildlife sanctuary since 1958; recent survey found species to be common here, occurring at 29% of forest stations; presence noted on nine separate small islands: total population of Ngerukewid and Kmekumer Is estimated at c. 60-90 birds. Uncommon on Peleliu and Angaur; status on Saipan (Palau) unknown. Immediate requirements include survey to establish main breeding grounds. No birds of either race known to be held in captivity.

Bibliography. Baker (1951), Collar & Andrew (1988), Enghring & Pratt (1985), Falanruw (1975), Glass (1988), Hay (1986), Jenkins & Aguon (1981), King (1978/79), Lemke (1984), Lister (1911), Ludwig (1979), Marshall (1949), Mayr (1938), Owen (1977), Pratt & Bruner (1978), Pratt, Bruner & Berrett (1979, 1987), Pratt, Enghring *et al.* (1980), Steadman (1992b), Stinson (1989), Stinson & Glass (1992), White & Bruce (1986), Wiles & Corry (1990), Wiles *et al.* (1987).

12. Nicobar Scrubfowl

Megapodius nicobariensis

French: Mégapode des Nicobar **German:** Nikobarhuhn **Spanish:** Talégalo de Nicobar
Other common names: Nicobar Scrubhen/Megapode; North Nicobar Megapode (*nicobariensis*); South Nicobar Megapode (*abbotti*)

Taxonomy. *Megapodius nicobariensis* Blyth, 1846, Nicobar Islands.

Formerly included in *M. freycinet*. Generally considered to form part of the *M. freycinet* super-species; apparently very close to *M. cumingi*. Two subspecies recognized.

Subspecies and Distribution.

M. n. nicobariensis Blyth, 1846 - C & N Nicobar Is, except Chauri and Car Nicobar.

M. n. abbotti Oberholser, 1919 - Great & Little Nicobar Is.

Descriptive notes. 43 cm; male 595-964 g, female 850-1021 g. Rather similar to *M. cumingi*, but considerably browner below and paler, with legs and feet greenish brown to red. Immature has head and neck brown and lacks red facial skin; underparts mostly rufous brown. Race *abbotti* darker above and below.

Habitat. Occurs in dense forest undergrowth. Breeds at highest densities along coast, especially by sandy beaches just above the high tide mark; sometimes further inland.

Food and Feeding. Snails, seeds, other plant matter, insects, etc.; species recorded include *Scarus plicatus* and *Helicina celebori*. Also ingests sand and pebbles to help grind down food. In captivity, chicks raised on termites. Feeds noisily in pairs or family groups.

Breeding. Breeding can occur more or less all year round. Monogamous. Mound-builder; builds mound of sand, leaves and plant matter, up to 150 cm high and over 10 m wide; some

mounds lower and flatter, built against buttresses of large living trees, or against, around or under rotting tree stumps. Up to 20 eggs found in one mound, possibly laid by several females; average of 2 pairs per mound; one record of two eggs laid at interval of 9 days. Chicks uniform snuff brown.

Movements. Presumably sedentary.

Status and Conservation. RARE. Mace-Land: *nicoabariensis* vulnerable; *abbotti* safe/vulnerable. Total population of race *nicoabariensis* could number 100-10,000 birds, but real numbers and trends unknown. Total population of race *abbotti* reckoned to number 2000-8000 birds; apparently stable. Until late 1980's and early 1990's, virtually no information available on species; in recent decades regularly said to be fairly common, but subsequently thought to be seriously endangered; main population, on Great Nicobar, was estimated to comprise under 400 birds in 1988, mostly along N coast; pressure from predation, egg-collecting and habitat destruction said to have increased in places in conjunction with economic development of islands; now extinct on Kunduli. Recent survey of Great Nicobar indicates species more common than was thought; in Mar 1992, stretch of 26 km of coast found to hold 39 active mounds and c. 78 pairs; extrapolation for whole island suggests minimum of c. 780 pairs actively breeding at time of survey; probably over 2000 birds on Great Nicobar alone; two national parks declared in 1992, covering 536 km² of island, more than 80% of which is covered with undisturbed primary forest. Evidence suggests that predation of eggs by man and monitor lizards (*Varanus salvator*) may be on relatively insignificant scale. On Great Nicobar, traditionally hunted by Shompene people; large population of E coast said to have been virtually wiped out by late 1980's, due to intensive and more efficient hunting by immigrant workforce, brought in for road construction. Main threat may be introduced predators, which should be eradicated. All recent information refers to Great Nicobar; extensive surveys of other islands required. Nominative race has long been said to occur to N, in Cocos Is., and perhaps to S, in Little Andaman Is., although good evidence lacking. No birds of either race known to be held in captivity at present.

Bibliography. Ali & Ripley (1980), Collar & Andrew (1988), Dekker (1992), Grimmett (1988), Mayr (1938), White & Bruce (1986)

13. Philippine Scrubfowl

Megapodius cumingi

French. Mégapode des Philippines **German.** Philippinenhuhn **Spanish:** Talégalo Filipino
Other common names: Tabon (Scrubfowl), Philippine Megapode

Taxonomy. *Megapodius Cumingii* Dillwyn, 1853, Labuan Island. Formerly included in *M. freycinet*. Generally considered to form part of the *M. freycinet* super-species; apparently very close to *M. nicoabariensis*. Population of Mindanao frequently placed in possible race *tabon*, but affinities of these birds uncertain; race *dillwyni* sometimes used for birds of N Philippines. Birds of Sulawesi were allocated distinct race *gilbertii*, but not reliably distinguishable from nominate race; race *bulukensis* described from Bulukbuluk I (SW of Mindanao), but validity very dubious. Three subspecies recognized.

Subspecies and Distribution

M. c. pusillus Tweeddale, 1878 - N & E Philippines.

M. c. cumingii Dillwyn, 1853 - N Borneo, Sulawesi, SW Philippines.

M. c. sanghirensis Schlegel, 1880 - Sangihe Is., Talaud Is.

Descriptive notes. 32-38 cm. Virtually no crest; iris brown, legs brownish to blackish. Rather similar to *M. nicoabariensis*, but much darker, and generally greyer below. Juvenile similar to adult, but with much more extensive feathering around eye. Races separated mainly on tones of coloration and size; *sanghirensis* larger, with upperparts much redder brown and underparts darker grey.

Habitat. Forested zones of hills and mountains at 250-2000 m; also beach forest and coastal scrub on small islands. In Philippines, mainly breeds near seashore, but occasionally recorded fair distance inland.

Food and Feeding. Known to feed on variety of larval and adult insects; worms and snails also recorded.

Breeding. Probably breeds all year round; in N Sulawesi laying in Mar, Nov and Dec; in Philippines breeding in May (Fugal), Jun-Aug (Palawan), Aug (Negros) and Dec (Calayan). Mound-builder in N Borneo and most of Philippines; burrow-nester in Sulawesi and parts of Philippines (Palawan, Negros, Panay), using decaying tree roots or stumps and solar-heated beaches. Several pairs may share same mound, sometimes shares burrows of *Macropygia*; egg-burrows can be 50 cm long or more. Chicks reddish-brown, with barring on back and wings.

Movements. No movements recorded, but periodical presence on small onshore islets indicate that some short sea crossings must occur. Like *crepitans*, generally escapes from danger by running fast through thick undergrowth, sometimes after short ground flight.

Status and Conservation. Not globally threatened. Mace-Land: Vulnerable. Total population might number c. 10,000-100,000 individuals, but apparently declining. Currently considered near-threatened. Formerly widespread, but now local and generally uncommon in Philippines, where suffers from egg-collecting, e.g. on Negros; also some hunting pressure. Few records from mainland Borneo in Sabah, now scarce here and on islands off N Borneo, due to excessive exploitation. In N Sulawesi, probably common in Danau Tana National Park, in early 1980's was common in Tana Toraja National Park, but has declined in recent years, probably due to illegal logging, and now only seen rarely, deep into primary forest, quite common in N Sulawesi in

early 1980's; potential threats in Sulawesi include habitat loss and increasing human population pressure. Main threats are overexploitation for food, degradation and conversion of habitat, and effects of introduced predators. Conservation requirements include extensive survey work, environmental education campaigns, management of habitat and designation of a series of protected areas. Legally protected in Indonesia. No birds known to be held in captivity.

Bibliography. Andrew & Holmes (1990), Bishop (1992), Dickinson *et al.* (1991), Holmes (1989), Lambert (1993), MacKinnon & Philipps (1993), Mayr (1938), Rabor (1977), Rozendaal & Dekker (1989), White & Bruce (1986).

14. Sula Scrubfowl

Megapodius bernsteinii

French: Mégapode de Bernstein

German: Sulahuhn

Spanish: Talégalo de Sula

Taxonomy. *Megapodius Bernsteinii* Schlegel, 1866, Sula Islands.

Formerly included in *M. freycinet*. Generally considered to form part of the *M. freycinet* super-species. Birds from Peleng I (Banggai) have been accorded separate race *perrifus*, but observed differences in overall plumage tones usually attributed to individual variation; this race has alternatively been assigned to *M. reinwardti*, presumably in error. Monotypic.

Distribution. Sula and Banggai Is.

Descriptive notes. c. 35 cm. Fairly uniform plumage. Differs from *M. cumingii* in having underparts similar to upperparts; chestnut lower back, rufous lower breast and belly, legs and feet orange or red.

Habitat. Variety of habitats, ranging from primary forest to coastal scrub. On Lalolo I (Banggai Is.), recorded as high as 450 m above sea-level; also heard in mangroves and in thickets in a coconut plantation. On Taliabu I (Sula Is.), not recorded in primary montane forest, but quite common in primary and selectively logged lowland forest, up to 250 m; fairly frequent in wooded savanna and around

margins of agriculture, where can occur in dense scrub. Limited evidence may suggest some degree of adaptability to disturbed habitats; however, this could simply reflect apparent preference for lowlands, where vast majority of logging takes place.

Food and Feeding. Insectivorous. Frequently forages in areas with fallen and rotting trees and branches.

Breeding. Eggs and 1 chick found in Dec, indicating laying from Oct or earlier; active mound in Sept/Oct. Apparently monogamous. Mound-builder. Mounds often built round rotting bases of trees; one mound was c. 100 cm high x 600 cm wide. Eggs said to require 2 months minimum for hatching.

Movements. Presumably sedentary. Frequently seen in pairs, sometimes in groups of up to 5 birds.

Status and Conservation. VULNERABLE. Mace-Land: Vulnerable. Total population roughly estimated to number c. 10,000 individuals, but numbers may be much higher; thought to be stable or declining. Until recently unknown in wild, with no records of any sort since 1938; in 1981, recorded on Lalolo I, which appeared to be less disturbed than other main islands of Banggai group; 2 birds recorded on Mangole I (Sula) in 1988. In Oct-Dec 1991, project, with participation of Indonesian biologists, found species to be widespread in Banggai Is., where recorded on 7 of 8 islands surveyed; on Peleng I, common in some areas, absent in others; local people reported presence of species on several other, unsurveyed islands; conservative minimum estimate of 7000 birds for total population of Banggai Is., but species probably declining. On Taliabu I (Sula Is.), species relatively common in two study sites, but infrequent to absent in others; extrapolation of data gives rough estimate of total population of Taliabu at c. 22,000-54,000 birds, of which c. 4000-10,000 should occur in proposed reserve. Main threats appear to be habitat destruction, predation, and hunting and trapping by man; likely to be severely affected by large-scale commercial logging, especially of coastal forests, that is going on in Sula and Banggai Is.; egg-collecting does not seem to occur on Taliabu I, where predation of eggs by monitor lizards (*Varanus salvator*) recorded, although significance probably minimal; in Banggai Is., introduced feral Red Junglefowl (*Gallus gallus*) apparently displace present species in some areas. Proposal in 1981 by FAO/UN to create protected area of c. 700 km² on Taliabu I, largest of Sula Is.; this should now be put into practice, before area lost to commercial logging; other protected areas should be designated. Species protected by Indonesian law, but very little, if any, effective protection. Conservation proposals include public awareness campaign. No birds known to be held in captivity.

Bibliography. Collar & Andrew (1988), Davidson *et al.* (1992), Holmes (1989), Indrawan *et al.* (1992), Lucking *et al.* (1992), Mayr (1938), White & Bruce (1986), Yong (1990).

15. Dusky Scrubfowl

Megapodius freycinet

French: Mégapode de Freycinet

German: Großfußhuhn

Spanish: Talégalo de Freycinet

Other common names: Common Scrubfowl, Incubator Bird (*freycinet* superspecies); Geelvink Scrubfowl (*geelvinkianus*)

Taxonomy. *Megapodius freycinet* Gaimard, 1823, Waigao.

Forms superspecies with *M. nicoabariensis*, *M. cumingi*, *M. bernsteinii*, *M. crepitans*, *M. javanensis*, *M. affinis*, and *M. reinwardti*, all of which were formerly lumped together as races of present species. Race *geelvinkianus* may merit treatment as full species. Birds of N Moluccas sometimes awarded separate race, *quoyii*. Species said to hybridize with *M. reinwardti* on some islands in Geelvink Bay, where *M. reinwardti* apparently absent and also in S Moluccas (where present species not known to occur). Two subspecies normally recognized.

Subspecies and Distribution

M. f. freycinet Gaimard, 1823 - N Moluccas, W Papuan Is.

M. f. geelvinkianus A. B. Meyer, 1874 - islands in Geelvink (Cenderawasih) Bay.

Descriptive notes. c. 35 cm. Uniform dark grey; shortish crest; with paler grey on bend of wing; legs and feet blackish to dark greenish olive or horn-coloured. Race *geelvinkianus* slightly paler.

Habitat. Occurs in mangroves and along margins of swamps, woodland and agro swamps, also in wet evergreen forest in lowlands, usually below 300 m; said to occur in limestone hill forests at c. 100-450 m on Halmahera; on Misol I breeds mangrove beaches or well inland.

Food and Feeding. Walks along forest floor, scratching in litter for insects, with constant clucking; pair can feed together.

mahera, but suffers intensive pressure from trappers. Elsewhere, recent sightings very scarce; single bird heard on Ternate in Jul 1989. Paucity of records suggest species could be approaching threatened status. Main threats are overexploitation for food, degradation and conversion of habitat, and effects of introduced predators; predation of young by indigenous *Accipiter henicogrammus* recorded. Extensive surveys required; some protected areas should be established in suitable habitat. Protected by Indonesian law. No birds known to be held in captivity.

Bibliography. Beehler *et al.* (1986), Bishop (1992), Holmes (1989), Mayr (1930, 1938), Ripley (1960, 1964), White & Bruce (1986).

16. Melanesian Scrubfowl

Megapodius eremita

French: Mégapode mélanésien **German:** Bismarckkuhn **Spanish:** Talégalo Eremita
Other common names: Bismarck Scrubfowl

Taxonomy. *Megapodius eremita* Hartlaub, 1867, Ninigo Islands.

Formerly included in *M. freycinet*. Generally considered to form part of the *M. freycinet* super-species. Known to hybridize with *M. affinis* on Karkar I (off NE New Guinea); comparison of specimens taken on Karkar I in 1914 and 1969 indicates that this population may have moved closer to present species than to *M. affinis*. Reported to hybridize with *M. reinwardi* in D'Entrecasteaux Is and Louisiade Archipelago, where present species not known to occur. Race *branchi* traditionally accepted for birds of Solomon Is (including Bougainville I and Buka I), but validity doubtful. Monotypic.

Distribution. Ninigo Group through Admiralty Islands, New Britain, New Ireland and rest of Bismarck Archipelago to Solomon Is.

Descriptive notes. c. 34 cm; 555-660 g. Very short crest; plumage very dark all over, generally greyish; grey on underwing extensive; forehead and part of face bare and reddish; legs and feet range from dark grey to olive green or horn-coloured.

Habitat. Rain forest in New Britain, occurring from sea-level up to at least 1500 m, but primarily in lowlands, apparently due to preference for deep soil, copious leaf litter and very sparse undergrowth; often in mesophyll vine forest; infrequent in swamp forest, hill forest and secondary growth, apparently due to heavy, waterlogged soils and dense under-

growth, or shallow soils with minimal leaf litter that typically cover limestone areas. On small islands, also forages in low, dense vegetation in open areas. Usually breeds at geothermal sites or on sandy beaches; at Liga, New Ireland, birds lay in school rubbish pits; in Solomon Is sometimes lays up to 10 km inland from coast.

Food and Feeding. Fruits and seeds; also crickets and other invertebrates. Searches around for arthropods and fallen fruit in leaf litter and amongst decaying branches.

Breeding. Laying Apr-Dec in W New Britain, with peak in Jun-Aug; apparently all year round on Savo I (EC Solomon Is). Communal burrow-nester, using geothermal sites (New Britain, Savo), solar-heated beaches (Admiralty Is), fallen, rotting trees (Bougainville I) and decaying matter between tree roots (E Solomon Is) or under bases of trees (Wuvulu I in Ninigo Is); also mound-builder (Ninigo Is, New Britain, E Solomon Is). On Savo eggs buried at depth of c. 88 cm, in sand temperature of 33°C; burrows average 40 cm wide by 90 cm long. Sample of 20 burrows studied at Garu (New Britain) for 6 weeks, during which production averaged 6-45 (4-11) eggs/burrow, but ratios of females/burrow and/or burrows/female unknown. Chick newly emerged from egg-burrow on Savo I measured 110 mm, with 310 mm wingspan.

Movements. In N New Britain, outwith breeding season (during rains) birds disperse extensively throughout forested areas, and may move mostly to S coast; birds seen flying across bay. Parties of birds sometimes fly out to small offshore islets at dusk; young birds, in particular, even fly into houses at night, apparently attracted by lights. Large numbers congregate at geothermal laying grounds; elsewhere, normally seen singly. High energy demands of egg-laying, together with huge concentrations at laying grounds, imply extensive dispersal into surrounding forests for feeding in between laying of successive eggs.

Status and Conservation. Not globally threatened. Mace-Lande: Safe. Total population may number 10,000-1,000,000 individuals; perhaps on decline. Widespread and fairly common on New Britain; seems to be less numerous elsewhere, although no recent information available from Solomon Is. Hundreds of burrows in thermally heated sand on Lou I, Admiralty Is, in 1970's. Largest known geothermal sites are in NC New Britain at Pokilli and Garu, covering respectively c. 707 ha and 67 ha; in 1970's, countless 10,000's of burrows at former, 11,776 recorded in partial count at latter; estimates in 1978 gave c. 2,000 birds at former and c. 53,000 at latter. Such vast concentrations highly vulnerable, particularly to habitat destruction and abusive levels of egg-collecting; latter still carried out by traditional landowners but currently on increase, traditional laws fixing sustainable levels of egg harvest for consumption and trading purposes now largely disregarded, with probably well over 1,000,000 eggs taken annually at Pokilli. Large colony at Matupit (NE New Britain) has suffered considerable human disturbance and damage, mainly through soil erosion. Breeding grounds also threatened by feral dogs, which kill adults and chicks, and also by pigs, which unearth eggs. In New Britain, steady growth of timber industry is major threat, as clear-felling removes foraging habitat, but areas of forest also cleared for agriculture; effects aggravated by ever-increasing human population; species apparently able to tolerate certain amount of selective logging of habitat. On Savo I (Solomons), c. 200 birds estimated to use laying grounds at one time in 1981; site plundered daily by local villagers, with no fixed quotas; species reported

Breeding. Birds calling and in breeding condition Oct-Dec in W Papuan Is; chicks in Jan on Misool I. Mound-builder. Perhaps also parasitic; said to lay in active mounds of *Eulipou wallacei* on Halmahera, although latter species not definitely known to build mounds. **Movements.** No information available. Presumably sedentary.

Status and Conservation. Not globally threatened. Mace-Lande: Safe; race *geelvinkianus* endangered. Total population may number 10,000-100,000 individuals; alternative estimate of under 5000 birds; thought to be stable or declining. Still common on Hal-

mahera, but suffers intensive pressure from trappers. Elsewhere, recent sightings very scarce; single bird heard on Ternate in Jul 1989. Paucity of records suggest species could be approaching threatened status. Main threats are overexploitation for food, degradation and conversion of habitat, and effects of introduced predators; predation of young by indigenous *Accipiter henicogrammus* recorded. Extensive surveys required; some protected areas should be established in suitable habitat. Protected by Indonesian law. No birds known to be held in captivity.

Bibliography. Beehler *et al.* (1986), Bishop (1978, 1980), Bishop & Broome (1979), Broome *et al.* (1984), Coates (1985), Harding (1982), Kisokau (1976), Mayr (1938, 1945), Meyer (1930), Pockley (1937), Roper (1983), Sibley (1946), Steadman (1991), Steadman *et al.* (1990), White & Bruce (1986), Wolff (1965).

17. Vanuatu Scrubfowl

Megapodius layardi

French: Mégapode de Layard **German:** Layardkuhn **Spanish:** Talégalo de Nuevas Hébridas
Other common names: Tristram's/New Hebrides Scrubfowl

Taxonomy. *Megapodius layardi* Tristram, 1879, Vaté, Vanuatu.

Formerly included in *M. freycinet*; alternatively linked with *M. laperouse*. Generally considered to form part of the *M. freycinet* super-species. Monotypic.

Distribution. C & N Vanuatu (New Hebrides) and Banks Is.

Descriptive notes. c. 30-34 cm. All dark brownish black; extensive pinkish red bare skin on forehead and face; iris brown, legs pale yellow. Juvenile duller, with brown legs. **Habitat.** Mostly found on floor of lowland forest or thicket; also occurs at medium altitudes. Normally breeds near coast.

Food and Feeding. Said to take insects, grubs, worms, snails and other invertebrates; also fruit, seeds and other plant matter. Scratches in damp leaf litter for food.

Breeding. Apparently breeds all year round. Burrow-nester, using decaying tree-roots and perhaps, where available, geothermal sites; possibly also mound-builder. Laying grounds vary in size: under 50 cm wide, where used by 1 female only; up to 10 m wide, where communal, with many burrows. Burrows 30-120 cm deep and up to 200 cm long. Incubation over 45 days; chicks pale brown with darker barring above.

Movements. Sedentary. Sometimes flies off to roost on offshore islets. Prefers to run rather than fly away from danger.

Status and Conservation. Not globally threatened. Mace-Lande: Vulnerable. Total population might number c. 10,000 individuals; thought to be stable or declining. Apparently still common in suitable habitat. Breeding grounds and general habitat threatened on some islands, e.g. Efate, due to encroachment of agriculture and other forms of development. Eggs have been collected on local scale for centuries, and much appreciated as source of protein. In past, only most accessible laying sites harvested, with insignificant effects on species as whole; increase in human population, combined with greater mobility, suggests effective protection required to ensure long-term survival of species. Some losses caused by introduced predators. Hunting permitted only Apr-Jun. Measures proposed include: establishment of reserves around major laying grounds; implementation of fixed quotas for egg-collectors; and stricter control of poachers. No birds known to be held in captivity.

Bibliography. Biggula (1992), Mayr (1938, 1945), Raethel (1988), Steadman (1991), Steadman *et al.* (1990), White & Bruce (1986).

18. New Guinea Scrubfowl

Megapodius affinis

French: Mégapode de Nouvelle-Guinée **German:** Neuguineahuhn **Spanish:** Talégalo Papúa

Taxonomy. *Megapodius affinis* A. B. Meyer, 1874, Rubi, New Guinea.

Formerly included in *M. freycinet*. Generally considered to form part of the *M. freycinet* super-species. Known to hybridize with *M. eremita* on Karkar I (off NE New Guinea). Formerly considered polytypic, with acceptance of races *jobiensis*, *decollatus* and *huonensis*. Name *affinis* may not be applicable to present species, in which case *M. decollatus* would have priority. Monotypic.

Distribution. N New Guinea and offshore islands, from Geelvink (Cenderawasih) Bay E to Huon Gulf, and as far S as Nassau Range, on S slopes of Snow Mts; exact limits of range uncertain in many areas.

Descriptive notes. c. 33 cm. Rather long crest; underparts vary from ashy grey to brownish olive; legs and feet dark olive green to blackish.

Habitat. Rain forest, occurring from sea-level up to 1800 m, and probably 2000 m; occupies, and breeds in, swamp forest along R Sepik (NC New Guinea). In Nassau Range (WC New Guinea), collected at 880 m and 1280 m, whereas *M. reinwardi* found at lower altitudes. In upland areas often sympatric with *Aepyodius arfakianus* and *Talegalla* (?*jobiensis*), sometimes breeding in close proximity.

Food and Feeding. No information available.

Breeding. Laying said to be all year round, with records from Feb, Mar/Apr and Oct (CN New Guinea); in S highlands (probably present species) Jan-May, dry season. Mound-builder. Mounds may apparently be used by up to 4 pairs; one mound said to have been used for c. 13 years; total of 28 eggs/chicks apparently taken from single mound in one year. This species thought to parasitize mounds of *Aepyodius arfakianus* and *Talegalla* (?*jobiensis*) (see page 290), although latter has also been claimed to parasitize mounds of present species.

Movements. No information available. Presumably sedentary.

Status and Conservation. Not globally threatened. Mace-Lande: Safe. Total population may number 10,000-1,000,000 individuals; thought to be stable. Widespread and common in Irian Jaya (W New Guinea). Found to be abundant in swamp forest along middle reaches of R Sepik in mid-1950's. Threats include degradation and conversion of habitat. Legally protected in Indonesia. No birds known to be held in captivity.

Bibliography. Beehler *et al.* (1986), Bergman (1963), Bishop (1978), Coates (1985), Dwyer (1981), Gillard & LeCroy (1966), Holmes (1989), Mayr (1938), Ripley (1964), White & Bruce (1986).

19. Orange-footed Scrubfowl

Megapodius reinwardt

French: Mégapode de Reinwardt **German:** Reinwardthuhn **Spanish:** Talégalo de Reinwardt
Other common names: Reinwardt's Scrubfowl; Tanimbar Scrubfowl (*tenimberensis*); Seram Scrubfowl (*forstenii*)

Taxonomy. *Megapodius Reinwardt* Dumont, 1823, Amboina; error = Lombok. Formerly included in *M. freycinet*. Generally considered to form part of the *M. freycinet* super-species. Very complex internal taxonomy, still poorly understood; recent research suggests possible elevation of race *forstenii* (incorporating *buruensis*) and reinstatement of race *tenimberensis* both to full species status. Validity of race *buruensis* has been questioned. Variation within Australian populations is slight and clinal, possibly warranting recognition of only one race, rather than three. Birds of Aru Is and those of New Guinea have been awarded separate races, respectively *aruensis* and *duperreyi*, but rarely accepted. Form *perrufus* of Peleng (Banggai Is) has been included in present species, but almost certainly belongs in *M. bernsteinii*, and in any case of dubious validity. Species said to hybridize with *M. freycinet* on some islands in Geelvink Bay (where present species apparently absent) and also in S Moluccas (where *M. freycinet* not known to occur); hybridization likewise reported with *M. eremita* in D'Entrecasteaux Is and Louisiade Archipelago (where *M. eremita* not known to occur). Eight subspecies currently recognized.

Subspecies and Distribution.

- M. r. buruensis* Stresemann, 1912 - S Moluccas, on Buru.
- M. r. forstenii* G. R. Gray, 1861 - S Moluccas, on Seram, Ambon, Haruku and Gorong.
- M. r. reinwardt* Dumont, 1823 - Lesser Sundas, extreme SE Moluccas, Aru Is and NW, S & SE New Guinea; possibly also islands of Torres Strait.
- M. r. macgillivrayi* G. R. Gray, 1861 - Trobriand, Marshall Bennett, Woodlark and D'Entrecasteaux Is and Louisiade Archipelago (off SE New Guinea); possibly also SE New Guinea.
- M. r. takimbarensis* P. L. Sclater, 1883 - Tanimbar Is.
- M. r. tumulus* Gould, 1843 - N Australia from Kimberley Division (NE Western Australia) to Melville I and N Northern Territory.
- M. r. yorki* Mathews, 1929 - Cape York Peninsula (N Queensland) and offshore islands, possibly including those of Torres Strait.
- M. r. castanonotus* Mayr, 1938 - EC Queensland (Cooktown to Yeppoon) and offshore islands.

Descriptive notes. 35-47 cm; male 851-1200 g, female 562-1200 g. Long crest; chestnut tinge on back; legs and feet orange to pinkish red. Female averages slightly smaller. Immature very similar to adult, but smaller, sometimes with paler head. Extensive local variation in size and colour; race *tenimberensis* shows less grey on mantle and paler grey below; race *forstenii* dark brown above, redder crown and shorter crest; race *buruensis* similar to *forstenii*, but slightly larger, with paler back; *tumulus* larger, darker and less olive.

Habitat. Rain forest and variety of other wooded areas, including swamp forest; sometimes ventures into more open areas, especially where habitat fragmented. Mostly in lowlands, but up to 1500 m in SE New Guinea and 1900 m on

Buru; in WC New Guinea occurs at lower altitudes than sympatric *M. affinis*. On Buru occurs in wooded areas with light undergrowth; breeds near coast and in hill forest. On Seram occurs in primary and secondary lowland forest, but also on small coral islets; highest densities recorded in scrubby secondary forest and coastal scrub; frequents similar habitat on Lombok, Sumbawa and Flores; on Sumba, usually found in fairly open forest. On Komodo, breeds in coastal woodland or scrub, or in similar habitat alongside dry riverbeds; mounds sometimes only c. 100-200 m from human habitation, though usually well hidden. In N Queensland (Australia), breeds in dense forest often along creeks, and frequently up to c. 50 km inland; sometimes breeds in clearings or near forest edge; also occurs in vine thickets. Even breeds on tiny, remote islands, e.g. Kakabia I (Flores Sea) and Mai I (Banda Sea).

Food and Feeding. Mainly plant food, including seeds, berries and roots; also fruits, shoots and flowers; occasionally snails, worms, beetles and other insects and their larvae. Walks along, pausing at frequent intervals to rake about in leaf litter on forest floor; sometimes examines whole patch of leaf litter in great detail, leaving irregular piles of turned leaves behind.

Breeding. Mainly Jul-Mar in NE Australia; peaks Nov-May in SE New Guinea, during and shortly after rains; eggs Feb-Mar on Buru, May on Seram, probably Aug-Nov on Komodo, and virtually all year round on Flores; chicks in Jun on Mai I. Monogamous. Mound-builder; occasionally burrow-nester, using heat from sun or possibly even rotting tree-roots. On Komodo, sample area of 250 ha contained 42 mounds, of which 23 active; minimum distance between active mounds c. 100 m. Mound built by both sexes of leaves, sticks, earth or sand, and general debris; often roughly circular or elongated; sometimes very large, on Komodo averaging 95 cm high x 715 cm wide, and containing c. 20 m³ of material, but in Australia some mounds much larger (see page 287); mound temperature c. 29°-38°C during incubation. Usually built on flat or slightly sloping ground, mostly in shade. Mounds may be used successively or simultaneously by different pairs, but these always work independently; often used regularly over many years, e.g. 1 pair used same mound for almost 5 years; same mound used for 8 years by total of 4 pairs, occupation starting and stopping outwith study period. Single female recorded laying 12-13 eggs, each at interval of 9-20 days, during period of c. 20 weeks; incubation period unknown, although said to be c. 70 days. Chick dark brown, with rufous barring above, and centre of belly buff.

Movements. Occurrence on offshore islands and in isolated patches of forest indicates capability of covering fair distances in flight. Usually seen in pairs; when alarmed, prefers to walk or run away or fly short distance into tree.

Status and Conservation. Not globally threatened. Mace-Lande: Safe; *forstenii* (incorporating *buruensis*) safe; *tenimberensis* vulnerable. Total population may number c. 100,000-1,000,000 individuals; generally stable. Widespread and common within Indonesian range; fairly common in parts of Flores and Sumbawa. Well adapted to secondary growth; in places, species exterminated by excessive human pressure, but has subsequently managed to recolonize. On Komodo suffers frequent predation of eggs by Komodo dragon (*Varanus komodoensis*). In Australia, uncommon to common and with some local increases, e.g. around Darwin; generally more common in areas remote from human activities and disturbance; superabundant on Deliverance I in Torres Strait; suffers some egg predation by pigs and goannas. Legally protected in Indonesia. No birds known to be held in captivity. Race *forstenii* (incorporating *buruensis*) could number 10,000-100,000 birds, and apparently stable; on Seram, moderately common in Manusela National Park in 1987, where apparently more capable of tolerating disturbance than *Eulipoa wallacei*, and recorded mainly in secondary forest and coastal scrub. Race *tenimberensis* may number 1000-10,000 individuals; thought to be stable or on decline; threats include overexploitation for food, degradation and conversion of habitat, and introduced predators; protected areas should be established.

Class AVES

Order GALLIFORMES

Suborder CRACI

Family CRACIDAE (CHACHALACAS, GUANS
AND CURASSOWS)

- Medium-sized to large long-tailed gallinaceous birds with predominantly arboreal habits.
- 42-92 cm.

- Neotropical Region and extreme S Nearctic.
- Forests, open woodlands and scrub, from sea-level up to 3900 m.
- 11 genera, 50 species, 88 taxa.
- 13 species threatened; none definitely extinct since 1600.

Systematics

Cracids are a group of ancient origin. The oldest fossil attributed to the family dates to the Middle Eocene, at least 50 million years ago, and was found in Wyoming, USA. The find was of a small, not particularly specialized cracid, and, judging from its limb proportions, it was definitely arboreal. Various other fossils also found in North America show that cracids very similar to the present day chachalacas (*Ortalis*) have existed at least since the Upper Oligocene. In South America, much more recent fragments of *Crax* and *Penelope*, dating from about 20,000 years ago, have been found in cave deposits from the Pleistocene of Brazil.

Although there are some fossil remains from the Old World that have been tentatively attributed to this family, all the living species are found in the Neotropical Region, although a few penetrate the extreme south of the Nearctic Region. Taking into account the distribution of the present day species and also the fossil register, it seems most likely that the family originated during the early Tertiary in Central America and perhaps southern North America, which at that time had tropical or subtropical conditions, at least as far north as Wyoming. Once they arrived in South America, probably long before the Pleistocene, they diversified more quickly, as is to be expected in a larger area. In support of this theory is the fact that the greatest diversity among present forms is to be found in north-western South America.

The cracids have been considered the most primitive family in Galliformes. Some anatomical similarities indicate a close relationship with the megapodes, which are also highly distinctive and primitive. It is interesting to note that Megapodiidae and Cracidae are mainly restricted to the Australasian and Neotropical Regions respectively, where other galliform birds, including the most typical representatives of the order, are poorly represented.

The distance between the cracids and other Galliformes is illustrated by the fact that, in spite of a few erroneous reports to the contrary, no cracid has ever been known to hybridize with a member of another family, whereas there are numerous such cases between turkeys, grouse, pheasants and guinea fowl. In addition, cracids constitute the only largely arboreal family in the order, with even the most terrestrial species nesting,

roosting, singing and sometimes feeding in trees, often at considerable height. This suggests that, contrary to what might be imagined, the ancestral Galliformes may have been arboreal, and the cracids their closest descendants; within the family, some of the apparently most highly evolved forms are those which have developed the most terrestrial habits. Another difference between the cracids and the typical families of the Galliformes is their small clutch size of only two, three or, at most, four eggs.

All these differences and others, especially those of anatomy, explain why the cracids have traditionally been separated at the suborder or superfamily level, either alone or with the megapodes. C. G. Sibley and J. E. Ahlquist, following up their important work on DNA-DNA hybridization, even proposed a

Subdivision of the
Cracidae.

[Figure: Francesc Jutglar]

The race grayi of the Blue-throated Piping-guan is one of the six forms currently included in the genus *Pipile*. This group provides an excellent example of the substantial controversy that besets the internal taxonomy of the Cracidae. In the second half of the twentieth century alone, different authors have considered all six forms to constitute a single species, or two, three, four, five or six separate species. Furthermore, their isolation in the genus *Pipile* is not unanimously accepted: they have been included in the normally monotypic genus of the Wattled Guan (*Aburria aburri*), or alternatively merged with the typical guans in *Penelope*; at the other extreme, some workers reckon them sufficiently distinct from *Penelope* to justify their separation in a different tribe.

new order, Craciformes, in which the cracids and megapodes would be included, in separate suborders. However, the more traditional treatment, followed here, places them together with the megapodes in the suborder Craci of Galliformes.

The internal taxonomy of the family presents numerous controversial cases, in terms of the validity of species, the assignation of genera, or even the grouping of genera into tribes or subfamilies. Proof of this is that the three most important recent reviews of the family reached many contradictory conclusions at all of these levels; these studies, by F. Vuilleumier, C. Vaurie, and J. Delacour and D. Amadon, were all published between 1965 and 1973.

The family can be divided into three easily identifiable natural groups: the chachalacas, the guans and the curassows. The first two are very similar taxonomically, so much so that the grouping of the chachalacas (*Ortalis*) and the typical guans (*Penelope*) into a single genus has been suggested. However, this extreme proposal is less apt, if all the differences are taken into account, including those in calls, displays and ecology. Therefore, the most suitable option is probably to divide the family into two subfamilies, with the chachalacas and all the guans in Penelopinae, and the curassows in Cracinae; these two groups have normally been labelled as tribes, in an attempt to show that the differences are slight, but systematic procedure insists that families be divided into subfamilies, and subfamilies into tribes. The Cracinae differ from the Penelopinae in the proportionally longer pelvis, the morphology of the heavier, larger bill, and larger size; the first and third of these features tie in with their more terrestrial habits.

The distinctive Horned Guan (*Oreophasis derbianus*) is a special case. While obviously a guan, especially on carriage and behaviour, so included in Penelopinae, it shows some affinities with the curassows. Its large size, its red "horn" and its "mooring" call suggest that it could be some sort of a link between the two groups. This, and some unique characteristics, such as the overall coloration, the bare crown and horn and the feathered base of the bill concealing the nostrils, explain why some authors would award it a separate subfamily, Oreophasiinae, or at least its own tribe.

The chachalacas (*Ortalis*) are normally considered to constitute the most primitive genus in the family, due to their small size, plain coloration and lack of dewlaps and wattles. However, the fact that they prefer more open habitats, while all other cracids are forest birds, and the fact that they come to the ground more often than the guans, might indicate that they are actually derived from the guans. In such a case, the smaller size and duller colouring of the chachalacas could be interpreted as adaptations to their habitat.

It is a notably homogeneous genus of 12 species, or anything from six to 17, according to different authors. All of the species are so similar that it would be difficult for any two of them to compete in the same area, and as a result they are all allopatric, with ranges that do not overlap; it has even been suggested that the entire genus constitutes a superspecies. There are a few possible exceptions, mainly in Chiapas, southern Mexico, where the Plain Chachalaca (*Ortalis vetula*), the West Mexican Chachalaca (*Ortalis poliocephala*) and the White-bellied Chachalaca (*Ortalis leucogastra*) all meet, perhaps with a

slight overlap. In these circumstances, differences in voice may play an important role as a segregating mechanism, although in these small areas of contact there seems to be a tendency towards ecological separation. For instance, where the West Mexican Chachalaca coincides, in the northern limit of its range, with the Rufous-bellied Chachalaca (*Ortalis wagleri*), and in the south, with the Plain Chachalaca, it occupies moister woodland at higher altitudes than the other species. In contrast, in the rest of its range, where it is the only chachalaca present, it can also be found in somewhat drier habitats and at lower altitudes.

Another area where it is said that two species of chachalacas overlap is north-west Jalisco, in central Mexico, where a series of up to eight possible hybrids between the Rufous-bellied Chachalaca and the West Mexican Chachalaca were reported. This led to the two forms being considered conspecific from 1957 until very recently, despite some patent differences, especially in coloration, a feature in which they represent the two extremes of the genus. In the end, a detailed study by R. C. Banks has shown that these hybrids came from an area in which *Ortalis* does not appear to exist naturally. Thus, they may have been the offspring of escapes, and certainly chachalacas are frequently kept in captivity in this area.

Cracids do produce hybrids, often fertile ones, quite easily in captivity, even between members of different genera. In contrast, however, there are remarkably few cases of hybridization in the wild between different cracids. One such case from north-west Colombia refers to one or two intermediates between the Grey-headed Chachalaca (*Ortalis cinereiceps*) and the Chestnut-winged Chachalaca (*Ortalis garrula*). This case was one of the deciding factors, along with the coincidence of chestnut primaries, in these two forms being considered conspecific, despite notable differences in plumage, size and voice; in this last aspect, they differ more than any two other species in the genus. The validity of these supposed hybrids has also been questioned, above all by J. Hafner, who studied the area thoroughly and showed that there was an appreciable gap between the distributions of the two forms, in the densely forested region between the Sinu River and the Gulf of Uraba, which

is probably unsuitable for any chachalaca. As a result, the apparently intermediate individuals were attributed to cases of occasional introgression, or even to strays of one form or the other. In any case, even if they are valid hybrids, they do not demonstrate more than sporadic, limited hybridization that does not necessarily negate the validity of the two forms as different species. Interestingly, although regrettably, the issue of whether or not they are valid species will almost certainly be solved in the near future, since the gap between their ranges is shrinking rapidly due to continuous deforestation in the Uraba region, so both forms will probably come into extensive contact, if they have not already done so.

Some definite cases of intergradation between different subspecies of the same species are well known. Such is the case of the nominate race and the race *ruficauda* of the Rufous-vented Chachalaca (*Ortalis ruficauda*), which are well differentiated by having the tips of their tails respectively rich chestnut and greyish white. In areas of contact between the two populations, intermediate birds are found with buffy tail tips, and in the area around Lake Maracaibo, in Venezuela, such birds have even sometimes been considered a different subspecies, *baliolus*. The existence of such intermediate birds suggests that it is better to consider these forms conspecific, at any rate for the time being, although future field studies may demonstrate that they are really two species which hybridize only to a limited extent.

Finally, there is also intergradation in the Speckled Chachalaca (*Ortalis guttata*) between the nominate race and the race *subaffinis*, in the lowlands of north-east Bolivia and adjacent Brazil, and this is probably one of the main reasons why this is one of the eight or nine forms in the taxonomically complicated *Ortalis motmot* superspecies for which nobody proposes full species status. All these forms are distinguished from the other species of the genus by having somewhat narrow, stiffened neck and breast feathers and generally less fluffy plumage, and the fact that the White-bellied Chachalaca shows the same features has led to its inclusion in this complex, whereas in the past it was often considered a subspecies of the Plain Chachalaca. The most widely accepted version, followed here, groups all the forms in this complex into four species: the monotypic White-bellied Chachalaca; the Speckled Chachalaca, with five subspecies; the Little Chachalaca (*Ortalis motmot*), with two; and the monotypic Buff-browed Chachalaca (*Ortalis supercilialis*). However, four races of the Speckled Chachalaca, *columbiana*, *araucuan*, *squamata* and *guttata*, are quite dissimilar and are geographically isolated. Delacour and Amadon, when reviewing this genus in their authoritative

The taxonomic status of the two members of the genus *Chamaepetes*, the Sickie-winged Guan (seen here) and the Black Guan (*Chamaepetes unicolor*), is amongst the least disputed in the family. Within the subfamily Penelopinae, comprising the chachalacas and the guans, they are the only species that show a fully, densely feathered throat, and as a result lack wattles or caruncles of any kind.

[*Chamaepetes goudotii*. Photo: Josep del Hoyo/Lynx]

The Nocturnal Curassow is the only member of the subfamily Cracinae, the curassows, that has its own monotypic genus. Although its habits now seem to be much less nocturnal than was hitherto thought, some characteristics, such as the cryptic plumage of both sexes or the brightly coloured face, are unique within this group. This species is also considerably smaller than all the other curassows.

[*Nothocrax urumutum*. Photo: Josep del Hoyo/Lynx]

The Highland Guan, another species placed in a monotypic genus, is one of the most unusual members of the family. It is the only guan with marked sexual dimorphism, the female having cryptic brown plumage. It is also the only species in which the male has bare gular skin hanging down to form a conspicuous dewlap, while such an appendage is completely lacking in the female. Finally, it is the only cracid in which the female is slightly larger than the male.

[*Penelopina nigra*,
Chiapas, Mexico.

monograph of the Cracidae, believed that either the four aforementioned forms were, in fact, four different species, or else three other forms, *motmot*, *ruficeps* and *superciliaris* were also conspecific with *guttata*. In order to avoid erecting "new" species they adopted the latter alternative, creating an expanded *Ortalis motmot* that they called the Variable Chachalaca, in order to emphasize the remarkable diversity of the forms included.

Penelope, with fifteen species, contains more species than any other cracid genus. Like *Ortalis*, it is a fairly homogeneous, not very specialized group, that similarly raises numerous taxonomic issues. There is relative agreement that the members of the genus fall into three species groups: one group of small species and two groups of large species. The group of small species is formed by the Band-tailed Guan (*Penelope argyrotis*), the Bearded Guan (*Penelope barbata*), the Baudo Guan (*Penelope ortonii*), the Andean Guan (*Penelope montagnii*), the Marail Guan (*Penelope marail*) and the Rusty-margined Guan (*Penelope superciliaris*); the first of the two groups of large species comprises the Red-faced Guan (*Penelope dabbenetii*), the Crested Guan (*Penelope purpurascens*), the Cauca Guan (*Penelope perspicax*), the White-winged Guan (*Penelope albigularis*), Spix's Guan (*Penelope jacquacu*) and the Dusky-legged Guan (*Penelope obscura*); and the second, the White-crested Guan (*Penelope pileata*), the Chestnut-bellied Guan (*Penelope ochrogaster*) and the White-browed Guan (*Penelope jacucaca*).

The three forms in the last group were formerly considered to be races of the same species, but apart from this there is no controversy concerning their status. In the other two groups, on the other hand, there are numerous cases which have in the past provoked a great deal of speculation, and today there is still a certain amount of disagreement.

The issue of whether the Bearded Guan is a valid species or should be included in the Band-tailed Guan, as a race, is one of the most disputed. The two are obviously close relatives, as indicated by their very similar general appearance, and the fact that they are the only two members of the genus with a rufous terminal band on the tail, but other important features differentiate them. As its name suggests, the Bearded Guan has the

front part of the throat feathered, as well as the upper part of the tarsus, which indicates that although both are mountain species, this one is adapted to a colder habitat (see Morphological Aspects). Another significant difference is connected with the outer primaries modified for the production of mechanical sounds in all guans (see Morphological Aspects); while the Bearded Guan shows only a slight modification, the Band-tailed Guan is one of the most specialized species of *Penelope* in this aspect. Because of this, and also their widely disjunct range, it is now more usual to consider these two forms as specifically distinct.

There is certain controversy about the affinities of the Baudo Guan. Although it is a small species, it has been associated with the *Penelope obscura* superspecies, sometimes known as the *Penelope purpurascens-jacquacu* complex, and even considered conspecific with one of its members, the White-winged Guan. It was alternatively included in the Andean Guan, as a race, based on slight similarities with two of the Andean Guan's races. C. Vaurie, in his revision of the family based on a careful study of a large number of specimens, offered convincing reasons for rejecting both proposals. More recently, in a study of the systematic relationships of the White-winged Guan and related forms, J. W. Eley concluded that the Baudo Guan's nearest relative was the Marail Guan. He suggests that an ancestral form of both would have had a wide distribution over much of tropical South America during the Pleistocene, and that climatic fluctuations led to the formation of these two species and also of the Rusty-margined Guan.

The validity of the Cauca Guan as a species has never been unanimously recognized, but those who do not accept it further differ as to the species of which it should be considered a subspecies, and it has been included either in Spix's or the Crested Guan. The fact is that the Cauca Guan is morphometrically closer to the former, with which it shares some plumage features, while in other plumage features it is more similar to the latter, with which it also shares the lack of a tracheal loop. Taking everything into account, Eley suggests that the species could have arisen from an isolated population of the ancestral form of Spix's and the Crested Guans before their differentiation, which would reinforce its taxonomical validity as species.

However, the systematic debate has not been as marked in any other member of the genus as in the case of the White-winged Guan. The fact that it was believed to be extinct for a century until its rediscovery in 1977 (see Status and Conservation), and that during all that time only three old specimens existed, has certainly been the main reason for the uncertainty. The species was alternately associated with Spix's, the Crested and the Baudo Guans, and even its validity as an independent taxon was questioned, as it was suggested that it had been described from a partially albinistic specimen of either the Crested or the Baudo Guan, or that it constituted a morph or variant of one of them. The existence of several abnormal specimens of the Baudo Guan with white patches scattered throughout the plumage, and the confirmation that the Crested Guan in captivity occasionally produces individuals with white primaries, and sometimes in the wild too, seemed to lend support to this line of thinking.

However, the rediscovery of the form allowed the examination of many more individuals, and also the collection of information on the natural history of the species, for instance on its vocalizations, and Eley's study using such information has shown it to be a valid species. It is one of the most distinctive forms in the genus, with at least two unique characteristics: the eight outermost primaries are white; and the bill is bicoloured. The voice is quite similar to that of the Crested Guan, far more so than to that of Spix's Guan, which is why, in contrast to the case of the Cauca Guan, Eley suggests that the species could have appeared after the isolation in west Peru of an ancestral form of the Crested Guan that was already differentiated from the ancestral form of Spix's Guan.

The six forms included in the genus *Pipile* have been the subject of so much controversy in terms of their relationships with each other and with other guans that virtually all possible permutations must have been proposed at one time or another. They have been merged into a single species, or at the other extreme considered six different species, as well as all the intermediate possibilities between these two. They have been included in the genus *Penelope*, when it was thought that they only constituted a distinctive species group within it. Another

author, however, suggests that they should be separated from Penelopinae into a separate tribe, Pipilinae, into which their relatives of the genera *Aburria* and *Chamaepetes* would also be incorporated. Delacour and Amadon disbanded the genus *Pipile*, merging it into *Aburria*, perhaps inappropriately, as the members of *Pipile*, widely distributed in South America, constitute a notably homogeneous unit and are clearly different from the Wattled Guan (*Aburria aburri*), which constitutes a monotypic genus restricted to the Andes.

The present version recognizes four species, the Trinidad (*Pipile pipile*), Blue-throated (*Pipile cumanensis*), Red-throated (*Pipile cunjubi*) and Black-fronted (*Pipile jacutinga*) Piping-guans. The form *grayi* is maintained as a race of the Blue-throated Piping-guan as it appears to intergrade with the nominate race in south-east Peru, while the form *nattereri* is included in the Red-throated Piping-guan as these two are morphologically very similar. New field work might, of course, provide evidence that these two forms should be treated as different species, or equally that the first three species are really conspecific. The only point of fairly general agreement is that the distinctive Black-fronted Piping-guan merits treatment as a separate species. The case of *Pipile* is a good one for illustrating some of the difficulties regularly encountered in taxonomic work, and the inevitable subjectivity involved.

As for the rest of the species of the tribe, the Wattled, Black (*Chamaepetes unicolor*), Sickie-winged (*Chamaepetes goudotii*), Highland (*Penelopina nigra*) and Horned Guans provoke much less debate than the genera previously mentioned, although the relationships of the Highland Guan have also been controversial. Vuilleumier considered it intermediate between the chachalacas and the guans, and the species has commonly been called the Black Chachalaca. Nevertheless, Vaurie studied the species in detail and deduced that it is not related to *Ortalis*, but rather that it was a very peculiar member of the guans. Certainly the species presents several features unique among the cracids, such as the female being larger than the male, and indeed it is the only guan presenting marked sexual dimorphism (see Morphological Aspects). The fact that one of the two species of *Chamaepetes* is black and the other brown, the colours of the male and the female respectively of the Highland Guan, was interpreted by Delacour and Amadon as suggestive of a link between the two genera.

As for the Cracinae, the curassows, the main discrepancies concern the assignment to genera. All species have on occasions been lumped in *Crax*, although nowadays it seems that there is general agreement in awarding a separate genus to the Nocturnal Curassow (*Nothocrax urumutum*), which is smaller than the rest, with a brightly coloured face and completely different plumage. However, Delacour and Amadon also merged the genera *Mitu* and *Pauxi* into *Crax*, to emphasize the

The genus *Aburria*, to which the Wattled Guan belongs, has traditionally been considered monotypic, although some authors have included the piping-guans (*Pipile*). However, the piping-guans form a homogeneous group that is widely distributed throughout much of South America, whilst the Wattled Guan is restricted to the Andes and, as can be seen here, presents certain marked peculiarities, including a completely feathered face and the distinctive worm-like caruncle hanging from the throat.

[*Aburria aburri*.

Hybridization between different cracid species is very rare in the wild but relatively common in captivity, even between members of different genera. This photograph shows a cross between a West Mexican Chachalaca and a Crestless Curassow, produced in the aviaries of J. Estudillo in Mexico.

[*Ortalis poliocephala* x
Mitu tomentosa.

Lynx]

close relationships. However, as pointed out by K. H. Voous, the genus, unlike the species, is an abstraction, and as such does not exist in nature, so pragmatic rather than scientific values should be used in order to decide generic limits. It does not seem appropriate to mix the true *Crax* or "bushy crested" curassows, all of them members of a superspecies, with other more obviously different forms. The species usually included in *Mitu* are anyway closer to *Nothocrax* than to true *Crax*. Besides, the norm in Cracidae is generally that species in the same genus are allopatric, and replace one another. This norm is maintained if the classic genera are maintained, but not if they are amalgamated, since various species, especially in *Mitu* and *Crax*, are broadly sympatric, with two species able to co-exist in the same forest.

The separation of the various forms into different species is much clearer than in *Ortalis*, *Penelope* or *Pipile*. It is interesting to note that the Alagoas Curassow (*Mitu mitu*), which is now practically extinct (see Status and Conservation), was long considered conspecific with the Razor-billed Curassow (*Mitu tuberosa*). As with the White-winged Guan, the lack of data and material prevented any detailed study. This case was even more enigmatic, as the specimen with which the species had originally been described was not preserved, and no other was obtained until the rediscovery of the form in 1951. Subsequently, a captive population was established, in which diverse aspects have been studied, including voice and karyotype, and this has shown that, although the two forms are very closely related, they have disjunct ranges and there are enough differences to merit their separation as two different species. For example, the Alagoas Curassow is unique in having a bare patch around the ear, and in having fourteen rectrices in both sexes, which are tipped pale brown, as opposed to white.

The forms included in the genus *Pauxi* have also been subject to diverse treatment as species or subspecies. When the Southern Helmeted Curassow (*Pauxi unicornis*) was described in 1939, it was considered a separate species from its better known northern counterpart, the Northern Helmeted Curassow (*Pauxi pauxi*), based mainly on the notably different shape of its helmet, which is cylindrical, not swollen, and its glossy,

curled crest. However, the subsequent discovery of a new race, *gilliardi*, of the northern species with a far less swollen helmet, prompted different authors to consider the three forms as subspecies of the same species. Later, with the discovery in Peru of a new race, *koepckae*, of the Southern Helmeted Curassow, geographically almost half way between the other two, but morphologically not approaching the northern form, the idea that they are actually two different species has been reinforced.

Over the years, several species have been described that have later been shown to be based on errors, and curiously they have always been forms in the genus *Crax*. Thus, "*Crax chapmani*" and "*Crax hecki*" were described from females of the rare barred morph of the Great Curassow (*Crax rubra*), while a female of the rare black and white morph and an immature male of the Blue-billed Curassow (*Crax alberti*) gave rise to "*Crax annulata*". The type of "*Crax incommoda*" turned out to be a rather unusual female of the Yellow-knobbed Curassow (*Crax daubentoni*), while that of "*Crax rubrirostris*" was a male of the Red-billed Curassow (*Crax blumenbachii*), since for a time it was thought that the male and female of this species were really two different species.
